mechanical analyses of soils, and authorities do not agree on this subject, especially as regards the addition of bases or acids. Probably, the actual acidity of the suspension, that is, the hydrogen-ion concentration, is the most important factor, rather than the quantity of acids or alcohols added. It is not surprising therefore that the various writers on the subject have not found a satisfactory explanation of this phenomenon. Indeed, the idea of the restrictive action of the soil towards the changes of reaction is too recent, and it is only when this possible relation is considered that the fact that certain soils show a remarkable change of reaction and others do not, when the same quantity of acid is added, can be explained.

To verify the influence of hydrogen ion concentration as compared with the quantity of alkalis or acids added, the author has made an experiment with two clay soils: one, brick earth with a 7.5 exponent of  $P_H$  acidity (1), the other, a peat-soil, with a 5 exponent; he placed them in suspension and added equal parts of acid and alkali, shaking, and allowing a deposit to form; after a certain time the column of clear liquid was determined by registering the number of cubic centimetres per hour. A similar action results from the data obtained in an acid medium, first a decrease in the quantity of deposit is noticed, then suddenly an increase up to a maximum is reached at the isoelectric point, that is to say, the point of least solubility; on the contrary, in an alkaline reaction, that is, with a weaker hydrogen-ion concentration, the suspension is always more stable, with a minimum deposit, after which, a high degree of alkalinity having been reached, there is again a decided increase of deposit.

The same rules, therefore, may be applied to the mineral ampholytes of the soil as LOEB (*J. Gén. Phys.*, 1920, 1921) proposed for organic ampholytes in relation to bases and acids, with which they combine in stoichiometric, that is, chemically fixed proportions, which revolutionises current ideas on the soil and its condition. The terms applied to absorption in colloidal chemistry must therefore be set aside, since the physico-chemical laws also apply, as is seen, simply to colloid minerals and, consequently to the soil; the word "colloid" should therefore be used only to indicate a particle with special dimensions but not with special properties.

To sum up, clays of different origin and varying reaction have the same isoelectric point, that is, they coagulate in suspension at the same degree of acidity, and the curve obtained for the speed of deposit as compared with the hydrogen-ion concentration has the same inclination as that of gelatine. Clay therefore acts as an amphoteric electrolyte, which can combine either with acids or bases, as is confirmed by the buffer action exercised by the clays themselves; this result is both of theoretical and practical importance.

543 - Partial Sterilisation of the Soil by means of Arseniate of Soda. — RIVIÈRE, G. and PICHARD, in *Journal de la Société Nationale d'Horticulture de France*, 4th Series, vol XXVIII, pp 141 142 Paris, March 1922

Before the war, at the Agronomical Station of Seine-et-Oise, where their work is now being continued, the authors had already started experiments on the partial sterilisation of the soil by means of different antiseptic salts, especially arseniate of soda, they have also observed the indirect beneficial action which this salt exercises by destroying bacteriophagous protozoa. They have obtained the following results on a culture of potatoes

Treatment	Yield per ha
Untreated	14 200 kg.
20 kg. of arseniate of soda per ha	16 200 kg.
30 kg	16 740 kg

It follows that arseniate of soda used in small quantities has no injurious effect on vegetation, but that its toxic properties are still strong enough to kill the protozoa which destroy the useful bacteria. Like other volatile antiseptics (carbon bisulphide, toluene, formaline, etc), it has therefore an indirect fertilising action, for which reason, and also on account of its comparative cheapness, it may be used in practice for the partial sterilisation of the soil in order to obtain a better yield, without the necessity in the first instance, for the use of nitrogenous fertilisers. 544 - Fertilisers in Spanish Agriculture. MINISTERIO DE FOMENTO, DIRECCION GENERAL DE AGRICULTURA, MINAS Y MONTEs, *Measures fertilizantes empleadas en la Agricultura, Resumen hecho por la Junta Consultiva Agronomica de las memorias de 1919 remitidas por los Intendentes del Servicio Agronomico provincial* pp 611. Madrid 1921

Summarised report of the Consultative Committee of the Spanish Ministry of "Fomento" (Agricultural Development), drawn up from the reports for the year 1919 and supplied by the Provincial Agricultural Engineers. The introduction is followed by information on the different provinces divided into 13 districts, for each province particulars are given as to the state of organic fertilisers, chemical or otherwise, as well as details as to the trade and manufacture, the report concludes with four summarised tables showing the unit consumption (per hectare) per province and per crop both of organic and residual fertilisers, and chemical manures, the number of hectares treated, the amount of fertilisers used, the cost per hectare and the total outlay in the different provinces, both for organic and residual as well as for chemical fertilisers.

In Spanish agriculture, in spite of the difficulties due to the special characteristics the use of organic fertilisers has been extended and improved, and the use of chemical fertilisers is of growing importance. The tests made by numerous experimental farms, the experience gained by numbers of farmers, the propaganda carried on by merchants, leaflets and

conferences, the campaigns of the agricultural press and other means of publicity have greatly contributed to the progress of the use of fertilisers in Spain. Much, however, still remains to be done before scientific research, testing and propaganda will enable further progress to be made in this branch of agricultural science and promote agricultural development by means of plant and seed selection and the use of motors. An enlightened interest in the fertilising trade and industry ought, it would seem, to do much to prevent fraud in the weight, quality and strength used; the cases reported have however necessitated State intervention for the protection of the buyer and the punishment of fraud. The inspection of chemical fertilisers comes under the Provincial Agronomical Service, and the Central Agronomical Station, the laboratories of the District Experimental Farms, the General Agricultural Stations and the Agronomical Divisional Organisations now exert a most salutary influence in this respect, which will be rendered still more effective by an improvement in organisation and staffing.

It is the duty of the Government, with the cooperation, of the people, to encourage the production of raw material for the manufacture of chemical fertilisers, and to support this industry within the country for the benefit of agriculture. Special attention should be given to the production of phosphates, for rich layers are known to exist in the south of Spain; these layers, being badly exploited, and means of transport insufficient, do not yield what they should, either as regards quantity or returns. It is desirable that three laboratories should be established in the most suitable localities for the exclusive study of chemical phosphatic nitrogenous and potassic fertilisers, their duty would be to collaborate in the necessary testing, propaganda and control, in the general interest of agriculture.

The tables contained in the report show that the total consumption of organic fertilisers and waste products (manure and other animal excrements, green fertilisers, sewage, human fertilisers, fish refuse, dry blood, bone powder, ashes, etc.) amounts to 330 608 498 qx, at a total cost of 46 1906 209 *pesetas* and the total area manured to 2 851 857 hectares, that is 115 qx per ha. The total quantity of chemical fertiliser used (superphosphates, basic slag, ammonia sulphate, nitrate of soda, cyanamide of calcium, nitrate of lime, potash, chloride of potassium, kainite, double salts, composite fertilisers) amounts to 11 366 136 qx at a cost of 357 809 759 *pesetas*, for a total area of 3 133 505 ha, or a unit of 3 62 qx per ha. The total quantity of fertilisers used in Spanish agriculture amounts to 341 974 634 qx, costing 819 806 058 *pesetas*. Among the organic fertilisers, the dung of horses, cows and swine naturally predominate: they total 309 038 334 qx of the value of 433 743 965 *pesetas*; the superphosphates are the most used of chemical fertilisers—5 594 836 qx, value 233 976 563 *pesetas*. The figures, taken in conjunction with the known fact that the two kinds of fertiliser are not used in sufficient quantities on all the land which needs them, or are not of sufficient strength, prove that it is necessary to increase the breeding of live-stock and also the manufacture and importation of phosphates.

545 - **Inoculated Leguminous Plants as Nitrogenous Fertilisers.** — BROWN, P. E. and STALLINGS, J. G. (Iowa States College) in *Soil Science*, vol XII, No. 5, pp. 365-407, bibliogr of 46 works New Brunswick, N J, Nov 1921.

The discovery of symbiotic relations between leguminous plants and their radicular bacteria has thrown light on certain branches of agricultural practice, has led to new applications and has given rise to numerous problems which are now being examined or are on the way to solution. For instance it is now understood why leguminous plant culture is an equivalent for nitrogenous fertilising and an explanation is given of the beneficial effect produced by spreading earth taken from fields previously cultivated over newly broken ground sown with clover

Some very important practical applications have resulted *e. g.*; the method of inoculation by bacterial cultures, and the principle that, to obtain better results, the bacteria proper to each legume cultivated should be used for its inoculation. The problems now under examination are: cross-inoculation, the grouping of bacteria from different legumes into homogeneous families, the preparation of highly efficient or virulent cultures, the non-symbiotic nitrogen-fixing power of the bacteria, the relation between the symbiotic process and the nitrogen content of the soil, the period of the activity and vitality of nitrophagous bacteria and their isolation from the soil, such are some of the technical problems which at present are receiving most attention

Only a few exact data are at present available as to the quantity of nitrogen added to the soil by different legumes

Numerous and careful researches made under varying conditions would be very useful. At the present time one has to rely on hypotheses rather than precise data, for instance, it is considered probable that in districts rich in nitrogen, legumes take less from the air than those which are poor in nitrogen. Data are available as to the quantity of nitrogen stored in the roots of legumes and in their aerial parts, but still more are necessary for each kind of plant, the different soils, the agricultural operations carried on, etc. here also, practice is based on hypotheses and not on the results of scientific experiment. Only by further research will definite and complete information be obtained as to the continuous supply of nitrogen to the soil

To compensate in some measure for the present lack of knowledge on the subject, the authors have obtained from Anglo-Saxon agricultural literature a rich harvest of data relating to the symbiotic fixation of nitrogen. the results cover a wide range, both as regards the total storage of nitrogen and the relation between the quantities stored in the parts of the legume underground and those above ground, the divergencies are due to a great extent to the nature of the soil and culture. thus HOPKINS concludes that the roots of alfalfa contain as much as half the total quantity of nitrogen, those of the common clover only  $\frac{1}{3}$ , and those of soya and cowpea barely  $\frac{1}{10}$ ; these of course are only very rough averages and liable to considerable modification.

Preliminary researches have been made by the authors in two districts

in Wisconsin possessing very different characteristics, one being loam and the other sandy loam, the former ranges from a deep brown to black colour and is rich in humus and nitrogen, the latter is light in colour and poor in organic matter and nitrogen. Analyses showed respectively 0.2701 and 0.1353 %. Some samples of soil were not treated, others were inoculated, others again were first sterilised by autoclaving for 1 hour and then inoculated. Common clover and alfalfa were cultivated, each experiment was repeated in pots each containing about 4.5 kg. of earth; and the same number of plants was grown in each pot. The underground parts of the plants and those exposed to the air were weighed both in their green and dry state at various stages of their growth, and the nitrogen content of both the tops and roots was then determined by the KJELDAHL method and also the nitrogen content of the soil.

It is difficult to give the results because there were irregularities and wide divergencies. It may be said however, that on an average the clover roots weighed at maturity 36 % of the plant, those of alfalfa 53 %, the figures were a little higher at the blooming period than at maturity, they were also rather higher in soil which was poor in nitrogen and organic matter than in rich soil while they decreased in sterilised soil. In the richer soil the total growth of the plants was more vigorous but especially so as regards the tops.

Regarding the fixation of nitrogen each plant stored 15 to 25 cgm. if the soil was not treated. The alfalfa fixed more in poor soil the clover more in rich soil when sterilised and then inoculated. The quantity of nitrogen in the roots averaged 27 % for clover and 46 % for alfalfa. The nitrogen fixed came to a great extent from the air and not from the soil even in the case of the roots. This fact is important because it shows that even if the tops are taken away and the roots only left, there is a gain in nitrogen.

The sterilisation of the soil has an unfavourable effect where results are obtained from soils sterilised and not restored, they must therefore be considered as abnormal.

The non-symbiotic nitrification is also a disturbing element.

However no definite conclusions can be drawn or extended application made of what applies only to two legumes and two kinds of soil, it is probable that the results of the experiments have also been influenced by the culture being effected under glass, there is nothing to show that results would have been the same in the open. The experiments will serve mostly as a guide and it is desirable that they should be continued and extended.

546 - **Tobacco Refuse as a Fertiliser.** — See No. 634 of this *Review*.

517 - **Experiments with Potash Fertilisers in the United States.** — I SMITH, R. S. Some Effects of Potassium Salts on Soils, in *Cornell University Agricultural Experiment Station, Memoir* 35, pp. 571-605, bibliogr. Ithaca, N. Y., 1920. — II PARR, S. W. and AUSTIN, M. M., Potash Shales of Illinois, KREV, F., Geology Distribution, and Occurrence

of the Potash-Bearing Shale of Union County; STEWART, R., *Finely-Ground Shale as a Source of Potash for Soil Improvement*, in *University of Illinois Agricultural Experiment Station Bulletin*, No. 22, pp. 227-252, 5 figs Urbana, Ill., 1921.

I. — The data on the effect of potassium chloride and potassium sulphate as fertilising elements on the soil do not agree; and for this reason the first work quoted has been written. The problem consists first in determining the effect of different applications of potassium chloride and potassium sulphate on the growth of wheat, both in soils, treated, differently, and in the aqueous extract of these soils; next, in determining the causes of the effects of these salts on the growth of wheat, in connection with the statements of other writers. The soils used were of a sandy clay character, somewhat typical of an extensive zone in the United States, and of high, medium and low fertility. After being analysed, they were put into pots and then limed.

The potassium sulphate increased the growth of straw in the highly productive soil and had no injurious effect on the medium soil; on the other hand, the potassium chloride had a toxic action on wheat in rich soil when applied at the rate of 0.5 per 1000, and in medium soil there was a slight decrease in yield with an application of 1 per 1000.

In the extracts from rich soil, potassium chloride stimulated the root growth of young wheat plants with concentrations corresponding to applications of from 0 to 1.5 per 1000; the greatest stimulation was observed with a treatment equivalent to 0.25 per 1000. With potassium sulphate there was a progressive stimulation up to 1 per 1000, but at 1.5 per 1000 it became decidedly toxic. Among the extracts from medium soil, those untreated had a toxic action on the root-growth of young wheat plants; an application of 0.1 per 1000 of potassium chloride had the most stimulating effect; with stronger applications, diminished growth and apparent toxicity were observed; a 0.25 per 1000 treatment of potassium sulphate had the most stimulating effect, while this effect was also diminished and toxic properties were evident with stronger applications. In the extracts from very poor soil, not treated with lime there was clearly a toxic effect on the root growth after an application of 0.25 % of potassium salts, but the application of lime caused a diminution of toxicity, even with a maximum treatment of chloride.

In every case potassium chloride produces a smaller accumulation of nitrates, but this effect was checked by liming; on the other hand, potassium sulphate stimulated, or seemed to stimulate the accumulation of nitrates in rich and medium soils. A maximum dose of potassium chloride diminished the nitrification of the nitrogenous matters applied, whereas potassium sulphate had a stimulating effect, except in the case of the maximum application on rich soil; lime tends to lessen the depressive effect of potassium chloride in very poor soil, but without restoring it completely.

The author did not find iron or aluminium in any of the soil extracts, and in those from very poor soil even manganese was wanting; the injurious action of potassium salts therefore should not be attributed to the

restitution of iron, aluminium, or even manganese in the case of very poor soil ; on the other hand, potassium chloride and potassium sulphate actively replace calcium. There is less calcium than might be expected in the extracts of the series treated with sulphate, and this is probably due to the insolubility of calcium sulphate. Magnesium is replaced in a less degree than calcium ; manganese is replaced in appreciable quantities in rich soil, and particularly so in medium soil. Soils which contain a maximum of manganese soluble in water have the lowest nitrifying power, show the least vigorous growth in pot cultures and the poorest root growth in extracts.

The effect of potassium salts on plant growth is therefore due to a complexity of factors, including sometimes the direct action of the salts themselves on plant growth, sometimes the action of bases replaced by potassium and especially that of manganese ; and this is in agreement with the literature on the subject, a summary of which proves that ordinary potassium salts generally have an injurious effect on plant growth when used in large quantities, and that this effect should be attributed in part to the basic exchange, in which the composition of the soil is an important factor ; another factor is the decided modification of the bacterial activity of the soil.

II. — The shales of the South of Illinois were found to be rather rich in potash, 5 % and more ; their composition also favours the production of Portland cement to such an extent that in collecting the potash, 5.3 % could be extracted. These shales contain petroleum in a free state, bituminous matter, pyrites and undecomposed potash rock of a feldspathic nature, as well as potash material of a glauconite character ; another shale contains up to 5.8 % of potash, but in a less stable form.

The extraction of potash by means of reagent solids and liquids is impracticable on account of the high cost of lyes and their recovery. These shales seem to contain potash in an assimilable form and that which is soluble in sulphuric acid seems to be due to glauconite potash ; of 5 % of raw potash or 5.6 % after calcination, 62 % is glauconiferous and can be assimilated by plants. The situation of these strata is such as to render their exploitation easy.

Experiments with pot cultures under glass in turfy soil prove that the application of these shales, finely ground, has a decidedly beneficial effect on melilot, rape, maize-forage and buckwheat, as well as on wheat, in sandy clay soil, after a general lining, in comparison with kainite, natural and calcined alunite, and leucite, alone or with magnesium and sodium chlorides ; the results are of such importance that from the economic point of view they justify extensive research, especially on open ground, and should arouse public interest ; it is proved indeed that potash of these shales can be directly utilised by pot cultures under glass, and that they give better results than any other.

The foregoing experiments in pots, and also with turfy soil, have clearly shown the effect of leucite ; in comparison with untreated soil merely

limed the increases in hundredths as compared with kainite are as follows :

	Barley	Rape	Beet	Flax	Clover
Kainite . . . . .	111	33	55	44	25
Leucite	44	24	48	25	86

548 - Experiments on the probable Effect produced by the Addition of Sulphur to the Soil. — AVANZI, I (Agrarian Institute of the Royal University of Pisa), in *L'Agricoltura Italiana*, year XLV, Numbers 13, pp 81-88 Pisa, 1922.

The numerous enquiries undertaken and the various hypotheses advanced in recent year as to the effect produced by the addition of sulphur to the soil has led the author to carry out a preliminary test by placing in open ground 20 boxes containing earth mixed with 13.56 % of organic matter and 13.76 % of carbonate of lime, treated respectively in duplicate controls, phosphorite, tetraphosphate, basic slag, mineral phosphate, sulphur, mineral phosphate and sulphur, tetraphosphate and sulphur, basic slag and sulphur, and superphosphate and sulphur, in the boxes were sown selected pure line autumn wheat, 16 plants in each box; the seed had been scalded, and after the wheat a sowing of buckwheat was made. The indices of the different tests were, for the seed wheat 100 — 102 — 91 — 102 — 106 — 99 — 99 — 105 — 109 and 102, and for the buckwheat 100 — 103 — 155 — 100.5 — 113.8 — 106 — 113.3 — 113.5 — 96.3 — and 103.

The result therefore would seem to have proved firstly, that phosphorite and tetraphosphate were less effective in wheat culture than basic slag and, more especially, mineral phosphate. As regards the crop of buckwheat produced, their effectiveness and especially that of phosphorite, seem to have been, on the contrary, rather greater, but still inferior to that of mineral phosphate.

The addition of sulphur to the soil apparently had a good effect on the production of wheat-ears whereas it produced varying results with regard to the straw and yield of buckwheat. The combined action of sulphur and phosphated fertilisers appear to have been favourable, taken on the whole, but considered separately, the results were in several cases contradictory.

These experiments, while suggesting further tests on different lines, lead the author to agree with other investigators who consider that any decisive opinion as to the practical advantage of treating soil with sulphur is at present premature.

G A. B.

549 - **Distribution of Manganese in the Organism of the Higher Plants (1).** — BERTRAND, G. and ROSENBLATT, M., in *Annales de l'Institut Pasteur*, Vol. XXXVI, No 3, pp. 230-232 Paris, March 1922.

In order the better to estimate the physiological importance of manganese, the authors have treated with the metal the largest possible number of the organs of a single species of plant gathered at a certain time, a dicotyledon, the tobacco of the peasants, and a monocotyledon, the Japanese lily.

The effects produced on widely differing organs first confirm the general opinion that manganese should be considered as of quite general occurrence in the organs of plants. Secondly, they show an interesting localisation of the manganese: the greatest quantities of the metal are found in those organs in which the most marked chemical transformations take place. The reproductive organs, in which the exchange phenomena are intense, are placed by the side of the leaves, the young shoots and generally of the chlorophyllian organs. The wood, on the contrary, which plays a rather passive part, is remarkably poor. Finally, the seeds contain a large reserve of metal destined later, no doubt, to supply the early needs of the young plant.

G. A. B.

550 - **Chemical Composition of Diss Ergot and Oat Ergot.** — TANRET, G., in *Comptes rendus de l'Académie des Sciences*, Vol 194, No 12, pp 827-830 Paris, 20th March 1921.

The author has examined the two kinds of ergot reported by Prof. TRABUT of Algiers as distinguishable in diss and oats.

After the closing of the Russian frontier, it was desirable to ascertain whether these ergots could replace that of rye, the only kind used up to the present in therapeutics.

I — Diss (*Lank Ampelodesmos tenax*) is a tall wild gramineae, which grows plentifully in North Africa, especially in the eastern part of Algeria. Its ergot resembles that of rye in form, but is longer, finer and more curved.

The author has analysed about 10 kg. of ergot, gathered in the province of Constantine in June, 1921.

The ergot is ground, treated with alcohol at a temperature of 85° and distilled. The residue obtained by distillation is composed of 2 parts; a red, watery fluid and a mixture of fats and resins. These are separated by ether, the reddish, pulverulent resin is insoluble. By a special process (which is not described), the author has extracted 10 gm. of *ergotinine* from 1 kg. of diss. This is composed of a mixture of approximately equal parts of crystallised *ergotinine* and amorphous *ergotinine* (*hydroergotinine* or *ergotoxine*).

From the fats 120 gm. per kg. of *ergostearine* has been extracted, that is to say from 4 to 6 times more than from rye ergot.

The aqueous fluid, tinged with red colouring matter, *sclerervthrine*, similar to that of rye ergot, after being treated with subacetate of lead and separated by alcohol at 90° boiling, gave on cooling, 8.80 gm. of

(1) See R. Nov. 1921, No 1097. (1d)

mannite and 0.70 gm of trehala 2.80 gm of glucose were afterwards extracted

0.40 gm of *ergothioneine* per kg of the alcohol extract deprived of its sugars were afterwards obtained

II — Oat ergot, short and thick is mostly found in the province of Oran, its size varies according to the year, but it is generally rather small (about 150 gm to the quintal), it does not necessitate sifting, and has not attracted the attention of dealers and veterinary surgeons

1 kg of ergot has furnished 60 gm of fats and 18 gm of resins, which have given 1.80 gm of raw ergotinine from which 0.80 gm of pure white crystallised ergotinine which is a high percentage. The quantity of ergostearine was 0.75 gm. Its aqueous fluids also contain sclererythrine, they yielded 32 gm per kg of a sugary mixture composed of 70 % of trehala and 30 % of mannite (this was from ergot eight months old) 14.2 gm of glucose per kg were measured

0.50 gm of *ergothioneine* were extracted

It will be seen therefore that the same elements are found in the 2 ergots examined as in rye ergot. Diss ergot is poor in crystallised ergotinine, whereas oat ergot is richer than the average ordinary rye ergot. It seems possible to substitute oat ergot for rye ergot in all its uses but diss ergot apparently cannot replace that of rye, except in periods of famine or crisis. Algeria could realise considerable profits from the crops of these ergots.

P. C.

551 — **Methods of Colloidal Chemistry in Plant Physiology. Sensitiveness of Lupins to Alkaline Earth Metals.** — BOAS, F. and MIRKENSCHLAGER, F., in *Centralblatt für Bacteriologie*, II. Abt. Vol. 55 Nos. 1-4, pp. 513-514, figs 3, Jena, 28th Feb 1922

A great number of researches on the biochemistry of lupins have been undertaken especially as to the causes of their morbid condition in calcareous soil. MIRKENSCHLAGER, recently discovered a relationship between the presence of protein in large quantities in the cotyledons of lupins and the injurious action of the lime, but he did not establish the connection of the two factors. He is now trying to do so in collaboration with BOAS, by the aid of colloidal chemistry.

As is known, every modification of the colloidal state of living proteins is of the greatest importance in the development of cellular activity. Great changes can be caused in this respect by acids, alkalis and salts. With regard to the action of neutral salts, it should be remembered that the alkaline salts (sodium and potassium) are only active in a highly concentrated state, whereas the salts of alkaline earths (lime and magnesia) even when slightly concentrated, precipitate the proteins. Therefore if the lupins contained proteins precipitated with comparative ease by these salts (owing to the state of these proteins or because they lack proteic or hydrocarbonated protective substances), this would easily explain the curious behaviour of these plants in limy soil. Now the seeds of lupins are very rich in proteins and very poor in carbohydrates.

in comparing *Lupinus luteus* and *Pisum sativum*, the authors found 45.07 % and 23.10 % of proteins, and 10.02 % and 53.02 % carbohydrates respectively. From analyses made by other authors there are still greater differences in the case of easily removable carbohydrates.

The authors have observed the action of the neutral salts on the proteins of lupins obtained by extraction. Their enquiries deal with 1) "flocculence" (precipitation); 2) viscosity.

**FLOCCULENCE.** — The proteins of the seeds are insoluble in water, but they dissolve during germination: it is possible therefore to prepare sufficiently concentrated solutions by using sprouting grain or young plants, without recourse to sodium chloride or other salts capable of modifying the original physical or chemical state of the proteins. To obtain the extracts, the authors crushed a certain number of the young plants, from 10 to 12 days old and passed the liquid through a piece of linen. They also used extracts obtained through greatly diluted caustic potash, so as largely to neutralise the slight acidity of the lupins caused by the presence of citric acid. The cloudy extract prepared by either method was poured into a number of test tubes similar to those used in serology for precipitation experiments, in quantities of 5 cc. per test-tube. The chloride of potassium added to the extract produced no effect; but if calcium chloride or magnesium chloride be added, a flocculence is immediately noticed; this is produced equally in the pure extract as in the alkaline, but it should be observed that in the second case, the citrate is also precipitated, and this fact should be borne in mind. In the test tubes in which flocculence takes place, the chlorophyll soon forms a sediment, because the internal viscosity of the fluid diminishes. This formation of sediment is more rapid with calcium chloride than with magnesium chloride. After 12 hours the chlorophyll also forms a sediment in the test tube to which potassium chloride has been added; but no trace of flocculence is apparent in the liquid which rises to the surface and which remains clouded; in the test tubes containing calcium or magnesium chloride, on the contrary, the flocculence was followed by a complete sedimentation not only of the chlorophyll, but also of the other proteins, which form with the chlorophyll a thick deposit at the bottom of the test tube, whereas the liquid at the surface is perfectly clear. The smallest quantities of  $\text{Ca Cl}_2$  suffice to produce these effects; a solution as low as 5 ‰ normal is very active.

**VISCOSITY.** — The flocculence of the colloids dissolved in the liquid cause a diminution of the viscosity. The following process was used in experiments on viscosity. The viscosimeter had a moderately fine capillary tube. The extracts were prepared from *Lupinus luteus* and *Pisum sativum* seed, left to swell for one day, then crushed and passed through a cloth: 10 gm. of water were used per 15 gm. of seed.

The lupin seeds are free from starch, whereas the pea seeds contain considerable quantities; but the starch quickly forms a deposit and, consequently does not affect the result. The extract of lupin obtained by distilled water and not treated with salts took 136 seconds to pass through the viscosimeter, and the pea extract, 228 seconds (the distilled water 53

seconds). The great difference between the two plants is due to the fact that the principal protein of lupin, the "conglutine", dissolves with difficulty in distilled water, whereas the pea proteins (principally legumine and viciline) dissolve in distilled water and produce a much more viscous fluid. If a 5 % solution of sodium chloride be used, the result is quite the reverse: they took 364 seconds and 228 seconds respectively. To observe the action of the salts, the authors preferred to use extracts prepared with a much less concentrated solution of sodium chloride (2 %), and after these were prepared they were subsequently diluted to half strength. To every 5 cc of liquid they added 1 cc of a 5 % normal solution of one of the three salts: sodium chloride, calcium chloride or magnesium chloride. After half-an-hour, examination showed that a rather greater diminution was produced by calcium chloride and magnesium chloride in the lupin extracts than that produced by sodium chloride; after 3 hours and a half, the difference became very marked; in the pea extract, on the contrary, the three salts acted in the same way and did not reduce the viscosity to any appreciable extent. These results prove that the alkaline-earth metals considerably modify the lupin proteins, whereas they remain practically inactive in the case of the pea proteins.

In conclusion, the salts of the alkaline-earth metals (calcium and magnesium) even in slight quantities (traces), cause the abundant proteins of the seeds and young plants of the lupin to become flocculent. As the vital activities of the living organisms are associated with a definite structure of their proteins, the "sensitiveness" of lupins to lime is explained: they become really intoxicated with this element. The flocculence of the proteins renders certain constituent parts of the living cells inert, and affects their functions: the movement of iron, for instance, is probably impeded. The results obtained *in vitro* then can be applied without difficulty to the living organism. It must be observed that whereas the injurious action of lime on lupins is well known, that of magnesia has never aroused the attention of cultivators, probably because magnesia is almost always found with lime (in marl, dolomites, etc.) and the natural tendency is to attribute the injurious effect noticed to lime only, whereas the magnesia is equally deleterious. However, a number of authors have already recognised that magnesia is also injurious to lupins: for instance, R. HEINRICH has noticed that magnesium carbonate when added to the soil, even in the proportion of 0.5 %, completely hinders the development; PFEIFFER and SIMMERMACHER have noted the injurious action of carbonate and sulphate of magnesium, etc., and thus research *in vitro* and cultural research are entirely in accord.

A noteworthy fact is that while the action of calcium and magnesium is almost the same during the first stages of development in the plant, it is different in the later stages: this proves that in studying the mineral needs of plants, they should not only be considered when fully grown, but also in the initial stages. The injurious action of calcium and magnesium is probably aided by the insufficiency of carbohydrates in the lupin seeds, for these protect the proteins, as has been proved by

A. MEYER. Calcium and magnesium act independently without the active assistance of the anion with which they are associated; this may be deduced from numerous experiments reported in agricultural literature. The complexity of the relations between the different salts contained in the soil explains certain divergences and apparent contradictions which have been remarked. The theory that calcium liberates hydroxylions must also be excluded.

552 - Influence of Mechanical Pressure on the Growth and Structure of Wood. —

KURZ, J., in *Centralblatt für Bacteriologie*, Part II, vol. 55, Nos. 11-13, pp. 293-297, 3 figs. Jena, 5th, Jan. 1922.

Numerous experiments have been made on this question. They have been directed on the one hand to the influence of the pressure as affecting the normal growth of wood, and on the other to the irregularities in the wood caused by strong external pressure. The second part of the problem, can be treated experimentally and also by making use of samples of wood growing under natural conditions, as, for instance, when two stems or branches have pushed one against the other, crushing and joining, or when a tenacious climbing plant or creeper has twined round a young stem. The structure of the wood thus produced has been described by KÜSTER, who also quotes the literature bearing on this subject. On the advice of KÜSTER himself, the author has examined a fine sample of *Ficus mysorensis* round which a *Ficus parasitica* had twined.

He first describes the normal state of the wood of *F. mysorensis*, as in the parts not subjected to pressure; this wood is formed of regularly alternating layers of parenchyma and sclerenchyma, the second rather the thicker, the vessels are comparatively rare, enclosed between the sclerenchyma fibres and bounded on one or more sides by the parenchymatous tissue. The frequency of the layers varies where they are wider, their direction is more regular, where they are thicker, they generally show irregularities and, instead of forming complete rings, they split into fragments and reunite, they shoot off from either side of the medullary rays. Similar irregularities are found in our wood, amongst for instance elms. They prove that the layers have no connection with the rings showing annual growth. If the section is well polished, deep, annular, concentric streaks of irregular form are seen, the microscope reveals no special structure, but only a brown coloration of the cellular walls. The medullary rays have from 1 to 6 layers of cells, the average being from 2 to 3.

The author next examines the part which has been subjected to pressure. He first enquires whether the growth of the wood continues under very strong pressure, or whether the activity of the cambium is suppressed; and favours the former hypothesis, basing his opinion on the researches made by SCHWENDENER, HOFFMANN and KÜSTER. On either side of the strong climber which exerted the pressure, the wood under examination formed, as it were, two long wedges, clearly differentiated from the wood of normal growth, both in appearance and structure, in the section

they appear to be separated from the normal wood by a line of demarcation visible even to the naked eye. In passing from the normal wood between the lateral zones, the woody layers change their direction: from tangential they tend to become radiant, and are then interrupted; the change of direction is abrupt, angular and takes place along the line of demarcation. The medullary rays reciprocally bend tangentially in a slight curve which does not affect all the rays near the edge of the two zones; towards the interior, on the other hand, where the zones become slender and the pressure has been stronger, the fold becomes more accentuated and assumes an angular form. The woody bundles and medullary rays, instead of meeting at right angles as in the normal wood, forming small squares or rectangles, meet obliquely and form lozenge shaped spaces. A change of structure is also to be noticed towards the line of demarcation, the fibrous fascicules of the normal wood become stouter, and their walls are very strong; these characteristics are also met with towards the interior of the normal wood, which does not undergo any special pressure. The wood subjected to pressure, which forms the two cuneiform zones is, on the other hand, of weak structure; the cells have mostly thin walls, near the line of demarcation, the sclerenchymatous parts are reduced to islets in the parenchyma; only at a certain distance from the line of demarcation does the normal structure reappear. The woody bundles and medullary rays remain continuous in passing from the normal to the compressed wood, but it is evident that the growth of the compressed wood has not continued in the direction of the cambium, but has branched off. In the particular case, the abrupt change of direction is due perhaps to sudden pressure.

553 - **The Multiplicity of the Species of Radicular Bacteria in Plants observed by means of Serological Processes.** - KLIMMER, M. in *Centralblatt für Bakteriologie*, II Abt., v 35, Nos. 11-13, pp. 281-283. Jena, 5th Jan 1922.

The author defines and confirms the opinion that there are numerous species of radicular bacteria in plants. He has used what are called the serological processes, as extensively used in human and veterinary bacteriology to differentiate and classify pathogenic bacteria (1).

(1) In the serological processes the bacteria under examination, in pure cultures, are injected into the bodies of animals used for experimental purposes. The animals thus treated react against the microscopic invaders by producing substances called "anti-bodies", these animals are afterwards treated and the serum containing anticorps is taken from the blood; by means of these anti-bodies the serum can cause characteristic modifications in bacterial cultures if identical with those injected; on the other hand it has no action on other species. It also modifies in varying degrees analogous bacteria cultures (group reactions). The modifications caused by the serums in bacteria cultures are many and various; sometimes the bacteria are killed outright; often the mobile species are paralysed and obliged to adhere to one another; the cultures may also be precipitated in the liquid; in most cases the bacteria also undergo a change which is shown by the fact that the dissolved blood prepared *ad hoc* becomes

The author, has employed agglutination, precipitation and fixation of the complement, applying a process already described by him. He considers the agglutination as negative when it takes place below the limit of 1 : 20, or if it also takes place among the controls that is to say without any addition of serum (auto-agglutination) or with serum from an animal not treated or normal serum. Precipitation is preferable on account of its simplicity, it is not usually necessary to dilute the serums unless the controlling tests also show positive results. The author uses the zonal or layer reaction, in which small tubes may be used and the consumption of serum lessened, the cultures for antigenous reaction are prepared in agar immersed in salt water killed by heat and the bacteria separated by filtering or they are centrifuged.

As a result of experiments undertaken in collaboration with KRIEGLER on 18 species of plants the author has been able to distinguish 9 species of nitrophagous bacteria namely

1<sup>st</sup> species found in *Lupinus perennis* L. *luteus* and *L. angustifolius* and *Ornithopus sativus*

2<sup>nd</sup> species found in *Melilotus albus* *Medicago lupulina* *M. sativa* and *Trigonella Foenum-graecum* it corresponds to the classic *Bacillus radicicola*

3<sup>rd</sup> species represented by the radicular bacteria of *Lotus uliginosus* *Anthyllis vulneraria* and *Tetragonolobus purpurea*

4<sup>th</sup> species includes the radicular bacteria of *Pisum arvense* and *Vicia Faba*

5<sup>th</sup> species confined exclusively to the *Vicia Faba* bacteria

Species 6 to 9 found in the nodules of *Trifolium pratense* *Phaseolus vulgaris* *Soja hispida* and *Onobrychis sativa*

By noting the strength of the serums used the author has been able to observe the relationships or analogies between some of the species mentioned. Results show for instance that whereas the specific serum prepared with the *Trigonella Foenum-graecum* bacteria agglutinates the same bacteria in the proportion of 1 : 10 000 it agglutinates the *Tetragonolobus purpurea* bacteria at 1 : 100 only a degree in which even the normal serum is active though only slightly. Any affinity between these two groups of bacteria must therefore be excluded. On the other hand there are rela-

tioned. These actions, called bactericidal, agglutination, precipitation, fixation of the complement, etc., are attributed each to a special antibody (bactericidal, agglutinative, precipitative, amoebocytic, etc.) which vary according to the bacteria injected. Some of the action take place even if the serum is greatly diluted, thus agglutination may be caused where the proportion is 1 : 10 000 and even beyond if cultures identical with those at the beginning are used (homologous cultures) in the case of analogous cultures the same serum agglutinates in lesser dilutions, and in that of different cultures it acts only at a very low ratio of dilution for instance, 1 : 10, as is also the case with the serum of animals not treated here the reaction is considered as negative. The serological processes which have been extensively used for twenty years in medical bacteriology to diagnose species and sub-species of bacteria have on the other hand, been very little used in agricultural bacteriology (Ed)

tionships or group reactions among the *Anthyllis*, *Lotus* and *Tetragonolobus* bacteria ; tested by the agglutinating reaction, they are confirmed by the fixation of the complement. The specific multiplicity of the *Phaseolus*, *Vicia Faba* and *Vicia sativa* and the close relationship, if not identity of the *Vicia sativa* and *Pisum* bacteria, already previously noted, have been confirmed by VOGEL and ZIPPEL by means of agglutination and precipitation experiments.

**554 - Improvement of the "Civitella" Variety of Wheat by Individual Selection in Tuscany.** — AVANZI, F., in *L'Agricoltura Italiana*, Year IV, Parts, 1-5, Pisa, 1921.

In certain parts of Tuscany, the name "Civitella" is given to a variety of rivet wheat which, though it has lost favour in some areas, is increasingly cultivated in others even to the extent of supplying the increasing demands for wheat from other districts.

As this variety has excellent qualities and is widely cultivated, the author decided to improve it by means of individual selection. This work was begun in 1917-1918 in the field of the Agricultural College at Pisa, and continued and extended in the following years. From the beginning of the experiments, the existence of two chief sub-varieties was distinctly seen.

A) consisting of the offspring of a more or less dense ear, bearing 3 to 5 fertile flowers,

B) consisting of the offspring of a rather compressed lax ear, with spikelets bearing as a rule 2 to 3 fertile flowers.

The greater number of individuals composing the Civitella variety usually grown may be included in the sub-variety A. The cultural experiments made during the last three years have also clearly demonstrated the greater productivity of this sub-variety, though its grains, while large and fine, are inferior to those of the sub-variety B.

By means of selection, starting from individuals belonging to each of the sub-varieties, four families were founded : 38-45-49-65

The Table gives the yield in 1920-1921 at Piaggia and San Cataldo (Pisa).

As it had been found that the above-mentioned families were more productive than the ordinary varieties, they were tested in parts of Tuscany showing marked differences both in climate and soil.

The results of these trials will make it possible to control the data obtained in previous years from growing family 38 and the other three families which, although very similar to one another, differ considerably as regards resistance to lodging and scald, as well as in their powers of adaptation to soils of various characters.

In the meanwhile the work has not been interrupted but extended to a number of new families that will have to be gradually compared with those previously isolated and bred, in order to determine by means of cultural experiment and chemical research, the lines which are most worthy of further propagation.

*Analytic data respecting the 4 families of "Civitella"  
obtained by individual selection.*

555 - "Rubin", an Early Spring Wheat for Central Sweden obtained by Crossing the Native Dala Variety with Kolben of Svalöf. — ÅKERMAN, Å., in *Sveriges Utsädesförmågs Tidskrift*, Year XXXII, Part 1, pp. 48-59. Malmö, 1922.

In the southern part of Dalarna, and in some districts of Central Sweden, the original Dala wheat, an awned native variety with dark ears (Dalårvarvete = Daba spring wheat), or other local wheats of a similar type, are still grown. These varieties are noted for their very early ripening and the excellent quality of their grain. On the other hand, they produce small, rather loose ears, with weak straw, and are especially susceptible to the attack of rust. Their yield is very light, being 20 to 30 % below that of Extra-Kolben.

For this reason, efforts have been made to introduce more productive types, such as Kolben, Extra-Kolben and others, although they have the defect of being late varieties, and in cold wet seasons never ripen properly, so that the grain is of inferior quality. In 1900, experiments were begun in Svalöf with the object of producing spring wheats suitable to the special physiological conditions of Central Sweden. The individual selection of Dala native wheat and early Norwegian Börsum wheat did not give satisfactory results and it was therefore considered advisable to carry out experiments in crossing.

In 1906, NILSSON-EHLE crossed Dala spring wheat with Svalöf Kolben wheat, and obtained by selection the line 0880, which was considered the best and at once put on the market, after the necessary cultural tests, under the name of Rubin spring wheat (Rubinårvete).

The object of crossing was to unite in a single type the earliness of Dala with the high yield of Kolben, and at the same time to obtain a high degree of resistance to rust to which the other native wheats and also the Norwegian *Borsum* variety are generally very susceptible. An attempt was also made to combine early maturity with stiff straw, and also, if possible, to eliminate the awns in order to lessen the mechanical action of the wind.

From the comparative cultural experiments made at Svalöf and the Sub-Stations of Ötgöta, Västgöta, and Ultuna, the following conclusions may be drawn.

**EARLY RIPENING** — As regards the length of the vegetative period, "Rubin" is hardly 2 to 3 days inferior to Dala and out-strips Kolben by at least 4 to 5 days. The number of days to heading was actually as follows:

*Svalöf*. 0880 Rubin 115 0, Dala 114 0, 0702 Svalöf-Kolben 118 3; 0841 Extra-Kolben 120 0

*Ultuna*. 0880 Rubin 113 5, 0841 Extra-Kolben 124 0; 0702 Kolben 123.6; native Dala spring wheat 111 5

*Tornby*. 0880 Rubin 114 4; 0821 Extra-Kolben 118 9, 0702 Kolben 117 3; native Dala spring wheat 111 4

*Skara*. 0880 Rubin 115 0; 0841 Extra-Kolben 121 7, 0702 Kolben 120 0; native Dala spring wheat 112 3

**GRAIN AND STRAW YIELD** — The author gives the data for the two Sub-Stations of Skara (Västgöta), and Ultuna. At Skara, produced in 1917-1921 an average of 2152 kg. per hectare, if this is taken as 100, Rubin produced 101, Dala 98, and Extra-Kolben 110. At Ultuna, Kolben produced in the period 1916-1921 (with the exception of 1918), an average of 2173 kg. per hectare. If, as in the preceding case, this is taken as 100, Rubin produced 82, Dala 61, and Extra-Kolben 103.

Rubin is thus clearly superior to Dala in grain production and also though to a less degree in straw-yield.

**RUST RESISTANCE** — Rubin is more susceptible to rust than Kolben, but is much more resistant than Dala. An empiric scale where 10 = free from rust and 1 = severely attacked gives results as follows: (*Svalöf* 1916), 0880 Rubin 5; Dala 1; 0702 Kolben 8; 0841 Extra-Kolben 9.

**STRENGTH OF STRAW** — If a scale of resistance ranging from 0-10 (0 = non-resistance, 10 very resistant) is taken, the figures are:

*Svalöf* — 0880 Rubin 8; Dala 5; 0702 Kolben 8; 0841 Extra-Kolben 4.

*Skara*: 0880 Rubin 9.4; Dala 5.3; 0702 Kolben 8.8; 0841 Extra-Kolben 9.3.

Resistance is about the same as that of the parent Kolben, but exceeds it in some cases.

**EARS** light-brown and awnless.

**WEIGHT OF HECTOLITRE AND WEIGHT OF 1000 GRAINS.** — Equal or a little lower than in the case of Kolben. At Ultuna, the averages for 1916-1921 were

**WEIGHT OF HECTOLITRE** (in kg.): 0880 Rubin 74.4; 0702 Kolben 73.9; 0841 Extra Kolben 72.4; Dala 73.4

**WEIGHT OF 1000 GRAINS** (in gm.): 0880 Rubin 33.4; 0702 Kolben 33.9; 0841 Extra-Kolben 34.5; Dala 30.3.

The object of the cross viz., "to obtain an earlier ripening Kolben", was thus attained to a very satisfactory extent. The new spring wheat is especially adapted to the conditions in Central Sweden, where it can with advantage be substituted for the native types. It may also be recommended for the high regions of the interior of South Sweden where Extra-Kolben is found to be too late in ripening. G. A

556 - **Orion of Svalöf an Early Black Variety of Oat for the Norrland obtained by the Cross Ligowo × 0668.** — ÅKERMAN, Å., in *Svenska Utsädesföreningens Tidskrift*, year XXXII, Part 1, pp. 4-16, figs. 2. Malmö, 1922.

In the northern and mountainous sectors of Norrland, the frostless season is very short and it is therefore necessary to grow the very earliest varieties of oats, in order that they may ripen some time before the first frosts and cold weather of autumn begin.

The vegetative season of the native oats is undoubtedly short, but their yield is very low, the quality of the grain is poor and the straw weak. For these reasons, 6-rowed barley has always been the favourite cereal in these latitudes, and scarcely any oats have been cultivated. For a long time the "Svenska Utsädesförening" has considered it advisable to carry out selection work with a view to obtaining a type of oat as early in ripening as the native varieties but at the same time producing a heavy yield, stiff straw and grain of good quality.

Since the end of 1890, the results of the individual selection of local native populations had been far from satisfactory; therefore in 1903, a first series of crosses were made between Ligowo (an oat well known for its high productivity and the excellent quality of its grain), and line 0600 of Nordfinsk Svartthavre (Black North Finnish Oats), and line 0668 of a native variety from Nordland (Norway).

From the first cross was obtained the line 01120 Björn of Svalöf oat, and from the second, the Orion of Svalöf oat, line 1101.

The Cross Ligowo × 0668 was effected in 1903 and the first cultural experiments made in 1910 at Svalöf. The line proved to be still far from homogeneous and it was therefore thought well to make a further selection in 1911 by isolating the line *b* which is the most cultivated at the present time.

Since 1914, the most important lines of Orion (01101 *b*; 01103; 01102 etc.), have been subjected to comparative cultural experiments on a large scale in various provinces of Sweden; they have been chiefly compared with Mesdag, a very early variety of oat, which is the favourite in the Northern districts. The data obtained from these experiments are as follows:

1) **EARLY RIPENING.** — Orion ripens on an average only two days later than the earliest types of oats grown in Norrland, but it is distinctly

superior to Guldregn. The following data were obtained from Holm (Ängernanland), as to the number of days from the vegetative period till maturity during the period 1917-1920: 01120 C. Björn II 90.; 01101 b, Orion 88; 01102, 99; 10 d. Orion, 89; 01104 328; 14 d Orion 88; Mesdag, 86; 0386 Guldregn, 95.

2) YIELD. — In Norrbotten and Vasterbotten, Orion produced 5.5 % more grain and 7.5 % more straw than Mesdag. The difference in favour of Orion increases and reaches 15.8 % (grain) if Orion line b is the type in question. The same returns were made from Jämtland. If the grain yield of Mesdag is estimated at 100.0 those of 01101 b Orion and of 01163 b Odál were respectively 129.6 and 126.6. On the other hand, at Holm and in the districts of Västermorrländ, where the climate is better, Odál takes the first place.

OTHER CHARACTERS. — Long, but comparatively stiff straw: grain of good quality; the weight of 1000 grains is greater than in the cases of Mesdag, Björn, and Nordfinsk Black Oats; the weight per hectolitre is equally satisfactory. In Orion, the glumes of the seed are very thick, so that the enclosed grain is relatively small. It must, however, be observed that in a very rigorous climate, strong glumes serve to protect the embryo against the action of frost and insure a higher capacity of germination.

Briefly it may be stated that the objects in view in making the cross Ligowo × 0668 have been obtained in a very satisfactory manner on the whole, since the hybrid produces a heavy crop of grain of good quality ripens early and has stiff straw.

Orion will certainly take the first place in the Provinces of Norrbotten, Västerbotten and Jämtland G. A.

557 — An Enumeration of the Dominant Characters of Barley. — FRASER, C., in *Scientific Agriculture*, Vol II, No 4, pp 113-116. Gardenvale, P. Q. December, 1921

The author unites in this article all the data respecting the determination of the dominant characters of barley.

The list is as follows.

- |                           |                                  |
|---------------------------|----------------------------------|
| 1) Black colour of palea  | dominant as regards white colour |
| 2) Two rows               | SIX ROWS                         |
| 3) Hood                   | awn                              |
| 4) Purple colour of palea | white colour                     |
| 5) Coloured grain         | colourless grain                 |
| 6) Narrow glumes          | broad glumes                     |
| 7) Loose ears             | close ears                       |
| 8) Adherent palea         | non adherent palea               |
| 9) Brittle rachis         | resistant rachis                 |
| 10) Awneel ears           | hooked ears                      |
| 11) Rough awns            | smooth awns                      |

1) BLACK COLOUR OF THE PALEA. — The dominance of black as regards white was already known before the revival of Mendelism and instances of this dominance were reported by RIMPAU. TSCHERMAK fixed the ratio in

the  $F_2$  as 3 : 1, and BIFFEN obtained the same results in the following crosses between white and black varieties :

*H. japonicum* × *Steudelii*  
*H. vulgare* × *Steudelii*  
*H. mutans* × *Steudelii*

He invariably obtained in the  $F_1$  black individuals and in the  $F_2$ , black and white individuals in the ratio as 3 : 1.

Although the recessive type was cultivated for a long time, it never produced any black forms.

2) NUMBER OF ROWS — In this case the dominance is not as absolute and indisputable as in the former. In the results of a series of crosses made at Ottawa (Canada), SAUNDERS observed cases of incomplete dominance. He discovered in some of the  $F_2$ , in addition to the extreme forms, a series of intermediate forms ranging from 2 to 6 complete rows. In the  $F_3$ , however, nearly all the six-rowed individuals behaved as true heterozygotes (typical intermediate forms) and produced a mixed progeny of which 25 % were two-rowed, 50 similar to their parents and 25 % six-rowed.

3) HOODED — The dominance of this character over the awned condition is proved by the following crosses

*H. trifurcatum* × *H. mutans*  
*H. vulgare* × *H. atrum*  
 Black Hulled × Beardless

In the  $F_1$ , there are always trifurcate individuals with supernumerary sessile flowers. In the  $F_2$  there are trifurcate forms and awned forms in the ratio of 3 : 1.

4) PURPLE COLOUR OF PALEA. — Dominant as regards white.

5) PIGMENTED, OR UNPIGMENTED GRAIN. — The presence of pigment in the palea seems to be correlated with the colour of the grain, whereas in wheat, as is well-known, the colour of the palea is quite independent of the grain. The character of "coloured grains" is dominant as regards that of "colourless grains."

6) NARROW GLUMES AND BROAD GLUMES. — In the greater number of barleys, the glumes are narrow, there are, however, some varieties in which they are oval-lanceolate. By crossing *H. abyssinicum* with *H. Steudelii*, or *H. abyssinicum* with *H. trifurcatum*, narrow glumed individuals are obtained in the  $F_1$ , whereas in the  $F_2$ , and the  $F_3$ , there are narrow glumed hybrids and broad glumed hybrids in the ratio of 3 : 1.

7) LOOSE AND CLOSE EARS — As SPILMAN has been able to prove in the case of wheat, the heterozygotes of the  $F_2$  are in intermediate conditions. Cases have occurred where the  $F_1$  had still looser ears than their loose eared parents. The same is reported of the  $F_2$ . According to BIFFEN this is probably due to a rather larger number of genetic factors.

8) ADHERENT PALEA. — Dominant as regards non-adherent.

9) STRENGTH OF RACHIS. — Many varieties of barley have a more or less brittle rachis. This brittleness attains its maximum in *H. spontaneum*,

the ripe ear falling apart of its own accord. On crossing *H. spontaneum* with six-rowed varieties with hooks and rather resistant rachis, individuals with brittle rachis are obtained in the  $F_2$ . Although very complex segregation has taken place in the  $F_2$ , brittle individuals and resistant individuals occur in the ratio of 3 : 1.

10) AWNLESS AND HOOKED FORMS — There are very few data regarding these. From *H. nigrosubinerme* (awnless)  $\times$  *H. hexastichofurcatum* (hooked), were obtained in the  $F_1$ , some individuals resembling the awnless parent, and in the  $F_2$ , out of the 41 individuals, 27 were awnless, 7 hooked and 7 awned. These 41 individuals were the progeny of a single plant of the  $F_1$ .

11) STRUCTURE OF AWNS — Many varieties of barley have a characteristic denticulation of the awns rendering them rough to the touch. The rough form is dominant as regards the smooth. G. A.

558 - Behaviour of the Character "Ramified Female Inflorescence" in the Cross with Maize Plants having normal Ears.—KIMPTON, J. H., in *United States Department of Agriculture, Bulletin No. 971*, pp. 1-20, figs. 5, Plates I-XVI. Washington, December 1921.

The variation of maize known under the name of "ramified" (*Zea ramosa*), is characterised by having branched female inflorescences, while the male inflorescences, which in normal types are little ramified at the base and possess a very well differentiated central axis, are much branched, the ramifications extending to near the top of the median axis.

For the crossing experiments, the Gordo variety of maize (from Chihuahua, Mexico), was chosen, this is characterised by the reduced ramification of its male inflorescence, which has two or three branches at the base and a very distinct central spike of which the length may be as much as 50 centimetres.

In the  $F_1$ , the character "branched" behaves as a recessive, and the ears of the hybrid are normal, having no ramifications. In the  $F_2$ , segregation takes place into normal individuals and ramified individuals in the usual ratio 3 : 1. Biometric determinations have, however, shown that the ramified plants that segregated in the  $F_2$  no longer possessed the typical form, for they had acquired some of the characters of the Gordo parent, the same occurred in the normal individuals that segregate in the  $F_1$ .

In the "ramified" group, the structure of the terminal panicle and of the female inflorescence showed great variability. Some of the plants classed as "ramified" from the characters of the male inflorescence, yet possessed unbranched ears. Among them a complete series could be found ranging from the typical ear to the ramified inflorescence.

Generally the intermediate female forms were accompanied by a male inflorescence of a similar intermediate form. In the  $F_3$  the progeny had ears ranging through all the intermediate forms up to the extreme types, whereas the male inflorescences were intermediate in character. In the  $F_4$ , the results obtained confirmed what had been observed in the preceding generations. Two of the hybrids certainly had normal ears with no signs

[557-558]

of ramification, but the influence of *Zea ramosa* was very clear in the male inflorescences. Although the progeny might differ considerably from one another, the results obtained in the  $F_4$  indicate the possibility of isolating constant intermediate forms, and make it more difficult to interpret the phenomena as being due to certain basic factors.

If the results obtained in the first and second generation may be regarded as representing a monohybrid ratio, this explanation certainly does not hold good in the case of the  $F_4$ . In addition to the chief determining factor, there are no doubt other genetic factors giving rise to constant intermediate forms. There is, however, no sufficient evidence to show whether these intermediate forms are due to multiple factors, or to factors which influence the chief factor in such a manner as to modify its expression.

**559 - The Improvement of the Oil-Bearing Sunflower by Selection, in Bulgaria.**

KIOUMIOURDJIEFF, I. V., in *Semlédiétje* (Agriculture), year XXV, Part 9, pp 117-119 Sofia, 1921

The commercial varieties of sunflower cultivated in Bulgaria for oil production are from the genetic point of view a mixed population composed of a large number of forms.

There is, however, to be found in Bulgaria a type of sunflower valuable both for the quantity and quality of its oil, but as it has never been selected, this type has become so contaminated and mixed that its oil yield has greatly suffered. It is therefore necessary to have recourse to careful sorting, and in making choice of seed plants, the established rules of physiological selection should be observed.

1) The fruit must be taken from plants that have not branched during the summer.

2) All very luxuriant plants should be rejected. It is best to select those of average growth.

3) The fruits ought to be of moderate size and their surfaces covered with seeds of the shape and dimensions best suited for the purpose.

One type of sunflower fairly frequently seen in plantations has thickish rounded seeds (like coffee-beans), with a fawn-coloured integument and spherical kernel, and this type should be preferred to any other.

Another form also occurs which bears equally short rounded seeds, with tough integuments, but of a darker colour and having light stripes on either side, this type might produce by selection a variety resistant to the insect (*Homocossoma nebulella*?), a parasite, which causes damage every year.

**560 - On the Advisability of Selecting the Native Tobaccos in Bulgaria.--** TOCHIEFF,

I. V., in *Semlédiétje* (Agriculture), year XXV Vol 8, pp 119-121 Sofia, 1921

The varieties of tobacco cultivated in Bulgaria are, from the genetic standpoint, populations composed of numerous distinct forms differing from one another in their morphological characters and physiological constants. The sorting of these populations would improve the quantity

and quality of the tobacco produced. For the first year, female parent plants should be selected, the following characters being taken into account:

- 1) The number, position and size of the leaves;
- 2) The nature of the stem, which should be sufficiently strong, little inclined to the production of suckers, and with leaves growing close together.
- 3) Resistance to diseases and to injurious insects, especially *Thrips*.
- 4) The earliness or duration of the vegetative period. In cold regions, such as for instance the hilly and mountainous parts of the Balkans early maturing types are necessary.

The inflorescences of the mother plants chosen according to the above requirements are isolated at the right time to prevent crosses.

The seeds of each plant are sown the second year in separate plots, the plants in each plot being carefully examined as in the preceding year, and the inflorescences isolated. When the plants have reached their technical maturity, the 4-5 first leaves are carefully removed, those from each plant being kept distinct, while the 4-5 leaves still remaining on the stem are left until the seed ripens.

The leaves thus collected are carefully analysed as regards the following characters:

- 1) Weight of leaves per plant;
- 2) size of leaf-blades,
- 3) thickness and percentage of veins,
- 4) colour and structure of leaves;
- 5) ignition properties.

The same operations are repeated in the following years, until the required characters have become fixed, and the lines thus obtained have acquired the necessary homogeneity.

561 - **Difficulties arising in Experiments on the Improvement of Fruit-Trees by means of Crossing and Selection.** — DORSEY, M. J., in *Scientific Agriculturist* Vol II, No. 4, pp. 118-120 (Gardenvale, P. Q., December 1921).

Sterility (auto-, or stamino-sterility), is one of the chief obstacles encountered in the course of genetic work on fruit-trees. Recent observations have shown that arrested development may occur at any moment during the complicated process of the sexual mechanism. From the genetic standpoint, the effects are equally important whether this arrested development manifests itself either in the gamete, or the zygote, for it can prevent the combination of factors which is for many reasons particularly desired. The study of pollen shows that in a great number of varieties especially in species hybrids, there is a variable quantity of aborted pollen. In certain cases, the abortive pollen is the factor that checks fruit-setting. If these abortive grains represent some determined combinations of character, it is clear that some of the possible gametic combinations are excluded. Similarly, if the development of the embryo is arrested before it reaches maturity, a number of possible new types are eliminated in the same way. Further eliminations may also take place during the interval between fer-

tilisation and the maturity of the seed. Seeds that are incapable of germination are the results of a subsequent loss of gametes, amongst which these may be combinations that are little disposed to further germination.

In order to be able to give a satisfactory interpretation of the phenomena of heredity, it would be well to determine in each case the moment in the biological cycle when the suppression of the essential organs took place. The frequency with which this phenomenon occurs and the resulting consequences could certainly be estimated by workers carrying out crossing experiments on a large scale who would note the approximate quantity of sterile pollen and the number of abortive pistils belonging to the large number of flowers that do not set seed, and of seeds that are incapable of germination.

It is thus extremely difficult to obtain any desired type by a cross based only upon the characters of the two parents, especially if the latter belong to different species, as actually occurs in a large number of cases.

It would be advisable, in the face of these difficulties not to try to obtain immediate results at first, but to make a thorough study of the material afterwards to be used in the work of improvement. In the first place it is necessary to determine the best varieties to use for the crossing experiments; for the best parents are the starting point for the production of new varieties.

Much has already been done in this direction, not only for commercial varieties, but also for the native species.

In the second place, the genetic history of some well known hybrids should be carefully studied with a view to increasing what is already known touching the transmission of fruit characters and to fix the laws of their heredity, which would provide a systematic and scientific basis for work, instead of a merely empirical estimate.

562 - **The Possibility of Transmitting by Vegetative Propagation the Character of High Productivity in certain Apple-Trees.** — DAVIS, M. B. in *Scientific Agriculture*, Vol II, No. 4, pp. 120-121, fig. 1. Gardenvale, P. Q., December 1921.

After a reference to previous experiments which would seem to have proved that positive results can be obtained in the case of citrus trees (SHAMEL) by grafting well selected scions on productive stocks, although only negative results were observed for apple-trees (GARDENER with the Ben Davis variety), the author gives an account of the observations made at the Agricultural Experiment Station of Ottawa (Canada) regarding the transmission by vegetative propagation of the character of productivity in the case of apple-trees.

A certain number of trees were chosen for the experiment, and in 1896, the first observations were made and data collected; in 1906, scions were taken from:

- a) the tree which had produced the highest total yield during a period of eight years (571.6 lb.);
- b) the tree which had produced the lowest yield (184.50 lb.);

c) the tree which had produced the most regular crop and a high yield (354.6 lb.).

Although differing in yield, the trees were nearly similar in other respects, such as growth, quality of fruit etc.

The scions were grafted on the Rose of Stanstead and on Dartmouth.

The 17 descendants of the tree that had produced the highest yield bore in 9 years 4374 lb. or 257 lb. per tree.

The 8 descendants of the tree with the lowest yield produced in 9 years 1269 lb., or 158 lb. per tree. Finally, the 12 descendants of the tree that had produced the most regular crop, which was at the same time a heavy one, bore in 9 years 2612 lb., or 219 lb. per tree.

The descendants not only differed in productivity, but also in the vigour of their growth, which was distinctly inferior in the progeny with low yields. There thus seems to be a very close connection between yield and growth. In order to complete and test these experiments, the following test was carried out. Scions taken from the three trees already mentioned were grafted upon 5 large trees, the branches selected for the purpose being as uniform as possible. Three scions, each taken from a different tree, were grafted on each stock, care being taken to vary the position of the graft upon the stock in such a manner as to obtain the most uniform conditions possible. Thus if the scion taken from a tree of low yield was grafted on the north side of the 1st stock, it was grafted on the neighbouring tree on a branch exposed to the south, and so on. The following Table gives the results of the five-year period 1911-1915. They confirm in the main the results obtained in the previous case, except that the offspring of the tree with the most regular crop and a large yield took the first place. The offspring of the tree with low yield was also noticeable for poor crops.

*Data regarding the crop for the Five-Year Period 1911-1915.*

Distinguishing number of trees	Progeny of unproductive tree	Progeny of tree with high yield and most regular crop	Progeny of the most productive tree
36-21	48.37	144.00	103.62
43-13	67.50	70.87	87.75
43-27	13.50	137.25	56.25

563 - Means of Obtaining, by suitable Crossing Varieties of Grapes without Pips. — SROUT, A. B., in *New York Agricultural Experiment Station, Geneva, N. Y., Technical Bulletin No. 82*, pp. 1-16, Plates I-VII, Geneva, N. Y., January 1921.

The structure of the vine flower has for a long time been a matter of interest to vine-growers and students of heredity desirous of producing types of grapes with few or no pips. It is desirable and in fact most necessary, for those engaged in the study of genetics to determine as accurately as possible the extent to which crossing operations can influence the distribution of the sexual organs in the flower, and to regulate them.

It is well known that in all varieties, fruit production depends upon the development of the stamens and pistils and upon their capacity to act as sexual organs in the processes of fertilisation and the setting of fruit.

The self-fertilising varieties, such as Delaware, Niagara, Winchell and Concord, bear flowers having equally developed androecium and gynoecium which are capable of functioning *inter se*, even upon the same flowers; these are therefore complete hermaphrodites and are fertilised by self-pollination.

On the other hand varieties such as Brighton, Lindley, Baty and Massasoit, have recurved instead of erect stamens or the stamens are more or less aborted, and have shrivelled and defective pollen-grains. The pistil is however normally developed and in such cases, self-fertilisation is rare, and the intervention of foreign pollen is necessary (imperfect hermaphrodites).

There is a third group (to which all the wild American species, and some of the cultivated varieties belong), in which the flowers are only provided with stamens. In this case, the pistil is more or less abortive, always incapable of functioning, and sometimes entirely lacking. The stamens on the contrary are normal and produce much pollen.

There is also a fourth group, producing pipless or almost pipless grapes. The pistils are able to develop into grapes, whereas the ovules even if they are present, cannot transform themselves into pips. The development of the fruit is caused by the stimulation exerted by the pollen tube which as it grows, penetrates into the pistil and hermaphroditism is imperfect.

There are in short 3 types of flowers: 1) with stamens; 2) perfect hermaphrodites; 3) imperfect hermaphrodites. No purely female forms are as yet known.

These flowers are not always very clearly distinguishable for there is a gradual passage from one type to the other through a series of intermediate forms. It is through the study and the selection of these intermediate forms that it may be possible to discover types possessing this degree or kind of "femininity" that is met with in the pipless varieties.

By way of preparing the ground and collecting material, the Agricultural Station of Geneva (N. Y.) made a careful study of the variations occurring in vine-flowers and the results obtained may be summarised as follows:

1) *Flowers with stamens*: in these there is either no trace of pistil, or the pistil is more or less aborted. The stamens of each flower and of all the flowers of a given plant are very uniform, but differences are noticed between one individual and another as regards length of filaments and the size of the anther. The filament is erect, the germinating capacity of the pollen in 95 % and plants of this class are typical males.

In wild species, as already stated staminate individuals frequently occur; according to observations made by the author, they seem inclined to have rather long filaments.

2) *Perfect hermaphrodites with erect stamens*: the flowers of this class may present considerable differences as regards length of filaments, size of anther, and the shape and dimensions of the pistils. Although the number of pips may vary from one variety to another, the development of the fruit is always subordinate to the formation of the pip. The stamens are erect, the pollen gives a high germination percentage, 75 %. There are, however, individuals, which although they are vigorous and well-developed and furnished with perfectly erect stamens, produced shrivelled and defective pollen.

3) *Hermaphrodite flowers with erect stamens and spiral filaments*: the filament is more or less undulating or twisted into a spiral, the anthers are normal; the pollen is more or less shrivelled and incapable of fertilising. The gynoecium on the other hand is normal and if it is fertilised with good pollen, regularly developed fruit is nearly always produced. This type of flower has been found on 33 plants of which the descent is known to the third generation.

From a cross between Winchell and Diamond (both hermaphrodites with erect stamens), Station Seedling No. 123, a hybrid also with erect stamens, was obtained. Worden (with erect stamens) was then fertilised with pollen from the above No. 123, and three other individuals, Nos. 931, 933 and 934 were produced, all having erect and straight stamens. The appearance of this type of flower in all the 34 descendants to the third generation gives a good idea of a case of mass selection.

4) *Flowers with filaments bent outwards, or with curved seeds*: in plants raised from seed it is not uncommon to find flowers of which the filaments at the moment of anthesis form a more or less wide angle with the pistil. The anthers are normal, the pollen is shrivelled and unable to germinate.

5) *Flowers with twisted anthers*: the filament may be simply bent, as in the Barry variety, or twisted to the point of being curled, as in Masasoit, with all the intermediate degrees. Pollen germination experiments give wholly negative results.

6) *Pipless or almost pipless types*. — The observations were made on plants of the type "Concord Seedless". In 1913, E. H. WETMORE of Rushville (N. Y.), sent to the Station a case of grapes which were nearly pipless. From the very small number of pips present, pipless descendants were obtained which differed from the normal type only in having rather smaller grapes. The flowers had very long stamens and normally develop-

ed anthers with pollen having a high germinating capacity (at least 95 %). The vines with pipless grapes are typical males, but the lack of pips would appear to be due, according to the author, to what may be called a slight degree of feminality. From crossing Triumph and Duches (two varieties with pipless grapes), descendants were obtained from which some of the grapes (the smallest), were almost without pips. The vines bearing these grapes have flowers with erect stamens long, or medium-sized, anthers and pistils of average dimensions.

Seedless Hubbard and Sultanina (Thompson's Seedless, a variety largely grown on the shores of the Pacific), also have flowers of the same type. The male characters are strongly developed in these varieties, whereas the absence of pips shows that the female organs are weak and only partly developed.

If a hermaphrodite variety is fertilised with the pollen of pipless types, grapes with few pips are obtained in the  $F_1$  although owing to segregation, there are no pipless individuals in the following generations.

In any case, the author is of opinion that the best way to create varieties of grapes without pips is indicated by the fact of intersexuality. Most of the individuals and varieties that are nearly or quite pipless have strong stamens. The pollen of pipless males can be used to fertilise other male individuals with weakly developed female organs that sometimes permit the formation of seed. It would no doubt be possible in this way to obtain families composed of individuals many of which would bear pipless grapes.

564 — **A Monograph on the Wheat Plant** (1). *Nature* Vol 109, No 2734 pp 366-368 London March 23 1922 and reviewed in *The Gardeners Chronicle*, Vol LXX No 1827, p 331 London Dec 31, 1921.

CEREALS  
AND  
PULSE CROPS

Prof J PERCIVAL'S monograph on the wheat plant, recently published, fills one of the many great gaps in agricultural literature and is a noteworthy contribution to present day knowledge on this ever important subject. It will be read and admired in all countries and for many years to come. Every detail is founded on the author's own personal experience and the study is peculiarly exhaustive.

The introduction shows how widespread is the cultivation of wheat and it is interesting to note that there is no month in the year during which the wheat harvest is not being carried on in some part of the world. This is indicated as follows:

*January* Australia, New Zealand, Argentina, Chile, *February* India, *March* India, Upper Egypt, *April* India, Persia, Asia Minor, Lower Egypt, Mexico, Cuba, *May* Japan, China, Central Asia, Morocco, Algeria, Tunis, Texas, *June* South of France, Spain, Italy, Greece, Turkey, Japan, United States (south of 40°), *July* France, Germany, Austria, Hungary, Roumania, Bulgaria, S Russia, Canada, N United States,

(1) *The Wheat Plant, A Monograph* by John PERCIVAL, M A, F L S with 228 illustrations. London Duckworth and Co (Ed)

*August* : England, N. France, Belgium, Holland, Central Russia, Canada, United States ; *September* : Scotland, Sweden, Norway, Canada ; *October* : N. Russia, Finland ; *November* : South Africa, Argentina, Peru ; *December* : Burma, Australia, Argentina.

Apart from the great wheat producing areas, wheat can be grown from beyond the Arctic circle to the Equator ; it is known to flourish from sea-level up to 10 000 ft. in Mexico etc. and according to HUMBOLDT, reaches an altitude of 14 000-15 000 ft. in Tibet. So long as the winter temperatures do not fall below  $-20^{\circ}\text{C}$ , and the air and soil are dry, the exposed plants suffer little. As regards water supply, an annual rainfall of 20-30 in. is sufficient although some of the Macaroni and Club wheats give remunerative returns in regions where the rainfall is not more than 12-15 in. per annum.

In Part I of the monograph, Prof. PERCIVAL gives the results of his investigations into the morphology, anatomy, growth and development of the plant. The earlier chapters contain detailed descriptions of the grain and its germination illustrated by a wealth of new and admirable pictures, far more illuminating than the well-known illustrations to be found in present botanical text books. The numerous details of the structure and behaviour of the plant testify to the closeness of the observations made, and will be of exceptional value to future investigators.

Part II opens with a discussion on the classification of wheats. This is a subject which the author has made peculiarly his own, seeing that for the last 20 years he has grown annually at the farm attached to the University College, Reading all available varieties, numbering nearly 2000 forms derived from almost all the wheat growing regions of the world. As the result of his comparative investigations, Prof. PERCIVAL concludes that in addition to the two recognised wild species 1) *Triticum aegilopoides* Bal. (wild small spelt) and 2) *T. dicoccoides* Körn (wild emmer), eleven races or cultivated species exist, eight of which, viz. *T. monococcum* L. (small spelt), *T. dicoccum* Schübb. (emmer), *T. durum* Desf. (macaroni), *T. polonicum* (Polish), *T. turgidum* L. (Rivet), *T. compactum* (Club.), *T. vulgare* Host. (Bread), and *T. Spelta* L. (large Spelt or Dinkel), are well known races ; whilst three, viz. *T. orientale* (Khorasan wheat), *T. pyramidale* (Egyptian cone wheat) and *T. sphaerococcum* (Indian dwarf wheat) are new creations. The first of these consists of two emmer-like varieties, differing only in awn colour, and characterised by the possession of long glumes and grain. The second consists of a group of 5 Egyptian wheats resembling the Rivet wheats in most respects, and in leaf colour, shortness of straw and ear shape strongly reminiscent of segregates of crosses between *T. turgidum* and *T. vulgare*. The third is an equally small group of round-grained forms similar to *T. compactum*. The further sub-division of these races into "varieties" follows the well-known system in KÖRNICKE and WERNER'S "*Handbuch des Getreidesbaus*". It should be noted however that certain forms have been transferred quite rightly to other groups e. g. several forms placed by KÖRNICKE in *T. durum* are transferred to the emmer group *T. dicoccum*, and the Persian Black (*T. dicoccum* var. *persi-*

*cum*) a form which has puzzled more than one specialist is also placed in this group, to the satisfaction of those interested in the genetics of this important mildew-resisting wheat.

A specially detailed description is devoted to the common breadwheat, with the numerous bearded and beardless varieties (pp. 265-306). The predominance of these last may be attributed to the digestibility of the flour and the endurance of the plant. The most ancient of cereals, *T. vulgare* now exists in some 14 varieties (7 bearded and 7 beardless), which are easily classified by the colour and degree of downiness of the glumes.

The systematic portion of the monograph is followed by a chapter of considerable interest on the origin and relationships of the races of wheat. Evidence from various sources, archaeological, ecological, pathological, genetical, etc. is skilfully marshalled to show their probable lines of development. The author as a result of his morphological studies comes to the conclusion that "there is not nor has there ever been a prototype of the bread wheats" and that "the characters of *T. vulgare* and its allies appear... to be those of a vast hybrid race initiated long ago by the crossing of wheats of the emmer series with species of *Aegilops*." He adopts the view that the present day wheats fall into the 3 series already mentioned. The multiplicity of the races is doubtless connected with the fact that, although as a rule self-fertile, wheat is occasionally cross-fertilised and results in consequent natural hybridisation.

Artificial hybridisation was first started at the end of the XVIIIth century by KNIGHT, but no definitely important results were obtained until 1846 when MAUND and RAYNBIRD produced undoubted hybrids. Since then, hybridisation has been carefully followed up and important results have been obtained. For example, BIFFEN, who first investigated the inheritance of resistance and susceptibility to the attacks of yellow rust (*Puccinia glumarum*), discovered that these characters form a Mendelian allelomorphic pair, and working on this basis, a means of circumventing rust by the production of immune varieties was worked out (1). A useful summary of most of the more important literature dealing with hybridisation and improvement of wheat is given, with details of the most recent hybrids obtained.

The concluding chapter contains an interesting survey of the yield obtained in different countries, the world's average being 13 bus. per acre. Historical research shows how greatly the yield has been increased during the last few hundred years. With the increase in stock raising and the consequent increase in the amount of manure available, there has been a steady rise in yield. Records show that in the XXth century, the average for the first 20 years was 31 bus. as compared with 10 bus. in the XVIIIth century. Occasionally there have been exceptional results: e. g. 96 bus. per acre of Yeoman wheat at Wye, Kent (England), in 1918 and 117.2 bus. per acre in Island County (Washington, U. S. A.) in 1895.

(1) See *R. March* 1922, No. 226. (*Ed.*)

Prof. PERCIVAL also gives details of the effect on yield of soil, cultivation and manuring, seed rate, variety, time and methods of sowing, and size of grain. M. L. Y.

565 - **The Chief Causes of the low Yields of Maize in South Africa and possible Means of Improvement.** — BOSMAN, G. J. (School of Agriculture, Glen, O. F. S.), in *Journal of the Department of Agriculture, Union of South Africa*, Vol. III, No. 6, pp. 507-514. Pretoria, Dec. 1921.

In recent years, the average yield of maize per acre in South Africa has been very low as compared with other countries. The author has here summarised the main causes of this deficiency, and the methods recommended for the cultivation of maize.

Apart from the employment of defective methods of cultivation, the rainfall of South Africa is undoubtedly the greatest limiting factor in maize production. It is considered, other factors being favourable, that 10 to 12 in. of rain during December-February are sufficient, and a steady rainfall of 1-2 in. per week seems to be the most effective. It is noted, however, that although the question of moisture is to a large extent beyond the control of the farmer, the proper preparation of the seedbed is a matter for careful consideration. A great deal of the maize crop, in South Africa suffers annually because the soil is simply surface scratched and the roots are unable to reach the moisture conserved in the sub-soil. Deep ploughing is considered advisable by the author, preferably a winter ploughing with a subsequent cross ploughing in spring, or where this is impracticable, the soil should be thoroughly cultivated or disc-harrowed. Maize does not succeed well on newly broken up soil, unless of a very sandy type.

Seed of poor quality has largely been used. Maize farmers have obtained their seed behind the sheller, where the large grains from the small degenerated ears are caught as well as those of good ears. This has gradually led to deterioration in crop value. To remedy this mistake, it is recommended that new seed of the same variety should be obtained and used in every alternate row. The continuous use of the same variety without introducing the "vigour" of a different strain is deleterious to the crop. By detasselling the plants from the old seed every fourth year, the vigour and stamina of the crop are assured.

Many farmers sow their seed broadcast and the disadvantages of this method are numerous, particularly when the difficulties of labour shortage are also considered. The greatest economy in seed is gained where the planter is used. To ensure adequate depth for planting the "listing" method is advised (i. e. the use of the ridging plough) and it has been proved that listed maize stands drought far better than maize planted in the ordinary way.

The insufficient use of the harrow has led to a very marked diminution in yield, and attention is drawn to the fact that a weedy field is doomed to failure in times of drought.

Another cause of crop failure may be attributed to inadequate knowledge of the right crop rotations. The following rotation as suggested by the author should, however, meet the requirements of most maize farmers :

*For a grain farmer on poor soil* — 1st year maize, fertilised, 2nd year, maize, 3rd year, cowpeas ploughed under

*For a maize farmer on more productive soil* — 1st year maize fertilised, 2nd year, maize, all available manure applied, 3rd year maize, 4th year cowpeas or velvet beans ploughed under

*For the stock farmer who grows maize* — 1st year maize, 2nd year, maize fertilised, 3rd year hay crop e.g. teff (*Eragrostis abyssinica*), Sudan grass etc., 4th year, cowpeas harvested for hay

*For the potato and maize farmer* — 1st year maize, 2nd year maize fertilised, 3rd year cowpeas, ploughed under 4th year potatoes heavily manured

*For the cotton and maize farmer* — 1st year maize fertilised, 2nd year cotton, 3rd year Kaffir beans, peanuts or velvet beans

There appears to have been a continued persistence in growing unsuitable varieties of maize, and in unfavourable zones. Large areas situated in a dry region have been planted with maize every year with the result that the crop is a success only once in 3 or 4 years. In such cases the author states that the substitution for maize of a more drought resistant crop such as Kaffir corn, would be distinctly advantageous. It is questionable whether maize should be grown in areas receiving a rainfall of less than 23 in a year.

Another mistake has been to grow late varieties in totally unsuitable districts.

Farmers in the drier districts where the growing season is short on account of the altitude or late arrival of the rain, are advised to cultivate the Flint varieties in preference to the Dents. Strict attention should be paid to local conditions as climatic influences cannot be made to suit the variety selected.

In consideration of the labour shortage it will probably be advisable to adopt an increased use of machinery and the so called combined harvester and binder and the maize husker are recommended. By this means the land is cleaned and made ready for winter ploughing the danger from insect pests is greatly diminished and the fodder can be stacked and saved as winter feed for stock.

With the maize husker the ears are snapped off, the rest of the plant being left standing. From 8 to 10 acres can be harvested in one day. Up to the present this machine has not been given a trial in South Africa.

Thousands of bags of maize are lost through the ravages of wild animals and it is stated that the only effective way of dealing with these pests is to use strychnine baits etc. The losses due to insect pests, especially the stalk-borer (1) are estimated at 25 % of the crop and 1 ½ million pounds sterling per annum.

M. L. Y.

(1) (*Paparpema niella*) The best means of combatting this pest successfully are described in Bulletin No. 3, 1920 Dept. of Agriculture, Union of South Africa (author's note)

566 - An Experiment with *Sorghum vulgare* from the Bombay Presidency, in the Singapore. — MATHIEU, E. H., in *The Gardener's Bulletin, Straits Settlements*, Vol. II, No. 12, pp. 423-426. Singapore, Aug. 5, 1921.

Report of experiments made in Singapore with two samples of *Sorghum vulgare* called Ahmednagar, and Jalgaon sent from the Bombay Presidency for trial purposes. The first proved of little value as a cereal crop, although possible of some value as forage. The Jalgaon sorghum however gave a comparatively closely packed head and may be considered of economic value as a cereal. It is to be noted that this plant, which comes from a region in India where the rainfall is light, has succeeded under very diverse climatic conditions elsewhere.

The prevalent idea that sorghum will not readily stand transplanting, has been contradicted by the results obtained during the present experiments. The results of the first cutting was :

Sown plot . . . . .	142 stems	weight with leaves, 31 lb.
" " . . . . .	142 panicles	" 8.75 lb. giving 5 lb. dry grain.
Transplanted plot . . .	223 stems	" with leaves, 102 lb.
" " . . . . .	223 panicles	" 23.75 lb. giving over 15 lb. dry grain.

The plots were identical in size, 280 sq. ft. planted 12 × 12 inches.

Yield per acre up to the present in Singapore is estimated at 714 lb. dry grain. The abnormal yield on transplanted plots is, however, worthy of notice.

A most effective means of scaring birds is described as follows : a skin of a flying fox is stretched out at full length on a bamboo frame, half rigid and half flexible, attached at both ends to the tips of the extended wings. The main bamboo is slightly bent like a bow, so that when grasped in the middle and moved about, the wings, following the movement of the bamboo, appear to be actually in flight. The scarecrow is attached to the top of a pole in the middle of the field and worked by a cord from a distance.

The sugar cane borer (*Scirpophaga* sp.), aphids and weevils have also done some damage to the plants but have been easily controlled.

FORAGE CROPS,  
MEADOWS  
AND PASTURES

567 - Sugar Sorghum a good Rust-resistant Feed. — CONSOLANI, G., in *Il Coltivatore*, Vol. 68, No. 8, pp. 246-248. Casale Monferrato, March 20, 1922.

The author calls attention to the usefulness of the sugar sorghum as a feed which can be grown in damp places owing to its resistance to rust, as proved by experiment with the "Silver Tip" variety; it also keeps its intense green colour throughout the period of vegetation in localities where maize-feeds and second-crop seed maizes, suffered greatly from the attacks of *Puccinia*.

Its other well-known qualities should also be taken into account, viz., its composition, high yield and resistance to rust.

The author advises sorghum as a feed for milch-cows especially (20 to 25 kg. per head per day, completing the ration with hay and oil-cake); the milk yield is considerably increased by its use.

F. D

**568 - Star Grass (*Cynodon plectostachyum*), a valuable Fodder Grass in South Africa.** — STENT, S. M. (Assistant Botanist) and MELLE, H. A. (Officer in Charge of the Botanical Experiment Station, Groenkloof) in *Journal of the Department of Agriculture, Union of South Africa*, Vol. III, No. 3, pp. 271-276, figs. 4. Pretoria, Sept. 1921.

The Star grass (*Cynodon plectostachyum*) is a native of East Africa, and has only recently been introduced into the Union of South Africa for experimental purposes. It has been grown at the Botanical Stations both in the valley on moist soil and on the dry-soil section, and reports have also been received from certain farms, all with reference to the pasture value of this plant.

In the Transvaal it is stated that this grass has proved a most valuable summer pasture but should not be relied upon in winter. This report was confirmed in Southern Rhodesia, and in addition it has been found in Nairobi that *C. plectostachyum* has proved more resistant to drought and of richer feeding value than kikuyu grass (1).

According to the chemical analysis made by the Government Chemist at Pretoria, the grass contains : % water 69.46, protein 5.50, fat 1.01, fibre 7.76, ash 2.89 and carbohydrates 13.38.

No extensive feeding tests have so far been made, but certain preliminary trials have shown that livestock appear to appreciate the flavour.

As regards cultivation, conservation of soil moisture is an important point and the plant has much difficulty in withstanding weeds.

An economical method of planting has been to use rooted plants and runners and plant behind the plough.

After harvesting with a mower there are generally three days interval before it can be stacked and it requires constant stirring. Experiments have shown that the best time to cut is between flowering and seed setting. A six months growing period should be allowed.

Owing to the soft and succulent nature of the plant it takes a considerable time to cure but gives a very good quality of hay. For economic purposes however it is recommended as more suitable as a pasture grass than as hay.

M. L. V.

**569 - Cultivation and Forage Value of the Velvet Bean (*Mucuna utilis*) in Rhodesia.** — WALTERS, J. A. T. in *The Rhodesia Agricultural Journal*, Vol. XIX, No. 1, pp. 21-28. pl. 3. Salisbury, Feb. 1922.

Twelve years of experimental trials in Rhodesia with the velvet bean (*Mucuna utilis* = *Stizolobium deeringianum*) have proved its high value as a forage crop and as a green manure. The two varieties employed viz. the Florida and the White Stingless are both long season crops (5 months).

Experiments were made to ascertain the value of sowing with maize, and it appears that for ensilage purposes this method is very satisfactory and especially if either sown simultaneously or at an interval of from 7 to 14 days (but not more) between the crops. The advantage of sowing the maize before the bean is that a support is thus provided for the twining

(1) *Pennisetum longistylum*. (Ed.)

vines. For grain purposes, similar trials were made, the beans and maize being sown alternately at a distance of 15 in. in the rows (*i. e.* half a stand of each). Both were sown on the same day in November, and resulted in a yield of 2862 lb. of maize, and 576 lb. of velvet beans per acre this following a very exhausting crop of buckwheat the preceding season.

**YIELDS AND HARVESTING.** — Good quality velvet bean hay is estimated to contain 14 % protein, and is therefore of almost identical value as a stock feed as lucerne hay (14.3 %). Green weights taken at the Agricultural Experiment Station, Salisbury show a yield of about 6.5 tons per acre which usually dries out to about 1 ½ to 2 tons of hay. Excessive drying should be avoided.

For seed purposes four separate experiments made at Salisbury in 1920-21 showed yields of 1270 lb., and 1210 lb. for pods + seeds and 1116 lb. and 880 lb. for seeds only per acre.

In America it is usual to feed the bean entire, either crushed or soaked for 24 hours, and its nutritive value is evident: protein 18 %, fat 4 %, nitrogen free extract 48 %, fibre 14 %.

Interesting results have been obtained where this crop has been systematically employed as a rotation legume with maize. Used as a green manure, there has been a distinctly higher maize yield. A chemical analysis made in 1921 indicates that when the velvet bean crop is ploughed under, the material above ground (excluding the root system) contains nitrogen 3 %, phosphoric oxide 0.47 %, potash 1.7 %, equal in a green crop of 6 ½ tons per acre to 191 lb. 30 lb., and 108 lb. respectively. Compared with other crops ploughed under, it is shown that the resulting yields of maize are superior to those where sunn-hemp (*Crotalaria juncea*) etc. are employed.

The high value as a stock feed has been confirmed in the United States, and LINDSEY and BEALS of the Massachusetts Agricultural College report that cows receiving a 40 % velvet bean ration gave an average of 5 % more milk than while on wheat bran ration. For pigs a ration of 20 parts. velvet bean feed + 20 pts. high grade peanut meal + 50 pts. maize meal + 10 pts. alfalfa was found satisfactory; for horses 20 % velvet bean + 30 % oats + 40 % cracked maize + 10 % wheat bran. It appears, however, that it is preferable to use the meal (bean minus pods) for pigs and horses.

#### FIBRE CROPS

570 — **A new Flax Seed in Ireland giving an exceptionally High Yield of good Quality Fibre.** — In *Journal of the Royal Society of Arts*, Vol. LXX, No. 3619, pp. 360-361, London, March 31, 1922.

A new pedigree flax seed has recently been produced by Dr. VAGAS EYRE, Director of the Linen Research Association Institute at Lisburn, near Belfast. Two new varieties of the Livornian strain were discovered, which on being tested, gave 80 % more fibre than any other flax seed on the market and the quality was on the average two grades higher.

It is estimated that the return is 100 % better than from the Dutch flax seed hitherto grown and it is reported by a well-known linen manufac-

turer that the spun yarns are of a more uniform quality. At present there are approximately 5 tons of this seed available.

Further distribution and commercial utilisation is under consideration, and while a portion will be given to Irish flax growers, another portion will be forwarded to the National Institute of Agricultural Botany at Cambridge, and the remainder sent to Canada, where climatic conditions are favourable for seed development.

M. L. Y.

571 - **Note on the Culture of the Cotton Plant in Tunisia.** — (Communicated by M. LOUIS-DOR, Delegate for Tunisia at the International Institute of Agriculture.

The cotton plant has not been much cultivated in Tunisia. The growers have limited their efforts to trials on a larger or smaller scale, assisted by the collaboration of the Board of Agriculture

**EXPERIMENTS CULTIVATION.** — The first attempts in the culture of the cotton made in the Experimental Garden date from 1899-1900-1901. They were not followed up at that time by the Tunisian agriculturists.

They were resumed by the Experimental Garden, the Colonial School of Agriculture and the Botanical Department in 1906 and continued until 1915. They had to be abandoned in 1916 owing to the mobilisation of the staff of these establishments

These trials were directed to the methods of culture and the varieties to be adopted in Tunisia. The results were published in the *Bulletin officiel de la Direction Générale de l'Agriculture*.

**SELECTION OF VARIETIES** — The tests having shown that the varieties cultivated were mixed, and this being against their adoption and detrimental to the quality produced, the Board of Agriculture proceeded to make a methodical selection.

This was done in two ways :

1) In 1912 and 1913, the Board made a contract with various planters authorising them, on payment of an indemnity, to take up from the land under cultivation all stocks which were not of pure growth and to keep the seed.

2500 kg. of selected seed were thus procured in 1912 and about 1500 kg. in 1913.

2) The work of scientific selection has been carried on by the Botanical Department since 1912 for the purpose of obtaining perfectly pure types to be afterwards multiplied and substituted for the varieties cultivated.

**PUBLICATION OF NOTICES ON COTTON CULTURE.** — In addition to making known the results obtained in their research establishments, the Board of Agriculture has published various pamphlets giving information to the planters as to the best methods of cultivating the cotton plant and the results obtained in neighbouring countries. These pamphlets are :

*Considérations générales sur la culture du coton en Tunisie.* — BRABANT ET NARLIN, 1911.  
*Notice sur la culture du coton en Tunisie,* VERRY, Inspector of Agriculture, 1912  
 18 p. *Rapport sur la culture du coton en Algérie.* — VERRY, Inspector of Agriculture, 1912. *La culture du coton en Egypte :* Ahmed el Alfî. Translated by SIBLOCH et LEPINEY of the Tunis Board of Agriculture, 1913, 134 pp.

**FREE DISTRIBUTION OF COTTON SEED.** — In order to surmount the difficulty experienced by planters in obtaining cotton-seed and to prevent the introduction of parasites, the Board of Agriculture has introduced all the seeds necessary for planters and has ensured their free distribution and disinfection.

With the seed distributed the following approximate areas have been sown :

15 hectares in 1906			50 hectares in 1911		
6	"	1907	200	"	1912
10	"	1908	800	"	1913
8	"	1909	100	"	1914
5	"	1910			

Of the area sown a portion, more or less considerable according to the year, remained unproductive, cultural results being very uncertain in soil which is not irrigated.

Since 1910 the attempts at cultivation on a large scale have been abandoned. From the results of the trial period we may conclude : that it is possible and advantageous in irrigated soil, which is however scarce in Tunisia ; and that its successful culture is uncertain in soil not irrigated. The profitable culture of cotton is only possible with high prices ruling.

To sum up, the practical trials in Tunisia, have, up to the present, shown that the growing of cotton in dry ground does not ensure sufficiently regular profits to enable it to compete with that of cereals or the vine. The area at present irrigated is small and occupied by fruit (dates) or vegetable crops which are more remunerative than cotton.

**572 - Cotton Ratooning Experiments in South Africa.** — OOSTHUIZEN, J DU P (Assistant Chief, Division of Tobacco and Cotton) in *Union of South Africa, Journal of Agriculture*, vol IV, No 2, pp 125-131 Pretoria, Feb 1922

Although ratooning is considered an undesirable method both in the United States and in Egypt, it was decided to give this cutting back of the old cotton stalks instead of planting afresh, a thorough trial in South Africa, in order to obtain reliable information as to the effects under the prevailing climatic conditions.

Experiments have been conducted at the Rustenburg Experiment Station in order to ascertain : 1) whether increased yields could be obtained by ratooning ; 2) whether the quality of lint would be deteriorated ; 3) whether any noticeable difference in the number of insects and their attacks was evident between first year crops and ratooned fields. With a view to reference as regards climatic conditions, figures are given indicating the rainfall and frosts during the years of experiment.

According to the results obtained from the 3-year tests made between 1917 and 1921, the 1<sup>st</sup> year yields were in nearly every case obviously the largest and the second and third lower in order of sequence. This was the case with both the varieties tested viz. Improved Bancroft and King. Where increased yields have been obtained on ratooned fields

by farmers in the surrounding district it is considered that in all probability some other factors, such as season, cultural methods etc. are responsible and the increase should not be attributed to the actual ratooning itself.

The lint from the three respective years was carefully examined and an examination of the grading table indicates that the lint from ratooned fields shows signs of deterioration, although this is not marked. However the silkiness of the first year cotton certainly showed a superiority compared with the somewhat coarse ratooned cotton.

Counts were made of the number of bolls attacked by the cotton bollworm (1), the most serious existing pest in South Africa, and it was found that, as a general rule, ratooned fields are more infested than first year cotton

M. L. Y.

573 - **Cultivation of Coconut Palms and Production of Copra in Dahomey, French West Africa.** — HOUARD, L. (Chef du Service de l'Agriculture du Dahomey), in *Bulletin des Matières Grasses de l'Institut Colonial de Marseille*, No 2 (1921), pp 25-35. Marseille, 1921

PLANTS  
YIELDING OIL,  
DYES, TANNING  
ETC.

For the last 10 to 15 years, the area devoted to the cultivation of coconut-palms has gradually become extended in the various districts of Dahomey, but the possibilities have been somewhat limited owing to the lack of manual labour and funds, and also the difficulties of obtaining suitable tracts for commercial enterprise. It is hoped, however, to urge the direct support of an Exploitation Society which will put matters on a better footing and which should result in a marked increase in copra production, giving better quality material and bringing about the utilisation of saleable products hitherto abandoned owing to lack of machinery etc.

After a general survey of the existing areas in Dahomey as a whole, the author estimates the present total number of existing palms as 150 000 and possibilities as regards coconut planting etc. as about 1000 000 trees. It is stated that should these new plantations be made, under favourable conditions, it may be expected to count on increase of 20 000 to 30 000 plants per annum, and working on this basis, after 30 years, the maximum number of palms will be established.

Observations made as to the type of soil etc. especially suited to the coconut palm have led to the conclusion that, although sandy soil on the coast line covered with thickly growing woody shrubs is evidently the most desirable, palms growing on similar territory from the physical standpoint but hidden completely with savannah grass, develop slowly and yield practically nothing. This fact is worth notice and explains the reason why certain well known savannah grass districts should be avoided for coconut planting.

Methods hitherto practised by the natives have been replaced by other up-to-date methods suggested by the Agricultural Service. The land reserved for coconuts is cultivated for the 2 previous years with manioc thickly

(1) *Heliothis armiger* (Ed)

sown, not so much to obtain a maximum yield as to choke the weeds which are very prevalent. Occasionally manioc has been substituted by a Cucurbitacea, the seed of which is used in the preparation of "goussi" oil. Wider spacing has been encouraged (7 to 8 m. each way) and also the transplanting of seedlings in preference to sowing *in situ*. Runner beans are largely grown as a cover crop when the palms are still at an early stage of development.

Certain cultivators near Agoue, the principal cultivation centre, have utilised with success old cottonseed (waste material from the mills) as a fertiliser dug into the ground about 150 m. from the palm.

A well developed plant is estimated to give an average yield of 60 to 80 nuts per annum. It is considered that 7 nuts will give 1 kg. of sun-dried copra. Improvements as regards the actual preparation of copra are in progress and should result in the production of superior quality material.

Normally the exports vary between 200 and 300 tons per annum. In less than 10 years according to the plans put forward with reference to young plantations it should be possible to count on an annual output of 1200 to 1400 tons.

The local consumption of the green nuts should be considered and this absorbs a large portion of the yield but this will have no evident effect on the yield from the new plantations reserved essentially for export purposes. Up till now the by products (coir etc.) have not been utilised and the husks have been burnt. The exploitations have been so limited in extent that the value of the by products has not been recognised by the natives and it has not been considered advisable to purchase the necessary machinery.

M. L. V.

#### 574 - The Tannin Content of some South Indian Wattles (*Acacia* spp.). -

SRINIVASAN, K. C. (Consulting Glue Chemist, Department of Industries, Madras) in *Journal of the Royal Society of Arts*, Vol. LXX, No. 3622, pp. 406-412, London, April 21, 1922.

Results of an investigation of the tannin content, optimum temperature of extraction and tanning properties of the bark of *Acacia decurrens* found in South India, and discussion concerning the wattle extract industry in relation to wood distillation.

Analyses of samples of air dried bark from full-grown trees were made and the results compare very favourably with those of other countries. The tannin was easily extracted, the optimum temperature was about 60°C when the proportion of non-tans to tans was about the smallest and most of the tannin is extracted.

According to the results obtained, the value of the bark is variable with respect to age. Barks from branches of trees of one, two, three, four and five years were taken and the percentage of tannins was 18.37, 24.37, 25.97, 27.62 and 29.07 respectively. It was also found that the thicker the bark, the higher the tannin value. Exudations of gum are valued at about £110s. per cwt.

Laboratory experiments on the spent bark of the high range wattles showed the possibility of producing about 30 % of good pulp with fine felting properties, readily bleached to an attractive ash colour. It has been reported that this spent bark contains 41.2 % cellulose, and the length of the fibre is about 1.2 mm., the latter is variable.

The wood of the wattle is estimated to yield about 61 % cellulose and 50 % pulp capable of utilisation in the manufacture of straw-board. Most promising results have been obtained during the destructive distillation trials. The ash is also of high economic value. Moisture 9.80 %, combined moisture 3.61 %, potassium carbonate 8.77 %, sodium carbonate 2.10 %, calcium carbonate 77.50 %, calcium phosphate 4.60 %.

It is considered by the author highly probable that with the scientific plantation of the most valuable species of *Acacia*, the possibilities of the establishment of important industries such as the manufacture of tannin extracts and of wood distillation will be realised. M. L. Y.

575 - On the Influence of Tar on Hevea Bark. - GANDRUP, J., in *Archief voor de*

RUBBER GUM  
AND  
RESIN PLANTS

Investigations were made in Java on the influence of tar on hevea bark which had been scraped out to different depths. The tar was applied partly warm and partly cold. Coal tar and another preparation made by the Dordtsche Petroleum Maatschappij called "Cambisan" were used. Scraped untarred portions were left on each tree for control purpose.

Results showed that the tar had no influence on the renewal of the scraped out bark spaces, and the reforming of the cellular tissues, cork and latex vessels showed no difference on the tarred and untarred spaces.

When, however, the trees were scraped to a depth of the usual tapping cuts, the coal tars killed the remaining bark up to the wood, but the "cambisan" had no influence excepting that to a certain extent, it hindered the drying out of the outer layers of cells lying exposed. It has therefore been recommended to avoid tarring the tapping surface, and to apply the tar only where the wood is exposed. For the control of pink disease (1) and die-back disease (2), the use of "Cambisan" tar is advised, as it remains for months forming a layer of tough solution and prevents the attacks of boring beetles. Black-thread canker (3) should not be treated with tar as it appears to cause larger wounds than those actually made by the disease itself.

These investigations are to be continued with brown bark diseased trees with the object of trying the system of treatment proposed by HARMSEN, viz : the scraping out of the bark and treating it with warm tar.

- 576 - **Cacao Cultivation in Grenada.** — WILLIAMS, R. O. (Curator, Botanical Department, Trinidad and Tobago, formerly Supt. of Agriculture, Grenada), in *Bulletin of the Department of Agriculture, Trinidad and Tobago*, Vol. XIX, Pt. 4, pp. 215-223. Trinidad, 1922.

Report on the various methods of cultivation of cacao employed in Grenada and the treatment of the insect pests prevalent in that neighbourhood. A comparison is also made with the methods adopted in Trinidad.

Apart from the generally recognised cultural operations, certain points are of especial interest to planters elsewhere. Attention is called to the question of temporary and permanent shade and the value of certain windbreaks. For temporary shade purposes, bananas, plantains, canes, etc. are used, but it is of interest to note that, in contrast with the usual permanent shade planting employed in other countries on cacao plantations, in Grenada, this is dispensed with and in its place much more attention is given to cultural operations, such as drainage, forking, manuring, etc. and a consequent preservation of good soil tilth, which appears to give very satisfactory results. If this idea of replacing organic matter naturally associated with prevailing climatic conditions, can be maintained economically, the author considers it preferable to using shade plants. It was observed that the loss from pod rot was minimised to a marked degree and this fact alone should more than compensate for extra expense and labour. It should be mentioned however, that in certain fields plants such as mango, breadfruit, etc. are cultivated and although these can only be designated as partial shade trees, their economic value is an important consideration to the grower.

The great value of carefully selected windbreaks has been fully recognised and the principal tree used for this purpose is the "galba" (*Calophyllum Calaba*) whilst almond (*Terminalia Catappa*), cashew (*Anacardium occidentale*) and mango (*Mangifera indica*), are used to a lesser extent. Protection is also afforded by hedges, and the "galba" and wild coffee (*Aralia Guilfoylei*) are chiefly used for this purpose.

As regards manuring, large quantities of farmyard manure are applied regularly, and a system of herding cattle in various parts of the field is practised. Horse beans (*Canavalia ensiformis*) have been sown and turned in as green manure or left as a mulch with satisfactory results on some of the best estates. An advantageous system has been found by which fields are treated the first year with farmyard manure, the second with leaves and sweepings, the third in the same way and if possible mulched, in the fourth, artificial manures are employed and in the fifth lime is applied before starting a repetition of the rotation.

The yield per acre in Grenada is estimated at 720 to 900 lb. which compares favourably with Trinidad, etc.

M. L. Y.

- 577 **Cinnamon: Sources, Production and Trade.** — *Bulletin of the Imperial Institute*, Vol. XIX, No. 3, pp. 319-348. London, 1921.

There has been a growing demand for cinnamon bark as a spice, and for the distilled oil for medicinal purposes. The entirely distinct and

cheaper oil distilled from the leaves is in still greater demand, largely as a source of eugenol and for the manufacture of vanillin

Up to the present, it has been agreed that cinnamon bark grown and prepared in Ceylon is by far the best for Western commercial purposes, but recently much of the area occupied by cinnamon has been replaced by coconut, Para rubber etc and the question has arisen as to the possibility of meeting the increasing demand from other sources. It appears, however, that *Cinnamomum zeylanicum*, the bark of which is considered to give the best quality cinnamon cannot be relied upon to reproduce in other countries the characters for which it is noted in Ceylon, even under very similar conditions of climate and soil. At the same time bark obtained elsewhere, which has not received the elaborate treatment of the Ceylon product may produce a large amount of good quality oil, as for example in the Gold Coast. The present article gives a detailed account of the present production of cinnamon throughout the world in order to indicate its future possibilities.

Firstly a description is given of the botanical sources of cinnamon and throughout the article interesting historical references are given as to early cultivation etc in each country. This is followed by details as to the characters and composition of cinnamon oils obtained by distillation of the bark. It is of interest to note the general relative value of some of the species described —

*C. zeylanicum* (native of southern India, Tenasserim and Ceylon) — Aldehyde from bark 58 to 76 %, from root bark only a negligible quantity is obtained and a small % of eucalyptol, eugenol, safrol and borneol, the leaf oil contains 70 to 75 % eugenol and 3 % cinnamic aldehyde.

*C. Cassia* Blume — A similar yield from all parts of the plant. Aldehyde from 80 to 90 % oil from twigs and leaves from 0.5 to 2 % aldehyde eugenol nil.

*C. Loureiri* Nees — Oil from root bark 1.17 %, leaves and shoots 0.2 %, containing 27 % aldehydes, 40 % linalol, eugenol and eucalyptol.

*C. Burmanni* Blume (= *C. Kiamis* Nees) — aldehyde 77 %, eugenol 11 %.

The following species contain little or no aldehyde and are utilisable only for their camphor and safrole content: *C. Camphora* C. Oliver, *C. Parthenoxylon*, *C. pedatinervium*, *C. Mercadori*, *C. Sintok*, *C. Lamala*, and *Canella alba*.

## WORLD PRODUCTION OF CINNAMON AND ALLIED BARKS

### I — BRITISH EMPIRE

CEYLON — *Cultivation and preparation* — The most satisfactory results have been obtained on a very sandy clay or fine white quartz sand with a good rich sub-soil, at altitudes of less than 1500 ft, on the S.W. coast between Negumbo, Colombo and Matura where there is an average temperature of about 85° F and a rainfall of about 85 in annually. Lateritic gravel has produced a quicker growth with coarser bark, and marshy

land has given an undesirable bitterness to the product and a much lower oil content

Better quality bark has been produced if the trees are freely exposed to the sun. As regards cultural operations manuring with coconut "poo-nac" or cowdung has proved beneficial.

Four or five shoots per stool are allowed to grow for about 2 years (6-10 ft high) before cutting begins.

The trees are comparatively resistant to diseases and insect pests, *Pestalozzia cinnamomi* Raciborski on the leaves and twigs and *Corticium salmonicolor* B and Br on the stem are the only two notified, but are not difficult to control. Mites of the genus *Friophyes* have caused some damage, but a Braconid hymenopterous insect probably parasitic on the mites has been observed.

*Production and exportation* — The decrease in area under cultivation and the consequent decrease in export is brought out clearly by the figures given. The 47 906 acres under cinnamon in 1909 shows a steady decrease to 34 662 acres in 1920. The export of bark and bark oil has therefore been on the downgrade ever since and in 1920, amounted to 3 933 552 lb and 73 246 lb respectively for quills and chips. There has, however, been a certain rise in the export of leaf oil, and for 1920 the return was 365 976 lb.

The quantity exported to the chief countries in 1913, 1919 and 1920 is shown in tabular form and also the annual amounts exported and the estimated value from 1909-1920.

The figures certainly suggest the importance of turning attention to production elsewhere.

**INDIA** The leaves are obtained principally from *Cinnamomum lamala* Nees and Eberm and var *intermedium* a species found wild in the tropical and sub tropical Himalayas at altitudes of 3000 to 9800 ft. The leaves distilled in Mysore come from another species possibly *C macrocarpum* Hook fil (1) which is stated to grow abundantly at 100 to 700 ft and is found also up to 3500 ft. This species grows well from self sown seed and stands any amount of rain and shade. Very little bark is collected from these two and the leaves only are utilised. In Bengal the species *C obtusifolium* is utilised for root bark which is reputed to be as aromatic as the best Ceylon cinnamon (2) the grey bark on the contrary, varies considerably in aroma.

There is no evidence of the cultivation on any commercial scale of the true cinnamon (*C zeylanicum*) but according to some of the best authorities after careful study of the various characteristics associated with the different species it seems probable that *C obtusifolium* etc may be classed as forms of *C zeylanicum*.

**SLYCHFLIES** — The distillation of oil from wild bark and leaves

(1) Referred to in *Indian Forests* Vol. 47: 77 1913, as *C zeylanicum* (Author's Note)

(2) See WATTS, *Dictionary of Economic Products of India*, Vol II p. 318 (Author's Note).

was begun in 1906, and a sample tested later was found to yield 21.7% of cinnamic aldehyde and 8% eugenol, but to differ distinctly from the bark oil of commerce.

Experiments proved that dried bark gave more than twice the amount of oil than from fresh bark and of a more agreeable odour the yield however, was strictly dependent on the season when collection took place the second or third week of rains giving the best results. Since 1916 attention has chiefly been devoted to the production of leaf oil. There were only 12 distilleries in 1915 as against 44 in 1920 and the export amounted to 15 669 and 39 507 litres respectively. It was estimated that the total output of leaf oil in 1920 was 50 000 litres.

No details are given as to the varieties cultivated.

**MAURITIUS** — Samples of bark and leaves on examination gave 0.8% of oil of fair quality, considered as of equal value commercially with Seychelles bark. The leaves gave 1.1% of oil also of fair quality. Neither the cultivation of cinnamon nor the distillation of its oils seems to have been developed in Mauritius.

**MALAYA** — A favourable report was made with reference to the bark sent to England to be tested very many years ago but cultivation has not been continued probably owing to low prices prevailing. Amongst the wild species found in the Malay region are mentioned *C. laccivanum*, *C. Parthenovylon* and *C. Culilayan* Blume (*Clove bark*) a native of the peninsula and the islands. The bark is grey smooth externally, interior yellowish brown very aromatic but the strong clove scent suggests a high percentage of eugenol. So far its sole use commercially has been confined to the use of the calvices of the fruit in medicine and curries.

**FIJI** — Both *C. zeylanicum* and *C. Cassia* have been grown successfully from seed and the bark and leaves distilled on an experimental scale at Naisumu. The plants seem to have become naturalised very readily. The species *C. pectinervium* Meisn (*Vassoria aromatica* Beccari) gives the well known Masaka bark of Fiji and New Guinea. This bark contains crystals of calcium oxalate similar to those produced by *C. Cassia* and is very aromatic.

**AFRICA** — Cinnamon has been grown experimentally at the Tarquah Agricultural Station in the Gold Coast and the bark submitted for examination in 1917 proved to possess an inferior quality aroma and flavour but the yield of oil was about half as much again as from Ceylon bark and was estimated to contain 68% of aldehyde. Three samples tested later and coming from the Achanti, Coomassie and Aburi Stations gave equally good results on distillation, with a 61.70% aldehyde content. Cinnamon is grown for local consumption in Zanzibar and experiments have been made in the Botanic Garden at Entebbe (Uganda).

**WEST INDIES** — Since 1782 cinnamon has been grown in Jamaica but not on any wide scale. The bark obtained from *Canella alba* has been utilised in Europe in the drug trade, but is in no way related to *C. zeylanicum*. *C. alba* is a native of Florida and the West Indies and is now mainly shipped from New Providence in the Bahamas under the name of "white

wood bark" and "cinnamon bark" (formerly known as "Jamaica winter bark" and "*Cassia lignea*").

## II. — OTHER COUNTRIES :

CHINA. — *C. obtusifolium* appears to be the only species utilised. It is found growing wild up to altitudes of 7000 ft. *C. Cassia* (unknown in the wild state) and *C. Loureirii* are only varieties. The best Chinese cassia is said to be produced from cultivated trees near Taiwu in Kwangsi (about 180 miles west of Canton). The first cut of bark is made when the trees are about 6 years old. The tree seems more readily adaptable to change of soil and climate than *C. zeylanicum*, and the bark might probably be so prepared as to equal Ceylon cinnamon in appearance. In microscopic structure these two barks are very similar except that the Chinese bark possesses a covering tissue rich in oil ducts over the sclerenchyma (which is the outermost layer in ordinary scraped cinnamon) and from this it may be inferred that the flavour of the drug could not be improved by scraping the bark.

*C. Burmanni* Blume, occurs wild to a small extent, but does not appear to have been either cultivated or barked.

FRENCH INDO-CHINA — It has been reported from various sources that apart from Indo-China, there has been a tendency for cinnamon culture to disappear from the French colonies, but the produce from Annam has been gradually increasing and here the industry appears to be profitable. The best bark (also from *C. obtusifolium* var. *Loureirii*) comes from Thanh-hoa in the north, although the amount produced is small; the second best bark comes from Nghê-An; and the third from the southern provinces of Quang-Nam (the chief producer) and Ngai. Most of the bark is obtained from wild trees. Trees 10 to 12 years old, averaging 8 to 12 in in diameter, are preferred and are generally felled before barking. The system of barking adopted consists in making 3 longitudinal incisions through the whole thickness of the bark on both stem and branches followed by transverse circular cuts, so that pieces 12 to 16 in in length can be removed. The taste of Annam cassia is said to resemble that of coriander.

The Saigon cassia appears to be distinct from *C. Cassia* in the structure of the bark, but has no special name and it is suggested that it is merely a geographical variety having regard to its resemblance in certain characters. It is in any case considered superior to Chinese cassia.

Some of the cassia from Cochin-China is derived from *C. Tamala*.

DUTCH EAST INDIES — Although *C. zeylanicum* has been grown to some extent in Java, it did not prove very profitable, owing to the apparent loss of high quality of bark when transplanted to another country. A negligible quantity of bark is derived from *C. Cassia* and the rest from *C. Burmanni*. This appears to prefer a high altitude; it is found wild throughout the Malay archipelago and yields cinnamon of high value. All the bark from Padang, Macassar, Sumatra and Timor is said to be deri-

ved from these species, but some of the bark from the Eastern archipelago is attributed to *C. iners*.

In the interior of Padang, where the trees are grown on a large scale, they are barked when about 8 years old, the best qualities coming from the trunk, the next best from the thicker branches, though this lacks flavour.

Javanese cinnamon is said to rank in value between that of Ceylon and that of Tellicherry (Malaba, W. India).

*C. Sintok* (Blume) is abundant in Java and the Malay Peninsula and also probably in Sumatra, but although apparently collected and sold in Java, it is not certain that it constitutes any part of the commercial bark of Sumatra. The bark is very aromatic and thicker than Chinese cassia.

**SOUTH AMERICA.** — Brazilian cinnamon, said to be derived from introduced *C. zeylanicum* is of decidedly inferior quality. The Cayenne sassafras (Brazilian clove-bark) (*Dicypellium caryophyllatum*), which is plentiful in the Guianas and Brazil is the chief product and yields on distillation an oil strongly resembling clove-oil.

**CONCLUSIONS.** — Although without doubt the bark of the true cinnamon *C. zeylanicum* as cultivated in Ceylon is the best obtainable and the other barks here enumerated cannot well be substituted for it medicinally, even if perhaps capable of replacing it by their cheapness as spice, the leaves could most certainly be readily used as sources of oil, eugenol and vanillin. In some cases, such as Annam cassia in China, bark collected from wild trees commands an even higher price than Ceylon cinnamon, and it has been suggested that these species might be improved by cultivation and by better preparation of their bark. In addition they would doubtless prove more adaptable to change of climate and soil than *C. zeylanicum*.

578 — **Effects of *Cucurbita Pepo* Seeds on Kidney Excretion.** — MASUROWSKY, B. (Columbia University), in *Proceedings of the National Academy of Sciences*, Vol. 8, No. 3, pp. 39-43, Easton, March 1922.

The author shows the effects on kidney excretion (discovered by him and proved by experiment) of pumpkin seeds (*Cucurbita pepo*), roasted and raw, which have a chemico-pharmacognostic value. The addition of 30 to 35 grams of these seeds to a vegetarian diet (with milk or butter) causes an average increase of 17 % in the quantity of urine excreted.

J. D.

579 — **The Utilisation of Paper Mulch in Pine Apple and Sugar Cane Cultivation in Hawaii.** — CHURCH, T. A., in *The Florida Grower*, Vol. XXV, No. 9, p. 6. Tampa (Fla), March 4, 1922.

HORTICULTURE

The experiments made by Hawaiian growers in the use of paper mulch spread over the ground for protection purposes have given most satisfactory results. The fruit grown on plots thus treated gave an increased yield of more than 3 ½ tons per acre. The plants appeared also to be in a much better condition than those on untreated land. In addition, the use of mulch reduced the expense of cultivation by two-thirds, and

served as a valuable form of protection against damage from heavy rains, soil-baking etc. It is also of interest to note that the soil under the paper was from 2 to 5° warmer at night than in exposed fields.

After the land is prepared for planting, the paper is unrolled and spread over the ground and holes are punched in the paper to make room for the seedlings. It is estimated that a group of 3 or 4 men can lay paper at a cost of less than 3 dollars per acre. The ideal paper for this work should be 300ft. long (the standard length of pineapple rows in Hawaii) 36 in. in width for double lines and should have good insulating qualities.

It is probable that one of the cheaper grades will be used for standard practice, possibly one made from bagasse, which is now burned as waste.

Paper mulch is also used extensively in sugar cane plantations in Hawaii, where the idea originated. In the new fields, the young cane shoots find no difficulty in piercing the paper which is also very effective as a preventive of weeds. In the old fields the paper is spread over the rows after the cane is cut and before the new shoots appear. The cost of labour has been reduced by more than 40 % through the adoption of this new method.

580 - **The Cultivation of Blueberries (Whortleberries) (*Vaccinium* spp.) in the United States** (1). — COLVILLE, F. Y., in *United States Department of Agriculture Bulletin* No. 974, pp. 1-24, plates 29. Washington, 1921.

Experiments in *Vaccinium* cultivation have been in progress in the United States since 1906 and up to the present 16 acres have been planted with 27 000 different hybrid seedlings and certain hybrids have been selected as of value from an agricultural standpoint and are in the hands of nursery-men for commercial propagation. In addition to this, certain wild whortleberry plants have been used with success as breeding stocks. The author gives the reports of these experiments combined with other points of distinct value to the intending grower. Certain points have already been dealt with by the author in a previous article (2) but it is of interest to note that in connection with the acid soil particularly suited to *Vaccinium* cultivation, a specific acidity of 100, corresponding to a hydrogen-ion concentration of  $P_H = 5$  is the most advantageous.

As regards propagation, budding appears to be the best means of producing a large quantity of cutting wood but the easiest methods have been layering and the so-called tubering, i. e. the forcing of new shoots in such a way that their basal portions are morphologically scaly rootstocks with a strong rooting tendency. A detailed description is given of the points which should be observed in following this system. An experiment has recently been made at Whitesbog in the use of lath instead of muslin shades, which allows each cutting to receive direct sunlight. The proportion of cuttings that rooted under the lath shades has so far shown the distinct advantage of adopting this method.

(1) See R. Feb, 1915, No. 191; R. March 1916, No. 271; R. April 1916, No. 409. (Ed.)

(2) See R. April, 1921, No. 367.

Wild plants and hybrids vary very much in their response to the different methods of propagation. Cuttings of the variety *V. angustifolium* and hybrids between this wild variety and *V. corymbosum* have shown a higher yield of rooted plants, and in such cases, mound layering has been found the more satisfactory.

Amongst the cultural operations advised it is noted that in 1919-20 BECKWITH of the New Jersey Agricultural Experiment Station conducted a series of fertiliser experiments and the most successful results were obtained with the following nuxture nitrate of soda 170 lb + dried blood 230 lb + steamed bone 340 lb + phosphate rock 340 lb + potash 170 lb. The yield was more than three times greater than from unfertilised bushes on the same sandy soil. The application of this fertiliser is recommended at the rate of 600 lb per acre.

*V. corymbosum* does not require yearly pruning but it has been found advisable to remove all the stems of *V. angustifolium* more than one year old, which have not made vigorous growth during the season, good results in fruit yield being thus obtained. A systematic burning once in 3 years of areas devoted to the cultivation of this variety has led to vigorous development in the form of stems bearing large leaves and an abundance of fruit buds which give excellent yields, the second summer after burning.

The industrial advantages attached to this crop are evident after observation of the yield and returns recorded at Whitebog (N.J.) viz an average yield of 96 bus. per acre sold at rather more than \$10 per bus. the receipts being at the rate of \$966 per acre. This record refers to plants 7 years old. The following year (1920) this planting yielded at the rate of 117 bus. i.e. \$1280 per acre. After a plantation has been once established its maintenance is relatively inexpensive.

551 - **Cultivation of the Loganberry in France.** — CROCHETIER, J. (Director of the Agronomic Station of the Somme) in *Journal de culture et ruralité* 11 Year Vol. XX No. pp. 158-159. Paris. March 4, 1921.

The author draws attention to the advantage of introducing into France the culture of this hybrid from the raspberry and blackberry which is already extensively grown in the United States and Canada and briefly mentions the multifarious uses of this fine fruit which grows in clusters of 5 or 6 and is about three times as large as the blackberry. The loganberry is already found in some gardens in Amiens and the author has grown it successfully since 1914 in the experimental grounds at Rivery. It is very prolific and hardy and easily withstood the severe cold of 1916-1917. It requires very little attention.

582 **Gramineae and other Lawn Plants Resistant to Drought.** — PURRILL, W. B. in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 1, pp. 10-13. London. 1922.

Observations made during August 1921 in the Royal Botanic Gardens, Kew.

Although the drying up of grasses was doubtless to be attributed

directly to lack of water in the soil and sub-soil, it has been found possible to identify certain secondary factors showing variation in the drought resistant capacity of certain species of gramineae and other lawn plants which should be useful for future guidance.

The perennial rye-grass (*Lolium perenne*) was evidently the most drought resistant grass. This can hardly be attributed to the morphological structure of the leaves and shoots, but possibly to the fact that it is deep rooted, tufted and possesses a somewhat extensive subterranean system. The importance of this fact was confirmed by the survival of the couch-grass *Agropyron repens* with its widely-spread underground stolons.

A few of the coarser grasses survived in places, e. g. *Dactylis glomerata*, *Holcus mollis* and *H. lanatus*, which was probably due to the hairy covering on stems and leaves.

The early flowering species of the perennial grasses appeared least able to withstand drought e. g. *Poa pratensis*, *Alopecurus pratensis*, *Phleum pratense*, *Arrhenatherum avenaceum*, *Avena pubescens*, *Cynosurus cristatus*, and *Bromus* spp. etc. died off readily. The previously mentioned *L. perenne* and *A. repens* are later flowering species. The *Festuca* spp. also appeared incapable of resisting drought.

Apart from the resistant Gramineae it was noticed that the greenest turf constituents were members of the Compositae. *Achillea Millefolium* continued green throughout the drought, as also *Anthemis nobilis*, while others which remained fresh were *Hypochaeris radicata*, *Hieracium pilosella*, *Crepis virens*, *Plantago lanceolata*, all with deeply penetrating tap-roots or well-developed stolons. Green low lying plants such as *Medicago lupulina*, *Trifolium repens* and *T. pratense* were very prominent as resistant species.

Among the weeds which were observed to remain green and flourishing and which had gained entrance owing to the dying out of unresistant plants may be mentioned *Nasturtium sylvestre*, *Coronopus didyma*, *Solanum nigrum*, *Polygonum aviculare*, *P. persicaria*, and *Chenopodium album*.

583 - Flower Bulbs on the French Riviera. — TSCHAEN, E., in *Journal d'agriculture pratique*, vol. 1, No. 5, pp. 96-97. Paris, Feb. 4, 1922.

The culture of flower bulbs on the Riviera, from Bandol to Lavandou, is carried on for two purposes: the production of bulbs ready for flowering and cut flowers. Millions of these bulbs are sent yearly to America, Holland and England, while from January onwards the cut flowers are sent to Paris, and the English and Belgian markets. The centres of the trade are at Ollioules and Hyères.

Formerly the Roman hyacinth predominated; but the eelworm so interfered with this culture as to cause its disappearance from the market. At present narcissi hold the first place. Owing to the high prices realised in recent years, this culture is of growing importance.

The period during which the flowers are gathered begins in December

for the narcissi and a little later for the hyacinths and lasts through the Spring; the bulbs are gathered from the middle of June.

The varieties of narcissus most cultivated are the bouquet or Constantinople narcissus (*Narcissus Tazetta*) and the jonquil narcissus (*Narcissus Jonquilla*). Several varieties have been produced from the Constantinople narcissus: 1) the pure white narcissus (*N. Tazetta totus albus*) 2) the pure white large flower narcissus (*N. Tazetta totus albus grandiflorus*) 3) the Golden Sun narcissus (*N. Tazetta auretta*) 4) the Grand Monarch narcissus (*N. Tazetta concolor*). The jonquil narcissus (*N. Jonquilla*) is also utilised for the perfumery trade. Two species of hyacinth are cultivated: the Roman hyacinth and the Dutch hyacinth, including a very large number of varieties.

It is stated that the profits arising from the culture of the hyacinth range from 15 000 to 50 000 fcs. the hectare. In the 1921 Exhibition the prices for narcissus bulbs ranged from 120 to 160 fcs. and those for hyacinth bulbs from 450 to 480 fcs. per thousand. From 200 000 to 300 000 bulbs can be reckoned to the hectare. Then the cut flowers should be taken into account. Bunches of from 10 to 12 flowers form bouquets which are sold by the 100 at prices ranging from 8-10 fcs. up to as much as 90-100 fcs. These prices are the same for hyacinths. The latter are likewise sold to the perfumery trade, at prices of from 2 to 3 fcs. per kg.

The bulbs intended for exportation, after having been inspected by the Phytopathological Department, are packed in cases containing 80-100 kg. and generally sent to Marseilles for consignment. F. D.

584 — **The Cultivation of the Date Palm in Mesopotamia and Investigations as to the Yield.** — Dowson, V H. W. (Agricultural Directorate) in *Agricultural Directorate, Ministry of Interior, Mesopotamia, Memoir III*, Pt. I, pp. 1-75, pl 54, 1 map. pt. II, pp. 1-23, tables 15, diagr. 4, maps 2, bibliography of 25 works, Cambridge, 1921

FRUIT  
GROWING

**DISTRIBUTION.** — The most important area of date cultivation in Mesopotamia, and probably, in the world, is that of Shat-Al'Arab where about 138 000 acres of date palms are to be found, and it is estimated that the total number of palms amounts to from 15 to 16 millions (average of 140 per acre). The second largest date cultivation centre lies around Baghdad, and apart from these nearly all the towns are surrounded by date groves of comparatively large size.

**CULTIVATION.** — **Soil.** — The best dates are produced near Badra and Mendali close to the limestone hills, but the palm is found to grow well on a variety of soils, viz. rocky loam, river silt and desert sand and is more tolerant of salt than any other cultivated crop in the country; water logged soils and excessively dry soils are however considered unfavourable.

**Tillage.** — The best methods are employed in the Shat Al'Arab districts. Here the land is dug every fourth year to a depth of about 4 ft. It is estimated that three men will dig 1 acre in 1 to 2 months (working only until midday), and they are paid an average wage of 30-36 rupees per week per 3 men. The system adopted is to dig the 4 ft. in 2

pits and the first is put below the second, old roots are removed and manure is added equivalent to about 3 tons per acre though liable to variation. Apart from the gardens in this district and near Baghdad, very little manure is used. A quarter of each well-cultivated Basra garden is dug deeply every year and the remaining three-quarters is only given a shallow digging. Where these methods are not employed the yield of dates is low and of inferior quality.

*Subsidiary catch crops.* — A list is given of the subsidiary crops to be found in date gardens, but it is stated that in the most profitable gardens, the space between the palms only permits the cultivation of citrus and other fruit trees, and no shadeless patches remain for vegetable and other low growing crops, and this is only possible in newly made gardens. In some cases there is a great demand for palm gardens as grazing areas, where catch crops are not planted and the ground is allowed to run wild.

*Irrigation.* — Although the date palm can apparently live for a long time without irrigation, has a serious effect on the yield, however, the diversity of water types seems to have no influence on development (the water is clear, salty, sulphurous, etc.). Water is provided by tidal inundation, by gravitation flow or by lift. The methods employed vary with the district, and descriptions applicable to each are given. As regards the lifting process, where flow water is not available, apart from the primitive water Hoist (*dahlia*) and the Animal Power Water Hoist (*charad*) and the big water wheels, the most improved appliance is the "noria" or Persian wheel (*naoor*) which consists of an endless chain carried by a wheel which is made to revolve by power provided by animal draft. As the chain revolves the buckets tip under the surface of the water in the well over which the "noria" is set, filled up and are carried upwards over the supporting or revolving wheel where they empty their contents into a trough fixed above the axis of the wheel. A similar machine is also in use with some slight variation as described by the author.

The most effective irrigating machine is stated to be the centrifugal pump worked by an oil engine. These have worked with success at Baghdad and Amara. An illustration is given of GWYNNE'S Invincible Centrifugal pump, 6 inch. suction, 8 inch delivery, used at Amara for irrigating a 15 acre date and vegetable garden.

*Pruning.* — Each year the dead and dying outer fronds are cut off about 1 ft. from the trunk, and when the palm is about 14 years old, the woody and expanded bases are cut away close to the trunk which kills off any existing sucker buds. When the dates are about  $\frac{1}{2}$  inch long, the erect spadices are pulled down below the fronds in order to facilitate harvesting, and at the same time the spines are stripped off the fronds.

*Fertilisation.* — This takes place in March and April, and necessitates the placing of male inflorescences amongst the female, as the date palm is dioecious and wind pollination cannot be relied upon.

*Ripening and harvesting.* — A description is given of the appearance

of the fruit at the four distinct stages, and of the local methods of gathering the fruits when ready and the division of the harvest between the garden owner and the "fellah" (agricultural labourer).

*Diseases.* — A saprophytic fungus has been found attacking the palms and fresh dates and also the following insects: *Tetranychus* sp., *Parlatoria Blanchardi* (does very little damage), *Oryctes* sp., a longicorn beetle (possibly the larvae of *Prietyrranus mordax*) and tineid moths (*Gelechiidae* sp.). The stored fruit is subject to attack from various small moths and beetles, amongst them *Ephesia*.

*Propagation.* — Although the date palm may be grown either from a seed or sucker, the seedling does not breed true and the dates are of inferior quality to the parent, and the sex may be different. Consequently, commercially the sucker method is employed, the offshoots are removed when about 4 years old and the young shoot is planted between the old palms. It is commonly stated by owners that the maximum yield from each palm is obtained when palms are planted at the corners of squares whose sides are about 8 yds. long, i. e. about 80 palms to the acre. The author considers that sufficient data are not available to state definitely what number of palms of each variety to the unit area will produce the maximum yield; but it would seem that the average is about 100. This question is a matter quite apart from the problem of obtaining the maximum profit from any *area*, where it is considered advisable also to grow other subsidiary crops.

*Packing and marketing.* — The 6 different types of packing receptacles are given, the chief being wooden boxes containing 68 lb. net, and the author proceeds to give data relative to the general production, exports etc., according to the Customs Report etc.

*Uses of the palm and its products.* — Apart from the well known use of the actual fruit and fibre it is interesting to note the various uses made of the trunk, heart of the crown, fronds, frond midribs, frond bases, leaflets and leaf stalks.

*YIELDS.* — The primary object of the inquiry which the author undertook during the autumn of 1919 on the Shat Al'Arab was to provide reliable statistics of the average yield of dates per unit area with a view to the discovery of a broad basis for just taxation. The individual yields of dates from 930 palms belonging to 19 varieties and from 36 different gardens widely scattered over the Basra county have been recorded and combined with an inquiry as to the average number of each variety of date palm and of fruit tree per unit area in 84 areas of equal size in 39 gardens, also widely scattered over the same county.

The accompanying Tables show the data obtained and the relative yield on each are examined. The average yield of "tamar" dates (third and last stage of ripening) per acre in the date lands in 1919 appear to have been 4920 lb.; the leading variety is Istaaamran (2183 lb.) followed by Halawi (1584 lb.) and Zahidi (378 lb.) etc. The last mentioned is, however, the least choice date and Istaaamran next; the Khadhrawi, Halawi and Dairi are good dessert dates but less common.

The prices fluctuate rapidly and within wide limits. A very rough approximation has been made and taking these figures as a basis, the gross value per acre appears to be about 272 Rs. The value per acre over the whole district of the "khalal" and "racab" dates (second stages of development) sold is estimated roughly at 20 Rs. M. L. Y

# VINE GROWING

585 - Factors influencing the Increase in Grape Yield in Western India. — PRAYAG S. H., in *The Agricultural Journal of India*, Vol. XVII, Pt. I, pp. 41-50, plates 2. Calcutta, Jan. 1922.

Report as to the success obtained in adopting certain improved methods of vine training, pollination, manuring etc. with a view to increasing the commercial value of local grape varieties in western India.

*Methods of training.* — Of the several types of training employed, the system giving the best yield has been the "umbrella" type and this has been found distinctly superior to the single stake system previously employed. The overhead system has also been a definite success and has given three times as much yield as the single stake. Four canes of each plant are extended in different directions until they meet the canes of the next plant. Short spurs are formed in this way, leaving more room for the development of flowers and fruit.

The author carried out an experiment keeping the long canes formed during the rainy season and pruning them, after leaving 10 or 12 buds instead of adopting the short-and-renewal spur method of pruning after 2 or 3 buds. The yields per plant obtained, by keeping the long canes, compared with the latter system were about four times greater. Further experiments are considered necessary, however, before the long-cane system can be recommended unreservedly.

The KNIFFIN or drooping system, much practised in America, has shown an advantage over the local single stake system only on very exceptional occasions.

*Pollination* — A special study was made by the author at the Ganesh-kind Botanical Garden, Kirkee, of the two classes of grape clusters in existence, viz. loosely set and closely set fruits. On examination in the laboratory of the pollen grains it was, however, considered that the flowers were not self-sterile. Other methods of improvement of yield such as girdling or ringing and coiling had therefore to be adopted.

*Manures.* — The most efficacious of the manures tried proved to be 1) a combination of fish manure and sulphate of potash; 2) safflower cake + bonemeal; the latter gave the higher yield, but when applied after the April pruning instead of in the autumn, in order to influence the production of strong bearing wood for the next season the fish manure combination proved preferable.

M. L. Y.

586 - Grape Preservation in Almería: Cultivation and Preservation Experiments made in Italy. — SANNINO, F. A., in *Rivista di Ampelografia*, Vol. III, No. 2, pp. 22-23. Alba, Feb. 28, 1922.

Hitherto it has always been considered that the facility of preserving Almería or Hoanez grapes, is due to the fleshy character of the pulp,

and to the usually resistant skin, but it has recently been proved that it is due rather to the extremely dry climate in the *Almérie* region.

Irrigation takes place several times in this area, and in September, at the vintage, the weather is always fine and dry; conditions unquestionably favourable to grape preservation.

In 1896, an exporter of Messina (a town situated in the rainiest district of southern Italy) obtained most unsatisfactory results, by keeping the table grapes in wood shavings and in sawdust, according to the custom of *Almérie*. New experiments were made in 1920, a very dry year, with the cultivated *Almérie* grape at the Royal American Vine Nursery at Palermo. Large yields were obtained and the grapes kept well; in 1921, a rainy season, the crop was poor.

Drought conditions are also useful at the flowering period, which is very short. As this vine possesses a female inflorescence, artificial cross-pollination is necessitated such as PAULSEN (Director of the Royal Nurseries, Palermo) made with the pollen of the male inflorescences of *Aramon Rupestris Ganzin*.

The *Almérie* grape after transport to Palermo and to Spadafora (near Milazzo), appears to be easily damaged by fungous diseases: oidium, mildew, and grape mould. The quality of the grape when left on the vine, and the quality when cut present two separate characteristics: the *Almérie* grape will keep for a long time after cutting if the grapes are placed in layers on sawdust inside the receptacle, but they will not keep at all, if left hanging on the vine, owing to their liability to rot. However the "*Marsigliana*", and "*Lacrima di Maria*" of Termini Imerese and the "*Catelanese*" of Somma Vesuviana are exceptionally good varieties, even for leaving uncut.

The trials made with the *Almérie* grape at Palermo and at Spadafora confirm the conclusions arrived at by GOBBATO and BRIGANTI namely, that this particular grape is adapted solely to warm and dry districts.

587 - **Forestry Journals, Forestry, Timber-Trade and Wood-Working Industries Journals and Serials.** — IMMINK, D. H., in *Tectona*, Part. XV, No. 2, pp. 105-122. Buitenzorg, Febr. 1922.

FORESTRY

A survey of the periodical and serial literature on forestry is attempted. Such a list, covering the German literature as well as that of other countries has, as far as the writer's knowledge goes, never been published before, while, on account of the rapid expansion of late years, it has become increasingly difficult to obtain a comprehensive view of this field. The principal causes of this expansion of the literature are the extraordinary progress of late years in forest-exploitation and forest-technology as well as the awakened interest in forestry in America and tropical countries and in tropical timbers generally. The list comprises the "Journals", and under the heading "Serials", the publications of forest services, universities, associations, clubs etc. on the scientific, technical and economic sides of forestry and connected industries, e. g.: Communications

of forest experiment stations, Yearbooks, Bulletins, Circulars, Leaflets, etc. Purely administrative progress-reports have been omitted.

TABLE I. — *Numbers of titles arranged according to countries.*

**588 - Forestry in the Straits Settlements.** — *Colonial Reports Annual No 111 Straits Settlements, Report for 1920* 35 pp London 1921

The total area of the forests under control is 42 964 hectares that is to say, 11 %, of the total area of the Straits Settlements The receipts and expenditure for 1920 were respectively 57 268 and 42 849 dollars (the dollar being equivalent to 2 shillings and 4 pence at par) as against 65 754 and 34 064 dollars in 1919 the total excess of receipts over expenditure was therefore 14 419 dollars Owing to the high prices realized for mangrove tree wood there was an increase in the receipts at Singapore but in all the other settlements a decrease the receipts having been exceptionally high in 1919 11 001 tons of wood for working were produced and 27 797 tons of firewood

In the forests under control at Sungai Ached (Wellesley Province) 100,000 mangrove trees were planted and 110 dollars for seed was the only expense

An inspection of the areas planted with "bakan" in preceding years in the forests under control in Tanjong Burong showed the success of re-afforestation If the cost of this work can be kept at a reasonably low figure it will very probably be profitable

**589 - Experiments in the Preservation of Acorns and Beech-Mast in Denmark.**

JOHANSEN, W., in *Det Forstlige Forsøgsvæsen i Danmark* vol 5 5th part pp 3-31 Copenhagen 1921

The following are the results of experiments on the preservation of acorns and beech-mast begun in 1903 and on acorn seeding begun in 1915

To preserve the germinating power of the acorns a low temperature is needed What degree of frost they will resist has not been tested but they keep well at 1° and 2° C Another necessary condition is access to the air, if deprived of air the germinating power is lost in about a year even at the low temperatures above mentioned The use of a solution of sublimate as an antiseptic is an advantage, a solution of sulphate of copper could probably also be employed, treatment with solutions of formaldehyde is not apparently of any practical use It has been possible to preserve the life of the acorns for three years the germinating power naturally decreasing gradually However, numerous vigorous plants were obtained from the seeds which survived The keeping of the seed seems to result in the survival of the fittest

Beech-mast is easily empoisoned by the use of fungicides but on the other hand if kept in a cold place can be preserved in a sufficiently healthy state for a winter or two.

After a close sowing there is a rather close correlation between the size reached by oak-seed in the first year and in the tenth, but their reciprocity is far from being invariable.

## LIVE STOCK AND BREEDING.

### HYGIENE

590 - **Plants Poisonous to Live-Stock.** — I. TALBOT, P. R., and HOOPER, J. C., Weeds Poisonous to Live Stock, in *Province of Alberta, Department of Agriculture, Provincial Schools of Agriculture, Bulletin No. 1*, pp. 401, figs. 15 + 4 coloured plates separate from text. Edmonton, 1919. — II. FLEMING, C. F., and PETERSON, N. F., The Narrow-leaved Milkweed (*Asclepias mexicana*), and the Broad-leaved or Showy Milkweed (*A. speciosa*), Plants poisonous to Live Stock in Nevada, in *The University of Nevada, Agricultural Experiment Station Bulletin No. 99*, pp. 32, figs. 10 Carson City, Nevada, December 1920. — III Two Vines reputed poisonous to Stock, in *Queensland Agricultural Journal*, Vol. XVII, No. 9, p. 36. Brisbane, January 1922.

I. — **PLANTS POISONOUS TO LIVE-STOCK IN THE PROVINCE OF ALBERTA, CANADA.** — It is estimated that more live-stock is annually lost in the Province of Alberta from eating poisonous plants than from any other cause. The Bulletin analysed gives the necessary information for the identification of the most dangerous wild plants growing in the Province, the best methods of preventing stock from eating these plants, the symptoms produced by their consumption, and the treatment of toxic disturbances caused by them.

The following is a list of the plants described: tall larkspur (*Delphinium glaucum* S. Wats = *D. Brownii* Rydb); low larkspur (*D. bicolor* Nutt. = *D. Menziesii* D. C. and *D. azureum* Michx.); death camas (*Zigdenus venenosus*); water hemlock (*Cicuta maculata*); white locoweed (*Oxytropis Lambertii*); woolly loco-weed (*Astragalus mollissimus*); showy loco-weed (*A. splendens*).

As preventive measures, it is advisable to: extirpate the poisonous species; fence in infested land, so as to keep out animals; give salt and good drinking-water to the stock; keep animals away from infested districts during the dangerous season and feed them so that they are not driven by hunger to eat poisonous plants (1).

II. — **TWO PLANTS POISONOUS TO CATTLE IN NEVADA.** — These are the narrow-leaved milk-weed (*Asclepias mexicana*), and the broad-leaved milk-weed (*A. speciosa*). The authors describe these plants, their composition and habitat as well as the toxic symptoms produced by them etc.

III. — **TWO PLANTS REGARDED AS POISONOUS TO CATTLE IN QUEENSLAND.** — These are two Asclepiadeae: *Marsdenia rostrata* and *Secamone elliptica*.

F. D.

(1) See H. C. LONG, *Plants Poisonous to Live Stock*, Cambridge University Press, 1917. (Ed.)

- 591 - **Is the Sorrel Dock (*Rumex Acetosa*) Poisonous to Cattle?** — CRAIG, J. F., and KEHOE, D. (Royal Veterinary College of Ireland), in *Department of Agriculture and Technical Instruction for Ireland*, Vol. XXI, No. 3, pp. 314-317. Dublin, 1921.

The sheep-sorrel (*Rumex Acetosella*), appears to be poisonous to the horse (CORNEVIN), and sheep (MULLER) on account of the potassium oxalate it contains. The authors wished to ascertain whether a nearly-related species, the sorrel dock (*Rumex Acetosa*), is injurious to cattle as is believed by many breeders. With this object, they carried out a series of feeding experiments during the spring and summer of 1920. The results obtained led to the following conclusion: although grazing cattle manifest a certain aversion to *R. Acetosa*, it does not produce any ill-effect of importance. It thus seems that this plant does not contain sufficient oxalates to be injurious to cattle. F. D.

- 592 - **Observations on the Treatment of Puerperal Infection in Domestic Animals by Treatment with Iodide of Ioduretted Potassium.** — NADSEN, M. I., in *Berliner Tierärztliche Wochenschrift* year XXXVIII No. 7, pp. 75-76. Berlin, February 1922.

The author had observed for some years that when the uterus of mares, cows, and sows suffering from uterine inflammation or puerperal infection was washed with a dilute solution of ioduretted potassium this solution rapidly lost its colour in some cases when it came in contact with the mucous membrane, whereas in others this effect did not occur or only to a limited extent. According to experiments made by the author this loss of colour is due to the iodine combining with definite substances present in the uterine solution and forming a colourless compound.

It is not at present possible to decide whether these substances are bacteria, or the products of their metabolism, but it is certain that they exercise a pathogenetic effect and that they are rendered innocuous by the formation of a colourless compound. This is shown by the fact that treatment with the iodo-ioduretted solution has a very favourable effect upon the course of the disease.

The decoloration and the therapeutic action of the resulting ioduretted solution are not always produced because uterine inflammation in domestic animals may be caused by a number of different species of bacteria (*Bacterium coli*, *Staphylococcus pyogenes albus* and *vitreus*, *Streptococcus pyogenes* etc.). However the simplicity of this treatment makes it worth knowing and practising by stock-breeders. F. F.

- 593 - **Notes on Contagious Abortion in Female Asses and Mares.** — BRANFORD R., and DOYLE, F. M. in *Agricultural Research Institute, Pusa Bulletin* No. 11, pp. 114, 5 pl. Calcutta, 1921.

Since 1911, the authors have observed at the Hisar Stock-breeding Station several cases of contagious abortion, a disease hitherto unknown in the district.

The signs of infection are not apparent, unless the disease develops when gestation is already far advanced and it is not easy to recognise complete abortion in mares. When this occurs the membranes and fluids of the foetus have a normal appearance, if the gestation period is nearly

complete, the young foal may be alive at the moment of birth, but generally dies a few days later.

In 1920, the authors succeeded in obtaining and isolating a pure culture of a bacillus resembling both morphologically and biologically the one described by GOOD and CORBLIT (1). The bacillus was obtained by inoculating tubes of agar with blood taken from the heart and liver of a foetus.

It occurred in the form of a short thick rod with rounded ends, and was Gram negative. A bacillus with the same characters was isolated from the stomach, liver, heart and the allantoic and amniotic fluids of the aborted foetus of a female ass.

The authors believe that the unknown pathogenetic agent finds its way into the body through the mouth; they consider that the incubation period lasts 6 weeks, which is contrary to the general opinion which limits it to a time varying from 10 days to 3 weeks.

Prophylactic measures (destruction of the foetus, isolation and disinfection of the infected animal) are of little use owing to the absence of distinct symptoms of abortion and the difficulty of discovering the diseased foetus, which almost immediately falls a prey to vultures.

Immunity, even allowing that this is conferred by an attack of the disease, does not last.

E. F.

**594 - Horse Pest.** THILGER, A. in *Department of Agriculture of the Union of South Africa Science Bulletin* No. 13, pp. 1-3, JICTORIA 1911.

THILGER's paper on this subject deserves mention as it gives an excellent synthetic review of all that is known regarding the natural and medical history of horse pest and has in appendix with a bibliography of 32 works dealing with the researches carried out on horse pest by the Bureau of Veterinary Research of the Government of the South African Union.

E. F.

**595 - New Endoscopic Methods for the Examination of the Horse.** SPIRZ, G. *Archivos da Escola Superior de Agricultura e Medicina Veterinaria* Vol. IV No. 2 pp. 77-83, pl. XVIII XX, Niteroi (Brazil) December 1911.

In order to diagnose certain diseases of the horse, it is necessary to carry out laryngoscopic and pharyngoscopic examinations, but the apparatus for this purpose has been very rarely used, as it has many serious defects. These difficulties can be avoided by adopting the technique devised by SPIRZ, by this means laryngoscopy or pharyngoscopy, become easy and can be carried out by anyone.

The following instruments are necessary: 1) a metal, so-called endoscopic tube, this is cylindrical and is 50 to 55 cm. long and  $1\frac{1}{2}$  to 2 cm. broad; 2) an *illuminating apparatus* consisting of an incandescent lamp of 5-6 volts fixed to the end of a rigid conducting rod a little shorter than the endoscopic tube. The rod can be easily introduced into and adapted to the interior of the tube and is provided with the necessary arrangements.

(1) *Journal of Infective Diseases*, July 1913 (Author's note).

for putting it into connection with a supply of electricity ; 3) a *supply of electricity*

An oral examination of the pharynx, or larynx must be carried out on the horse when it is lying on its back, or on one side, the head and neck being so arranged that the angle formed by the neck with the buccal cavity is as nearly as possible 180°, or in other words, the head and neck must be almost in a straight line. The arrangement of the head and neck is of great importance for the success of the examination, as if carried out as advised, the endoscopic tube may be easily introduced, and the operation can be quickly performed.

SPITZ'S method affords a more extended and clearer field of observation than is obtained with other methods. The author has adopted it since 1912 in a fairly large number of laryngoscopic and pharyngoscopic investigations. The results obtained were excellent and not attended with the slightest trouble

If an endoscopic tube of slightly less diameter is used, the same technique allows of pharyngoscopy through the nose, and hence of the examination of the orifice of the Eustachian tube

E. F.

596 - **The Simultaneous Method of Inoculation with Anti-Rinderpest Cattle-plague Serum.** — POOL, W. A., in *Agricultural Research Institute, Pusa, Bulletin* No. 120, pp. 1-7, with 2 Appendices, Calcutta, 1921

This article contains brief instructions for inoculating cattle with anti-rinderpest serum by means of a new method that confers lasting immunity and is called simultaneous, because while a sub-cutaneous injection of it is made beneath one shoulder, the other shoulder is injected with blood taken at the time the fever runs highest, from an animal suffering from rinderpest. On the seventh, or eighth, day individuals that have not reacted to the first injection are given a second inoculation of virulent blood (5 cc), without any further injection of serum.

The author gives a short account in the following paragraphs of : the means of obtaining the serum, the cases where inoculation should not be practised, the measures to be taken to prevent the introduction of piroplasms together with the virulent blood, and the contamination of healthy animals by those that have not yet been immunised

E. F.

597 - **On an Acute and Epidemic Form of Parenchymatous Hepatic Inflammation in Sheep.** — KNUTH, P. and STEPHAN, J., in *Berliner Tierärztliche Wochenschrift*, year XXXVIII, No. 7, pp. 73-74, Berlin, February 16, 1922.

One of the authors of this article, KNUTH, has observed numerous sheep affected a disease that quickly causes the death of 25 % of the flock. The clinical symptoms of the disease are as follows: yellow colour of the exposed mucous membranes; difficult respiration; a flow from the nostrils of whitish mucus mixed with blood; soft pitch-coloured excrement mixed first with mucus, and later with blood; very weak pulse; corneal reflex entirely absent, pupil dilated and not reacting to direct light, rectal temperature 41° C.

The examination of the internal organs belonging to three animals revealed the following lesions: slight swelling of the mucous membrane of the stomach and small intestine, the spleen swollen, dark brown, hardened, with reticulation clearly recognisable in sections, the liver very swollen, brittle, dried up, brownish-yellow in colour and the lobules no longer distinctly separate, the gall-bladder full and distended, the cardiac muscle dark-red, rigid and dry.

A microscopic investigation of thin slices of the liver revealed the typical syndrome of acute parenchymatous fatty degeneration of the liver cells. Since the negative results of the microscopic examination of the blood and organs excludes all possibility of bacterial infection, the authors diagnose the disease as a *fatty parenchymatous degeneration of the hepatic cells that manifests itself in an epidemic form*. They believe it to be due to plants eaten by the cattle while grazing (1).

This work is important a) as being a contribution to our knowledge of a hitherto little known disease described by several authors under the name of *epidemic parenchymatous hepatitis of sheep* b) because the syndrome of symptoms described can easily be mistaken for those induced by phosphorus or arsenic poisoning or the toxic effects of some leguminosae.

G. F.

#### FEEDS AND FEEDING

598 - The Use of Calcium Salts in the Feeding of Animals. — Ohio Agricultural Experiment Station, Bulletin 31 pp. 1 fig. Wooster Ohio 1917

The bulletin analysed contains the following 6 papers:

I — FORBES F. B. HARRISON J. O. MORGAN, L. G. and SCHUTZ J. A. *The metabolism of calcium salts in a growing pig* — Experiments to determine the metabolism of the mineral constituents of the ration were carried out in November-December 1917 with 5 young castrated boars of the Poland China breed. There were 3 experimental periods of 10 days each separated by intervals of 7 days. To a basal ration consisting of maize flour + linseed cake + wheat sharps (7:1:1) with salt in the proportion of 1:450 were added various mineral supplements which are given together with the chief results obtained from them in Table I.

It was found that the characteristics of the metabolism of swine fed almost exclusively on the grain of cereals were as follows: loss of calcium, abnormal gains in magnesium and phosphorus, very acid urine containing much ammonia. An excess of potassium was present in the basal ration, whereas sodium and chlorine except for the small quantities supplied in the form of kitchen salt were lacking.

The insufficient assimilation of calcium is an important factor in determining the gains in phosphorus and to a lesser degree, in magnesium. The increasing ingestion of calcium in the form of precipitated carbonate or powdered limestone, causes a marked increase in the calcium, magnesium and phosphorus gains.

(1) The authors have carried out some experiments in order to identify these plants; they will give the results in a subsequent paper. (Ld.)

The addition of 1 part of salt to 450 parts of grain, the basal ration, causes a gain in both sodium and chlorine. The gains in sodium and potassium were as a rule, almost equal. The need of sodium was more quickly satisfied than that of chlorine. All the mineral additions, especially the precipitated bone-meal, served to increase the chlorine gains as compared with the basal ration without any addition.

The magnesium content of all the rations was sufficient. When the magnesium metabolism was negative, the loss was due to the hindering effect of other factors, especially to insufficient ingestion of calcium. All the mineral additions had a favourable influence upon the magnesium gains. In some cases, the improvement of the latter were to be attributed entirely to the increase in the amount of calcium ingested.

Ground limestone, precipitated bone-meal, degelatinised bone-meal and precipitated calcium carbonate had much the same effect on the calcium gains, whereas ground mineral phosphate was clearly less effective.

The gain in phosphorus was distinctly increased by all the additions containing calcium, whether in the form of the carbonate, or the phosphate.

The solubility of the compounds seems to be the chief cause of the gains; precipitated calcium carbonate and precipitated bone-meal are the most effective, ground mineral phosphate having much less effect. Compared with the potentially acid, basal ration, the compounds containing calcium carbonate lowered the acidity and the ammonia of the urine, but precipitated bone-meal (containing bicalcic phosphate) increased them.

Mineral additions had no effect upon the digestibility of the ration.

One third of the sodium evacuated by the organism was found again in the urine and one third in the faeces. A larger proportion of potassium found its way into the urine, and still more into the faeces.

Generally, over 90 % of the chlorine passed into the urine.

The capacity possessed by the digestive apparatus of absorbing mineral foods is limited in the first place by their solubility and afterwards, amongst other factors, by the rapidity with which these substances pass from a soluble to an insoluble condition in the blood and lymph, either by means of a synthetic process, or as a result of excretion. The gains in absorbed mineral nutrient substances are governed by the requirements of nutrition, and are not increased by limiting elimination which would immediately decrease absorption.

The most effective, and certainly the most soluble mineral additions used were precipitated carbonate and precipitated bone-meal. Other compounds may be more practical, though less effective, if the pigs will eat them and can tolerate them when fed in sufficient quantities. The most urgent mineral need of growing animals, after common salt, is satisfied by calcium carbonate. When, however, the assimilation of the phosphorus, which is normally present in the ration for the building up of the skeleton, is thus assured, some form of calcium phosphate must be given.

With a certain loss of phosphorus, all the need for mineral additions can be satisfied by calcium phosphate. The phosphate is dearer than the

carbonate, but it is more easily tolerated, and if fed separately from the ration, is more acceptable to the stock.

TABLE I. — *Effect of mineral additions on the metabolism of calcium, magnesium and phosphorus.*

Mineral added	Amount ingested per kg. of live weight			Amount ingested per kg. of live weight			% assimilated of the amount ingested		
	Ca.	Mg.	P.	Ca.	Mg.	P.	Ca.	Mg.	P.

II. — FORBES, E. B., HALVERSON, J. O., SCHULZ, J. A. and WELLS, E. B., *Metabolism of some calcium salts in growing swine.* — A second experiment to ascertain the metabolism of the mineral constituents of the ration was carried out from August to October 1918 with 4 castrated pigs of the Poland-China breed. The chief object of the experiment was to compare the effects of the addition of mixed minerals with those of minerals introduced separately. The results connected with the metabolism of calcium, magnesium and phosphorus are given in Table I, Experiment II.

As in the preceding experiment, the metabolism of sodium, magnesium, chlorine, sulphur and nitrogen was also studied. The results were practically the same, although there was a larger proportion of potassium in the urine. The authors bring out the independent behaviour of sodium and chlorine. All additions containing calcium were useful, from 5 to 10 tenths of the calcium administered was retained by the organism; no appreciable difference existed in the capacity of assimilating the various additions.

III. — FORBES, E. B. and SCHULZ, J. A. *The effect of mineral*

*additions upon the development of swine.* — Thirty Duroc-Jersey pigs of the average weight of 62 kg. were divided into 5 lots and given experimental rations for 86 days dating from April 30, 1917. The basal ration was the same as in the two previous experiments. The mineral additions were chosen so as to supply 5 mg. of calcium per head and per day. At the end of the experiment, the animals were slaughtered and their skeletons physically and chemically examined. The pigs of the lot given precipitated calcium carbonate and those which received precipitated purified bone-meal had relatively compact, strong skeletons, whereas the bones of the pigs that had been supplied with ground mineral phosphate were only a little denser than the bones of the control animals (ration without supplementary calcium salts) and were less resistant than those of the latter, as well as containing a smaller amount of ash per unit of volume. The skeletons of the pigs given precipitated bone-meal occupied an intermediate position as regards density and resistance. The proportion between the phosphorus and calcium present in the bones of pigs was fairly high whether they had received mineral phosphate, or the basal ration. In this, the bones differed from those of the young animals killed at the beginning of the experiment in order to determine their initial composition, in which the proportion of magnesium present in the skeletons of the young pigs was relatively lower than that of the calcium.

IV. — FORBES, F. B., HUNT, C. A., SCHULZ, J. A., and WINTER, A. R. *Effect of mineral addition on the development of swine.* — The experiments described in this paper began on July 26, 1919 and lasted nearly 16 weeks. They differ from the preceding experiments in that the mineral addition instead of being mixed in a given proportion with the rest of the ration, was fed separately and *ad lib*. Further, a larger number of additional substances were given and more determinations of the physical characters of the bones were made. The pigs were hybrids with a predominance of Duroc-Jersey and Chester-White blood.

The animals were divided into 8 lots each containing 5 individuals with an initial weight of about 21 kg per pig. The basal ration consisted of maize flour, wheat sharp and linseed meal cake (3. 1.) with the addition of 1 part in 500 of kitchen salt. The mineral additions were given to 7 lots in the buckets of an automatic distributor, 5 % of sodium chloride being added each time. During the first 5 weeks, the pigs did not relish these additions to their ration, but later when they were shut up in a brick-paved sty, they ate them in large quantities. The additions given to the various lots, the amount eaten, and certain characters of the bones determined after the animals were slaughtered are summarised in Table II.

The penetrability (hardness), was determined by means of a specially constructed microdynamometer measuring the penetration of a diamond-pointed punch 5 mm. in diameter under a pressure of 9 kg. The operation was carried out upon a transverse section from the narrowest part of the diaphysis; its faces were exactly parallel, and polished by a special apparatus. Both these machines were invented by Dr. Joseph HEAD, of Philadelphia.

TABLE II. — *Effect of an unlimited supply of additional mineral substances upon the bones of swine.*

Lot	Mineral substances added	Amount ingested per head and per day gm.	Ca. present in the additional mineral supplied	Resistance coefficient		Penetrability of tibia	Ash per cc. of tibia	Composition of fat-free dry bones			
				Humerus	Tibia			Ca.	Mg.	P.	CO <sub>2</sub>
1	Ground mineral phosphate	12.1	3.72	212	151	71.1	783	59.8	1.75	31.1	7.40
2	Ground limestone	20.1	7.84	268	183	56.3	774	60.1	1.49	30.3	8.15

Mineral phosphate did not make the skeleton stronger as compared with the effect of the ordinary ration without any addition, whereas all the other mineral supplements produced considerable and almost identical increases in the strength of the bones.

Degelatinised purified bone-meal makes the bones damp, less fat and more acid (both as regards volume and dry fat-free material), than any other mineral addition. The calcium and carbon dioxide contents (except the hardness, exceeded those of all the other lots, but the magnesium content was the lowest of all. The bones of the control lot were relatively poor in mineral constituents other than magnesium.

The hardest bones (Lot 3 of Table III), were characterised by a larger proportion of calcium, carbon dioxide, and ash, and by the low magnesium content of the fat-free, dry bones, as well as by the smaller amount of magnesium in the total number of mineral constituents determined (calcium, magnesium, phosphorus and carbon dioxide).

The softest bones (Lot 1), were characterised by the larger amount of magnesium and phosphorus and the smaller quantity of calcium and of carbon dioxide in the total of the constituents determined.

The difference between these 2 lots bring out the relative value of ground mineral phosphate and of purified bone-meal as mineral supplements for young animals. The mineral substance of bones is a mixture of carbonates and phosphates capable of change as a result of the selection of the carbonates serving as part of the alkali reserves of the organism. The authors are of opinion that in lots 1 and 8, the low proportion between carbon dioxide and the phosphorus of the bones shows that some elimination of the calcium carbonate has taken place to compensate for the lack of

potential alkali. This causes the formation of softer bones owing to the large proportion of magnesium phosphate.

V — FORBES, F. B., *Additional foods consisting of more or less appetising mineral preparation for swine, cattle and horses* — The author has made 19 experiments with pigs and 15 with cattle. He has found that horses also readily eat precipitated bone-meal and purified degelatinised bone-meal.

In this experiments with pigs, the author observed that purified degelatinised bone-meal which under certain conditions was the most liked, could be rendered still more acceptable by the addition of a little acid.

Meat meal increased the flavour of the mineral supplement with which it was mixed. The best results are obtained with blood meal or fish meal. Coriander seeds, and molasses also increased the flavour of the added minerals but not as much as the above-mentioned meals. On the other hand anise, fenugreek, caraway, fennel, charcoal, humus and ground lucerne hay had no effect. Preparations in the form of fine powder caused disturbances.

VI — FORBES, F. B., HAINFORD, J. O. and SCHUIZ, J. A. *The effect produced upon the alkali reserves of the pig by a diet of grain and mineral supplements* — Two pigs were fed a basal ration composed of maize flour + wheat churps + linseed meal cake + kitchen salt for 33 days. This period was followed by another during which precipitated calcium carbonate was added to the ration and the experiment terminated with a further period of 23 days during which precipitated bone phosphate was added to the basal ration.

The mineral additions were given at the rate of 0.2 gm. per kg. of live weight.

The consumption of calcium carbonate which is potentially basic increased the carbon dioxide pressure of the blood plasma and decreased the ammonia content and the hydrogen ion concentration of the urine. Bone phosphate being potentially acid had just the opposite effect. It is therefore probable that the alkali reserves of the blood plasma can be greatly altered by the character of the mineral substances added to the ration. F. D.

599 — **Boiled Cotton Seeds as a Stock Feed.** GRAHAM, I. (Chief Dairy Expert), in *Queensland Agricultural Journal* Vol. XVI No. 5, p. 10. Brisbane November 1921.

The cotton-grower is often unable to render his cotton seed suitable for a concentrated stock-feed owing to the fact that he has no available means of decorticating and grinding it. For this reason the author advises a simple method of preparing cotton seed which has been practised by many stock breeders in Queensland and is within the power of all to practise. This consists in boiling the seeds for 15 to 20 minutes, taking care to keep them beneath the water in the pot. Boiling softens the integument and makes it relatively easy to press out the seed. The weight of the boiled seeds is double that of the raw. The operation should be carried

out every day. Boiled cotton seed can be fed with bulky dry or green, foods such as chopped straw, buckwheat etc. It can also be given to milch cows which eat it with avidity. F. D.

**STOCKS  
BREEDING**

600 - **Variability in Domestic Animals and the Value of Statistics in Researches connected with Stock Breeding. Part. II.** — FEIGE, E. in *Fühling's Landwirtschaftliche Zeitung*, Year LXX, Nos. 17-18, pp. 335-348, figs. 3. Stuttgart, September 1921.

The author continues his researches on the variability of domestic animals; his method and objects are the same as he has described elsewhere (1). He deals with documents compiled from data collected in the Herdbook of East Prussia published by the "Insterburger Verband". Only the four first volumes of this work (including those for the years 1912-1915), have so far been published, therefore the number of generations registered is still too small to permit of thorough statistical analysis. Another difficulty also presents itself in this connection viz., that among the animals under consideration, some cattle of other breeds have found their way, so that a noticeable amount of genealogical heterogeneity has been introduced into the material.

The cows in question are adult animals of the Black Pied East Prussian breed; in some series they number 2500. The measurements taken are: width of chest, depth of chest, width of pelvis, height at withers, height at croup, width of hips, and length of body; the fat content of the milk was also taken into account.

In this case also, the variation curves of the dimensions of the body are asymmetrical; this (although its causes may be theoretically different), here depends upon special kinds of variation proper to the material viz., upon the fact that the animals studied belong to several fundamental and not yet differentiated biological forms, or else the effect of selection is still visible. From the systematic standpoint, the Black Pied breed of North Germany appears to be a homogeneous group, but the statistic method shows by the irregularity of the frequency curves, that no genotypic unity really exists. According to the tables drawn up and reproduced by the authors, the asymmetry of the frequency curves is not always the same, and manifests itself in different ways in each of the measurements under consideration. The question is no doubt one of lines that are different according to the genotypic point of view, each line possessing its own special characters. It is also necessary to consider, within the limits of each line, the behaviour of each character and the frequency subdivision of each of its values.

This different behaviour of the various characters as regards the distribution of the frequency of each of their possible dimensions, is a problem of great importance in stock-breeding, but its solution depends upon a knowledge of the hereditary behaviour of the genetic factors correspond-

(1) The first part of this work has been summarised in R. Dec. 1921, No. 1248. See also R. July 1921, No. 739. (Ed.)

ing to the different morphological characters. It is, however, evident that it is not by prolonged selection alone that the modifications of the germ-plasm necessary for increasing the variations of the characters can be obtained, but only by means of the combination of the dominant hereditary factors, which must be analysed thoroughly and known. In conclusion, these researches have led the author also to confirm the statement that, individual characters and their variability may be learnt from the statistical analysis of the variations of forms and capacities, but that, the mechanism of character transmission can only be discovered by the application of exact methods to unilinear generations.

As regards capacity for milk production, the "Insterburger Verband" gives (for a total number of 7534 cows), the fat content of the milk, instead of the amount of the milk, because external causes can only produce very slight variations in the fat content. Here again the tables and the variation frequency-curves lead us to conclude that there is no question of genealogically equivalent lines, for the data show the behaviour of a phenotype, not of a genotype. On the other hand, a distinct separation of each line is practically impossible, because the material has not yet attained a sufficient degree of genealogical homogeneity. E. F.

601 - **The Mating of Nearly-Related Cattle.** BUCKLES, C. H., in *Hoofd's Dairyman*, Vol. LXIII, No. 5, p. 115 Port Atkinson Wisconsin February 1922.

The above is a short popular article written for cattle breeders and giving an explanation of the terms "inbreeding" and "line-breeding". The first is applied to the mating of closely related animals, for instance brother  $\times$  sister, or son  $\times$  mother, while the second signifies the union of more distantly related individuals such as (uncle  $\times$  niece, or cousin  $\times$  cousin). It should be noted that the difference is merely one of degree, so that all persons are not of accord as to the method of distinguishing the two types of mating.

Both are usually adopted in order to retain for as long as possible the characters of an especially prepotent sire. As an instance of inbreeding, the author mentions the case of a Holstein bull celebrated for transmitting milk yield capacity to its offspring. This animal was mated with its own daughters in order to retain its blood in the largest possible number of successive generations. The Jersey breed is a good instance of the results of line-breeding.

The breeders can, according to requirements, mate animals related in the first degree, or those less closely connected by blood, or they can combine the two methods. It is well-known that the chief defects produced by prolonged inbreeding are: a) a decrease in the fertility, size and resistance of the animals; b) the possibility of transmitting and accentuating defects as well as the desired characters. E. F.

602 - **Bill for the Improvement of Agricultural Live Stock in England.** — *The Ministry of Agriculture and Fisheries*, Leaflet No. 212, pp. 1-6 London, 1921.

STOCK RAISING

The British Government has included in the budget of the Ministry of Agriculture an annual sum of about £ 35 000, to be expended in making

grants to agriculturists and Agricultural Associations for the purposes of  
*a)* enabling them to use bulls, stallions and boars of good breeds ; *b)* defraying half the expenses devolving upon Dairy Farms, or individuals, whose milch cows attain records in milk yield.

Grants are made preferably to Associations, which, like individuals, have the right to the collaboration of Live Stock Officers who are nominated by the Ministry and mentioned in the bill in question.

Among the chief provisions respecting the allocation of the grants may be mentioned those relating to bulls (the others are of similar character).

*a)* Grants are made to Associations up to  $\frac{1}{4}$ , and even  $\frac{1}{3}$ , of the value of the bull ; the maximum sum being £ 20.

*b)* If the Association acquires a bull collectively, it must obtain in addition to the sum required for the purchase of the animal, sufficient capital to bring in enough income to cover all expenses connected with the said animal, including life insurance

*c)* Should the Association arrange with the owner of a bull that the services of the animal are at the disposal of its members, it incurs the following obligations, to 1) pay the owner a sum equal to the Government grant ; 2) pay a service fee of not less than two shillings and sixpence for each cow served , 3) guarantee that at least 35 cows shall be served annually , 4) allow the owner of the bull to have at least 15 of his cows served free of charge

If the Association accepts these conditions, the owner of the bull (not the Association), is legally responsible for the custody, keep and insurance of the animal.

F. F

603 - **Thirty Year's Experimental Stock Breeding in Utah.** — HARRIS, L. S., and BUTT, N. J., in *Utah Agricultural Experiment Station, Circular No 46*, 64 pp Logan, Utah, 1921

A summary is given of the most important facts discovered in the course of thirty year of experimental work performed by the Utah Agricultural College since its foundation. A catalogue of the publications of the Station (286) is given in the Appendix. The following is a short account of the stock-breeding work (1)

**CATTLE FEEDING** — The animals used in the experiments were cattle of the native breed reared in the open

*Composition of rations* — In the experiments with lucerne + mixed hay + straw + wheat + bran, the best proportions were those corresponding to the nutritive ratio of 1 : 4.81. When, however, mixed feeds are used the nutritive value of each food must be taken into account, rather than the nutritive proportions of the ration. If cattle are given all the straw they can eat + wheat + bran, there is no need to trouble about the nutritive proportions of the concentrates to be added to the ration.

*Comparison between different forage plants* — It has been found that

(1) The other work is connected with irrigation and its effects on different crops — dry-farming — soil physics — agricultural machines — rural economy — fruit growing — the parasitic insects of cultivated plants (Ed)

the respective nutritive value of lucerne hay, meadow clover hay and timothy grass hay with equal rations of grains (1) is in the proportion of 91 : 75 : 97, whereas the proportion of the amounts consumed daily is as 100 : 80 : 95. The first and third cutting of lucerne were superior to the clover and timothy grass both as regards rapidity in increasing live weight and the amount of food necessary to obtain 1 kg. increase in live-weight. The amount of dry matter required to produce 1 kg. increase in live-weight was highest in the case of lucerne, lowest in that of forage-maize (maize cut before the ears were quite ripe), and intermediate between that of timothy grass, the proportion being as 100 : 94 : 91. In comparison with other forages, lucerne is especially rich in digestible protein and poor in digestible fibre.

A ration of lucerne hay + straw + grains proved superior to one of lucerne hay + grain. The ration of mixed hay + grains was superior to the ration lucerne hay + grains, but inferior to the ration lucerne hay + straw + grains. Chopped maize forage was one of the best fodders; on the other hand, timothy grass did not prove so satisfactory. As the result of a comparison between the digestible matter in different foods, the following products were ranged in descending order: barley 100; pea meal 89; bran 70; maize stalks and ears 68; lucerne 64; timothy grass 63; straw 51.

*Comparison between black vetch and lucerne* -- The black vetch, Golden Vine, produced in 1900, 149.3 kg of protein per hectare, and lucerne produced 179.6 kg. The protein of the vetch hay was rather more digestible than that of the lucerne, especially when the vetch had been cut at the beginning of the flowering season when its digestibility is highest. The stems were more digestible than the leaves, in this, black vetch differs from lucerne. The chemical composition of vetch hay cut at the beginning of the flowering season is superior to that of lucerne, but after the flowering is over, the loss of nutritive substances is very rapid.

*Comparison between successive cuts of lucerne* -- As a cattle feed the nutritive value of the first, second, and third cuts of lucerne (19.89 kg. of hay per kg. of grains as basal ration) was respectively 100 — 75 — 110, the relative amounts consumed per head and per day were in the proportion of 100 (viz., 10.5 kg.) 97 105. The third cut contained least dry matter and digestible matter ingested per kg. of increased weight. The five-year average increase in live-weight obtained per hectare was much higher for the first cut and decidedly lower for the third, the proportion being for early cutting, as 100 : 80 : 69.

*Comparison between cutting lucerne early or late.* — The object of these experiments was to determine the best time for cutting lucerne. It was found that as regards the amount of increase in live weight produced per hectare, the relative value of the cuts was as follows: early cut (immediately after flowering) 100; average cut (one week after flowering begins) 71. Cattle fed with lucerne hay, with or without grain supplement,

(1) By grains is understood not only the grain of cereals or other seeds but also their by-products, such as milling offals (bran, sharps etc., cakes etc.). (Ed.)

ate a little more hay per day and made more rapid gains in live weight when given early cut lucerne hay than with late cut lucerne hay. Given equal weights of hay, the earlier cut produced the best results. In the case of the second and third cut, the proportion was as 100 : 85 : 75. The amount of hay consumed per head and per day was about the same whether the hay was cut early or late, although rather larger quantities of the former were eaten than of the latter. The amount of dry matter and digestible matter required to produce 1 kg. increase in live weight was however decidedly less in the case of the early crop and more in that of the late crop.

The proportion for the 3 cuts was as 100: 131: 166.

*Sugar-beet pulp as a cattle feed.* — A larger quantity of dry matter per kg. of gain in live weight was consumed when only lucerne hay + pulp was fed, than when the hay was replaced to some extent by grains. Cattle given lucerne hay + pulp made practically equal live-weight gains through the whole feeding period. Larger and cheaper gains were obtained by feeding grains during the last part of the fattening period than at the beginning. Table I gives a summary of a feeding experiment with lucerne hay, beet pulp and grains which lasted 107 days. It shows clearly that it is very advantageous to feed by-products of milling with beet pulp.

TABLE I. — *Results of a feeding experiment with lucerne hay, beet-pulp and grains*

Ration			Average increase in live weight per head and per day	Kg. of food consumed for 1 kg. increase in live weight			
Lucerne hay	Bran and sharps	Beet pulp		Lucerne hay	Bran and sharps	Beet pulp	Total dry matter
entire	entire	none	725 gm	9.8	4.6	—	12.66
entire	none	entire	670	11.5	—	31.4	13.05
entire	entire	entire	1025	7.2	3.2	17.0	10.68
entire	1/2	entire	825	9.2	2.0	19.1	11.65
1/2	entire	entire	910	4.3	3.6	21.3	8.87

In another experiment, it was found a good plan to add 900 gm. of grains to a ration of lucerne + pulp, because each kg. of grains replaced 3 of lucerne hay, or 17 of pulp. The increases in weight were larger and the production cost diminished when the ration of pulp was limited to 1/4 or 1/2 the amount consumed *ad lib.* by the animals and when lucerne hay was fed *ad lib.*, but not the beet pulp. On limiting the lucerne ration in the same way and giving the stock all the pulp they could eat, the increases in live-weight fell and the cost rose, although it was better to limit the ration of one or other bulky feed than to give both *ad lib.*

*Beet pulp and molasses as feeds.* — More rapid and economical increases in live weight were obtained when molasses was substituted for

part of the grains ration than when grains + lucerne hay were fed. Each kg. of molasses decreased the amount of lucerne hay and grains consumed for 1 kg. increase in live weight by 0.55 kg. and 0.3 kg. respectively.

*Roots as a feed.* — In an experiment lasting 88 days, in which two lots each of 3 animals were given mixed hay + forage maize + grains, the lot receiving 7.4 kg. of mangels per head and per day gained 62 gm. per head per more than those given no roots day. The cattle fattened on ration containing roots lost the most in dressing. In order to replace 794 kg. of dry bulky feed, 4200 kg. of roots, or about five times as much was needed.

*Grass and hay compared.* — In an experiment of 21 days' duration, in which three lots of 3 animals each were employed, it was found that grass is not superior to good hay, and that unripe grass is of less value than ripe grass. Steers at grass require a grazing ground 28 % larger than is necessary for animals fed on cultivated forages. In order to produce 1 kg. of live weight, more dry matter is needed in summer than in winter.

*Comparison between forage plants of different kinds.* — Two years' experiments with steers at grass have shown that the animals do better in a meadow composed of mixed species than in one where only one sort of grass is grown. Of the various species cultivated singly *Avena clatior* ranked first, *Phleum pratense* second, and lucerne third.

*Value of grains in the ration.* — It was found unprofitable to feed grains with lucerne hay during the period preceding fattening. The cost of producing 1 kg. live weight increases as the fattening progresses. There is no advantage in keeping steers for the butcher on rations producing a slight increase in weight during the winter, in order to subject them in the following spring to a short period of intensive feeding.

In one experiment lasting 84 days in which groups of 4 steers were employed and fed an ordinary ration of mixed hay and 1.8 kg. of grains per head and per day, the animals given most roots gained 680 gm. per head and per day, while those fed on straw, or forage-silage, gained respectively 665 and 580 gm. The weights of the 3 feeds consumed were in the proportion of 2.8 : 1.0 : 2.3. Equal amounts of hay and grains were eaten. The steers receiving respectively 1.8; 2.7; 3.6 kg. per head and per day in addition to mixed hay increased in live weight 445; 690; 720 gm. per head and per day. The cost of producing 1 kg. of live weight decreased as the quantity of grains was increased.

*Ration of grains alone.* — Two-year-old cattle fed for 175 days on a ration of grain only gained in live weight 840 gm. per head, per day. To obtain 1 kg. increase in weight, 5.7 kg. of grains were required. When the animals were not given bulky fodder, they drank very little and seldom chewed the cud.

*Value of shelter.* — The best results, both as regards rapid increase in live weight and economy in feeding, were obtained when the animal was allowed to use an enclosed meadow, or a shed, at will. Cattle living in the open eat more than those kept in the stall, but they are more thrifty.

*DAIRY COWS. — Feeding on grains.* — Experiments with lots of 3 cows were made for periods of 21 days, in order to determine the effect

of grains on milk production. In the case of animals given good lucerne hay and 1.8 kg. of a mixture of bran and sharps per head, and per day, it was found that the addition of grains had little more effect than that of an equal amount of lucerne hay. Butter production was cheaper if 1.6 kg. grains was fed instead of 3.2 kg., although the milk yield was a little lower and less regular. The total milk yields were respectively 2154 and 2160 kg. and the butter (water-free) production 112 and 89 kg. An increase in the amount of concentrates did not make the milk richer.

*Comparison between different forages* — Lucerne hay + grains proved more economical for the production of milk and butter than mixed hay + grains, but the amount eaten was about the same. Calculating from the quantity ingested, the ration lucerne hay + forage maize produced milk and butter with a little less dry matter consumption, as compared with the ration of lucerne hay alone. If the calculation is made from the amount distributed, there is practically no difference. The butter of cows fed on lucerne was darker in colour and firmer than that of cows given forage-maize.

*Comparison between the different cuts of lucerne.* — The production of 3 lots composed of 5 cows was recorded for 2 years. It was found on comparing the milk production obtained with lucerne hay of different cuts with the addition of 0.65 kg. mixed grains per cow and per day for each kg. of butter (water-free), per week, that the hay of the second cut is quite equal to the later crops, although not so readily eaten by the stock. Table II shows the value of the different crops of lucerne for dairy cows.

TABLE II — *Value of the different cuts of lucerne  
as a feed for dairy cows*

Costs.	Nutritive units	Butter (water free) produced	Butter per 100 nutritive units
1st	6 381	319 kg	5.00 kg.
2nd	5 828	312	5.36
3rd	6 410	307	4.78

*Value of succulent feeds* — The average of two experiments made in winter with lots containing 6 cows, showed that the value of sugar-beets as regards milk production is only 14 % of that of lucerne hay. Sugar-beets and beet pulp are almost of the same value as a feed for dairy cows.

A slight increase in the butter-fat content of the milk was observed on feeding beets, or pulp, to the cows, but the milk yield and butter production were not perceptibly changed.

*Value of grazing.* — 16 cows were studied for periods varying from 1 to 4 years, with a view to ascertaining the effect of grazing on yield. The passage from dry feeds to the early spring grass greatly increased the milk and butter production and raised the fat content of the milk slightly, for a short time. These effects were more noticeable in the case of cows

at the beginning of their lactation, than in that of animals whose lactation period was far advanced. The lactation of cows stall-fed with grass was longer than that of cows at grass. The change from dry fodder to green fodder did not effect the production of stall-fed animals as much as that of those grazing in the open: 14 grazing cows that were given grains produced 911 kg. of milk and 36 kg. of butter in 108 days, as against 831 kg. and 33.1 kg. produced by cows receiving no supplementary ration. The lactation of the first set of cows being longer, it appears that a *small* ration of grains is advantageous to cows at grass. Cows put out at grass for a short time first lost weight, but afterwards this was regained.

*Food-capacity of the cow and production.* — The cows eating the most were without exception the most productive and the most economical. Cows differing only from one another to the extent of 90-136 kg. or less, showed no certain proportion between production and weight. An inferior cow consumes in proportion to its production more food than a good cow.

*Variations in milk production.* — With the advance of the lactation period, the milk yield of cows decreased about 9 % per month. It has been found that if the amount of butter produced daily about the 6th month of lactation, is multiplied by the number of days the lactation period lasts, a very close approximation to the annual butter production is obtained.

*Value of recording production.* — The records of 26 herds of dairy cows at Richmond (Utah) for a biennial period ending in 1913, proved that the difference between the annual production of butter (water-free) of the best and of the worst cow of a herd ranged from 18 to 148 kg. There is no correlation between the production of the 3 first months and the annual production. There is a decrease in yield when the cow remains dry for more or less than two months. A dairy cow of a good breed shows a marked tendency to long lactation; she is as superior to a poor cow, in annual butter production as in butter production during the first month. Cows calving in the autumn produced during the 12 first consecutive months over 20 kg. more butter than those calving in spring. Although the cost of feeding the former was higher, the average profit per head was 4 10 dollars more than in the case of the cows that calved in spring.

Table III gives a summary of these comparisons.

TABLE III. — *Comparison between the best and the worst herd.*

		The best herd	The worst herd
Annual milk production . . . . .	kg.	4 397	2 232
Annual butter production . . . . .	kg.	149.9	89.4
Cost of feed per annum (1). . . . .	fr.	229.01	177.29
Profit on cow (difference between the value of the milk and the cost of feeding). . . . .	fr.	362.57	174.18

*Skim milk for the feeding of calves.* — Experiments lasting 4 years proved that if properly fed, calves can very well be reared on skim milk. Calves so reared do not increase as much in weight as those given whole milk. The amount of dry matter consumed per kg. of increased weight was practically the same in either case, but when skim milk was given, the rapidity of the increase was only 70 to 80 % as compared with the effect of whole milk. Up to the age of 3 ½ months, calves required less milk and less dry matter per kg. of increased weight than was needed by pigs.

When however the calves were 5-6 months old, they ate a larger amount of dry matter (chiefly in the form of hay), than pigs.

**DAIRY INDUSTRY: BUTTER-MAKING.** — *Skimming milk.* — When a centrifugal separator was used, the loss of butter (water-free) was 2.7, 8.1 and 15.4 kg. according to whether the milk was in shallow or deep bowls respectively. Cold milk and a slow movement of the separator hinder the maximum output, which is obtained at 29-30° C, and by setting the speed prescribed for each type of machine. When milk is set in pans, the skimming operation is performed most satisfactorily the shallower the pan and the cooler the dairy. The temperature of the milk should be kept at 1° C or lower.

*Churning.* — Under average conditions, a cream with 30 % butter-fat can be churned at a lower temperature and more profitably than a cream containing less fat. A higher fat content is sometimes a hindrance owing to the greater adhesiveness of the cream, which tends to stick to the sides of the churn instead of forming butter. Under ordinary conditions, from 0.4 to 0.64 % of acidity has little effect on the result of churning.

**CHEESE-MAKING.** — *Effect of the quality of the milk.* — Better cheese can be made from good milk than from milk of poor quality; 2.52 kg. of fresh cheese per kg. of butter-fat can be made from milk containing 4.8 % of fat, while as much as 2.84 kg. of cheese per kg. of fat can be made from milk with a butter-fat content of 3.4 %. The average obtained was 11.31 kg. of cheese per 100 kg. of milk, or 2.77 kg. per kilogram of butter-fat in the milk. The fat lost in the whey was on an average 0.15 % whatever the fat content of the milk might be.

*Loss of weight during ripening.* — The cheese lost 6.9 % in weight in 1 month and 9.3 % the 6 following months.

*The best temperatures.* — The best temperature for the milk at the time of adding the rennet was found to be 30° C. Ripening the cheese at 18° C and at lower temperatures, had little effect upon its loss of weight. The smell of cheese seems to be affected by the temperature of the vat during the process of cheese-making.

*Paraffined cheese.* — When the pressed cheese was stamped and put into paraffined boxes containing from 2.6 kg. to 13.6 kg., the losses in weight during ripening were lower, and less handling was required; the cost of production was, however, increased from 11 to 34 centimes per kg. During the first 90 days, the paraffined and unparaffined cheeses lost in weight, 5.5 and 8.6 % of their respective weight. Both paraffined and

unparaffined cheeses did best when kept in cold rooms, instead of in ordinary cellars.

**PIG FEEDING.** — *Value of green food* — Pigs eating green food increase more in weight than those that are given none, and they need much less grain to make 1 kg. of live weight. Lucerne is an excellent supplementary forage to feed with grains, but it is too coarse and bulky to be given alone to pigs and does not provide them with sufficient nourishment.

The addition of lucerne to other feeds produced little increase in the weight of the animals.

*Importance of exercise.* — Pigs turned out on to 7 hectares of good meadow land cropped with 8 species of forage, lucerne forming at least one half, grew more rapidly and needed less grains per kg. of increase in live weight, than those of any other group. Pigs weighing about 34 kg., kept feeding in small moveable pens, grew more slowly and required a greater quantity of grains to produce 1 kg. of live weight, than the animals allowed to range at will.

The exercise alone increased the weight of the pigs and the amount of food consumed, while it decreased the quantity necessary for producing 1 kg. of live weight. The results obtained from grazing supplemented by grains were slightly better than from grass fed in a trough, or the farmyard.

*Amount of grains* — As regards the amount of grains necessary for 100 kg. increase in live-weight, the lot of pigs at grass which were given  $\frac{1}{4}$  the whole grains ration were superior to all the others used in the experiment. They needed less food and increased more in weight. A grains ration consisting of wheat bran + maize meal + crushed wheat was a little more effective in increasing live-weight when fed dry rather than moist, but the amount required to obtain 1 kg. increase in live weight was less when the ration was moistened.

*Comparison between different grains* — In the case of pigs from 11 to 19 weeks old, and in experiments lasting 5 months, it was found that more rapid and economical gains were made by the lots given equal parts of peas and bran. Next in order came the mixture wheat + wheat bran followed in descending order by: maize + wheat-bran, barley + wheat-bran. The amounts of the 4 mixtures consumed to obtain 1 kg. of weight were respectively 3.63; 4.02; 4.55 and 4.62 kg., the daily increases in live weight per head being 495 — 313 — 286 — 254 gm. per pig. Other experiments showed that wheat is the best food for pig-raising, both as regards speed and economy in live-weight gains. The nutritive value of maize and barley is about equal, but rather quicker increases in live weight are obtained with the latter. Peas + wheat bran proved a little more satisfactory than the mixture barley + bran.

*Size of pigs and cost of increase in live-weight.* — The amount of grains required per 1 kg. of increase in live-weight was larger as the pigs grew heavier. Animals weighing 34 to 45 kg., when kept entirely on grains, needed on an average 3.79 kg. of grains for 1 kg. increase in live-weight,

while pigs weighing 68 to 91 kg. required 2.4 kg. and those weighing 113 to 136 kg., required 3.24 kg.

*Effect of previous feeding.* — The lots of pigs given a preliminary course of half-rations of grains and grazed on lucerne, increased in live weight more quickly and economically than those previously fed on skim milk. The addition of a small quantity of grains during the preliminary period, decreased the expense and increased the live-weight gain of the pigs given skim milk and turned out to grass during the second period.

*Value of skim milk.* — In an experiment lasting 108 days, 11 young pigs fed exclusively on skim milk increased in weight much more slowly than the others (309 gm per head and per day), and suffered in their general health. With skim milk alone, 33 kg were required to obtain 1 kg. increase in live-weight; with grains alone, 4.70 kg were necessary. If mixed, 7.7 kg of skim milk and 2.92 kg of grains were required. Skim milk is more suitable for very young pigs than for older animals.

Pigs kept in the sty, or in the field, increased in live-weight with practically the same rapidity and consumed the same amount of grains + skim milk to produce 1 kg of live weight (2.18 kg of grains + 18.3 kg. of skim milk in the former case and 2.36 kg grains + 15.4 kg skim milk in the latter).

• *Proportion between skim milk and grains.* — In fattening pigs (for 76 days), the average daily increases in live weight were highest (735 gm per head) when the skim milk was fed in the proportion of 5 times the weight of the grains, than when larger amounts were given (650 gm increase), or when grains alone were given (305 gm. increase). In the case of older animals, the best proportion was 1 kg of grains per 3 kg, or less, of skim milk. In all cases the youngest pigs increased in weight more rapidly than the older animals.

*Comparison between whole milk and skim milk* — As compared with skim milk, whole milk can be used to replace double the grains in a ration of milk and grains. The addition of grains to whole milk nearly doubles the nutritive value of the latter.

*Succulent Foods.* — For pig-feeding, apples have little more value than an equal weight of grass. It required 4.08 kg of apples + 2.08 kg. sharps + 4.17 kg. skim milk to produce 1 kg. increase in live weight, as against 2.55 kg of sharps + 3.5 kg of skim milk in a ration without apples. Forage silage is of no use to pigs. The addition of roots to a basal ration of grains decreased the rate of the increase in live weight and lowered the dressing yield: 3.9 kg of roots are required to replace 1 kg. of grains.

*Molasses and sugar-beets as a feed.* — A ration of skim milk + sharps + molasses given to pigs feeding on lucerne, increased the live-weight 513 gm per head and per day. Without the skim milk, the gain was 327 gm and without milk or molasses, it was only 227 gm. For pigs that have not the run of a meadow, molasses is a very economical feed. Molasses can well replace an equal weight of sharps.

*SHEEP FEEDING* — *The nutritive value of certain kinds of grains.* — Lambs given lucerne as a bulky feed made the following increases in live

weight per head: wheat grain 52 gm.; whole wheat meal 50 gm.; grains + wheat bran; 54 gm straw + grains 47 gm. In order to produce 1 kg.

TABLE IV. — *Lamb feeding experiments.*

Ration	Daily increase in live weight per head gm.	Kg. of food consumed to produce 1 kg. increase in weight				
		Lucerne	Grains	Pulp	Molasses	Dry matter
Lucerne hay + grains . . . . .	99	6.35	2.69	—	—	8.04
Hay + bran + molasses . . . . .	91	8.10	1.50	—	1.42	9.52
Hay + pulp <i>ad lib</i> . . . . .	94	7.97	—	17.86	—	8.00
Hay + limited ration of pulp . . . . .	60	12.53	—	15.17	—	11.89
Hay + pulp <i>ad lib.</i> + grains . . . . .	150	4.23	1.56	10.14	—	5.13
Hay + limited ration of pulp + grains	97	6.45	2.39	9.45	—	8.37

increase in live weight, the lot fed with grains ate nearly double the amount consumed by the lot given straw + grains, but the latter ate the largest quantity of bulky feed (13.43 kg lucerne hay + 0.81 kg straw), and the lot having grains ate the least (8.47 kg. lucerne hay). The cost of production was lowest in the case of the lot given straw + grains and highest in that of the lot fed whole wheat meal.

The best ration for fattening lambs was lucerne hay + mixed grains, or lucerne hay + grains with or without beet pulp. Table IV gives a summary of the results of a 78 days' experiment with 17 lambs per lot.

*Rations containing pulp* — In an experiment lasting 107 days, with 16 sheep in each group it was found that the lowest daily gains in weight were made and the largest quantities of dry matter consumed when the ration consisted only of lucerne hay + pulp, although if grains were also added, the daily gain was still further reduced. The results of this experiment are given in Table V.

TABLE V. — *Experiments in Sheep Feeding.*

Lucerne ration	Bran and sharps ration	Pulp ration	Increase in weight per head and per day gm.	Kg. of foods consumed to make 1 kg. increase in weight			
				Lucerne	Sharps and bran	Pulp	Dry matter
whole	whole	0	73	6.5	5.5	—	10.49
whole	0	whole	32	16.6	—	36.7	18.06
whole	whole	whole	91	5.3	4.7	11.2	9.77
whole	$\frac{1}{2}$	whole	86	5.9	2.5	11.8	8.50
$\frac{1}{2}$	whole	whole	73	3.7	5.9	15.1	9.78

*Value of roots.* — Although the dressing loss was greater when roots were added to the rations, the sheep increased more in live weight during the fortnight's experiment when 921 kg. of roots were given in the place of 86 kg. of grains + 175 kg. of hay. An increase in weight of 82 gm. per head and per day was made during 112 days by sheep fed only 1.3 kg. of roots + 0.34 kg. of grain.

*Comparison between different forages* — In the experiments without supplementary feeds, it was found that lucerne hay is a much more satisfactory forage than meadow hay or timothy grass hay. Meadow grass hay fattens sheep better than timothy grass hay. Less increase in weight was obtained from forage silage added to a ration of grains + hay than from dry maize forage.

*Shelter.* — Sheep kept in the stalls increased more in weight than those in the sheds.

*HORSE FEEDING* — *Comparison between lucerne and timothy grass.* — Draught-horses fed lucerne hay maintained their live weight more easily, ate more bulky feeding stuffs and were in better condition than those given timothy grass hay. The former drank more, but the amount of water consumed per unit of dry matter was larger in the case of the horses fed on timothy grass hay. Resting horses were kept in good condition when receiving 9 kg. of lucerne per head and per day, but 15 kg. were required when the animals were working hard. Not more than 9 kg. of lucerne hay should however be given to horses engaged in heavy work, the rest of the ration ought to consist of grains.

*Value of chopped hay* — Chopping hay and mixing it with grains was not found satisfactory and even proved injurious in the case of timothy grass hay, owing to the irritation produced in the mucous membrane of the mouth. Finely chopped lucerne or clover on the other hand gave excellent results.

*Comparison between different grains.* — The live-weight of horses is not so well maintained in summer with a ration of maize + timothy grass as with oats + wheat + clover. During the winter, the value of both rations was practically equal. In spring and summer, maize is a better supplement than oats to a ration of mixed hay + wheat or bran. Sharps and bran can be advantageously used in place of oats, if they are fed with lucerne hay, or timothy grass hay. Grains fed to horses should not be ground.

*Amount of grains.* — Moderate rations of grains were relatively more effective than larger rations, but horses, like cattle, thrive well on relatively large quantities of grains. In summer horses eat smaller quantities of grains in proportion to hay than they do in winter.

*Composition of the ration.* — A small quantity of protein (about 127 gm. per head and per day), proves as beneficial with horses as double that amount. The nutritive ratio as 1 : 15 was as satisfactory as a much closer ratio. In the case of horses, the value of foods seems to depend more on the number of calories than on any other factor. There also seems to be a direct connection between the digestible matter of a forage and its nutritive value.

*Watering.* — The best time for watering horses is immediately before meals. Horses that drink before they eat have larger appetites.

*Moist beetroot pulp as a food.* — Up to 9 kg. of pulp can be fed to horses per head daily without any apparent ill effects. In a ration of lucerne hay + oats, 9 kg. of pulp take the place of 1.5 kg. of oats.

*Use of cover-cloths.* — It is not advisable to cover horses in the stable at night, even in the coldest part of the winter.

**POULTRY REARING.** — *Registration of production.* — The use of trap-nests can be superseded by external palpation which enables 99.5 % of the eggs being registered with certainty (1).

*Annual food consumption.* — The annual food consumption per fowl was : Leghorn 34 kg. (25 kg. of dry matter) ; Wyandotte 45 kg ; Plymouth Rock 50 kg. The hens reached their maximum weight just before the chief laying period, during which they lost weight.

*Advantage of exercise.* — The results were obtained with Barred Rock and White Plymouth Rock fowls by giving them a scratch food, but this was of no advantage in the case of Leghorns. Young fowls that were allowed plenty of exercise laid more and heavier eggs, with a higher percentage of fertility, than the hens confined in a run.

*Average egg-production (2).* — The study of all the available records of single combed Leghorns has shown that fowls of this breed lay until their 6th year. Their average production is about 130 eggs the first year ; 120 the second ; 110 the third ; 85 the fourth, and decreases by 10 for every successive year until the eighth.

In a flock of good layers, the hens producing a large number of eggs the first year continue to be prolific until their second, or third year. The largest number of eggs is however generally not laid the first season. In fact, nearly all the fowls of a flock of very high egg production at the Experiment Station of Utah, were mediocre or bad layers the first year, hence the real index of the value of a hen is its egg production during the 3 first years of egg-laying. Most long-living hens lay over 500 eggs ; the majority produce over 600, while some hens lay 800, or even more.

*Selection based on egg-production.* — The total egg production of a flock during the first 3 years appears to average about the same as its production the first year, but if the first year is high, the production of the following years is considerably increased by the selection of the best layers. Surrounding conditions have much more effect upon the egg production of a flock during the first year than later, and these factors influence a flock of low production more than one of high production. The egg-laying period of equally good flocks is about the same for each of the first 3 years. The difference in the performance of good and bad layers remains fairly constant throughout the year. If the good and bad layers of the same flock are compared, it is found that the bad layers fall off a little more rapidly in egg production during the second half of the first year

(1) See *R.* April 1919, No. 497. (Ed.)

(2) See *R.* March 1915, No. 310. (Ed.)

and not so quickly the second year. The distribution of egg production does not appear to depend upon age, at all events, not before the hens are 3 years old, but the total production has an influence on distribution quite independently of age. The distribution of production in dual purpose breeds differs from that in the case of laying breeds (Leghorns) in which the maximum production is reached earlier and decreases more gradually.

*Egg-production during winter* — In winter time, egg-laying appears to be influenced by external conditions and varies therefore from one year to another. The larger the number of eggs a fowl lays, the higher is the percentage of those laid in winter. Under normal conditions, pullets lay more eggs in proportion during the winter than are produced by older hens.

*Early hatching* — The date of hatching had no effect upon the 3 years egg production of birds hatched between March and the end of April, but the fowls that began laying last were always poor layers.

*Colour of the eggs* — In the case of breeds laying eggs of variable colour, each hen usually lays eggs of a uniform shade which makes it possible to obtain by selection a breed producing eggs all of the same colour. The colour of the egg-shell is an individual peculiarity, but the colour of the yolk is altered by feeding. Green foods such as the leaves of lucerne, produce a yolk of normal colour, not of a pale shade.

*Size of the eggs* — Great differences were observed in the size of the eggs laid by various breeds, individual variations also existed between hens of the same breed. Adult Leghorn hens laid eggs weighing 55 % more than those of pullets belonging to the same breed. The Barred Plymouth Rock is not inferior to the Leghorn as regards the size of its eggs, but Wyandotte eggs weigh 77 gm more per dozen than Barred Plymouth Rock eggs and Light Brahma eggs are 11.5 % heavier.

*Incubation* — Eggs in an incubator decrease in weight much faster than those under a hen, which shows that they have much more ventilation in the incubator. The large moisture content of the air in the incubator proved also very favourable to hatching out many and heavy chicks. Under conditions of great humidity, the eggs lose 12 % of their weight by evaporation, instead of 14 and 18 % respectively when the surrounding air is fairly moist, or dry. The best results were obtained during the first second and third successive periods of 6 days, by bringing up the moisture to 4 — 5 — 6 % respectively, or with about 15 % moisture during the whole incubation period. The necessary moisture is better supplied by damp sand rather than by free water.

The carbon dioxide content of the air was considerably higher under the hen than inside the incubator, but the amount present in the latter had no effect upon the number of chicks hatched out. The carbon dioxide of the air unites with the water in the egg and softens or dissolves the egg-shell. This is probably one of the principal reasons why the high moisture content of the air in the incubator has such a beneficial effect.

*Ducks.* — To rear ducklings up to the age of 9 weeks it was necessary to give them for every kg of increase in live-weight, 3.02 kg. of grains +

3.02 skim milk + 0.16 kg. meal scrap. When the birds were older, they ate still more.

*Turkeys.* — The quality of the meat is much improved by fattening turkeys in small flocks kept in small enclosures, and feeding them with wheat, and maize, meal mixed to a paste with skim milk, sugar-beets, and green lucerne. The birds should be supplied with plenty of gravel.

604 - **Breeding Morgan Thorough-Breds on Government Farms in the United States.** — REESE, H H, in *U S Department of Agriculture, Department Circular* 199, pp 1-18, figs 13, 1 pl Washington, Nov 1921

HORSES

The specific characters of the Morgan horses, which constitute a national American breed, are well-known. The breed originated about a century ago from a single stallion of exceptional prepotency. In spite of the unusual qualities of this breed, no care has been taken until recently, either by private individuals or the State, to maintain its purity, so that most of the horses are the results of unsuitable crosses and have lost their original qualities.

In 1906, on the initiative of the Ministry of Agriculture and of the Experimentation Station of the State of Vermont, a small lot of stallions and brood-mares were collected for the first time near Burlington; in 1907, these animals, together with some others were transferred to a farm near Weybridge, presented by private individuals to the Government of the Union, and officially known by the name of the "U S Morgan Farm". The farm was subsequently enlarged and now includes about 400 hectares. It is provided with modern and first-class stabling etc., and continues successfully the work of preserving the breed, by collecting together numerous stallions and brood-mares from the different States of the Union.

Systematic breeding has produced a considerable increase in the weight and size of the individual animals, even in the course of a few years, and has succeeded in fixing all the special characters of the breed.

605 - **Trade in Irish Horses.** — *Department of Agriculture and Technical Instruction of Ireland*, Vol XXI, No 3, pp 310-313 Dublin, 1921

Before the War, pure-bred Irish horses were largely reared for hunters and light riding-horses. During the War, the cessation of all hunting, and the fact that a type of heavy animal was necessary for the artillery caused a sudden and considerable drop in the number of light Irish horses sold, and a great rise in the price of the heavy type of agricultural horse. The number of horses in Ireland for each year from 1914 to 1920 was respectively: agricultural horses 393 646; 359 848; 382 271; 389 711; 413 617; 407 748; 399 889; total 619 345; 560 917; 598 978; 597 692; 618 807; 624 501; 624 266; The number of horses exported during those years, not counting those destined for the army, were respectively: 30 940; 17 818; 6 878; 5 602; 20 081; 21 782; 24 824. Thus the exportation of good light horses was resumed at the end of the War. Since 1919, horse-breeding in Ireland has assumed its

pre-War proportions and has been much improved by the Horse Breeding Act of 1918, which came into force in January 1920, and prohibits the use of unlicensed stallions for service.

In a normal year, horses are exported from Ireland to the value of £1 250 000 to £1 650 000. The animals are crosses between a pure-blood Irish stallion and an ordinary mare; according to the type of the mare, the products are hunters or army horses cavalry horses, remounts and artillery horses.

The hunters fetch from £40 to £100 or more; the draught-horses £40 to £50, and good army horses from £30 to £40, or £40 to £50 if from 4 to 5 years old and trained.

During the pre-War period, Irish army horses were exported only to France, Italy, Germany, and Austria, while draught horses were sent to Holland, Belgium and Italy. With the return to normal conditions, these countries have resumed the importation of horses from Ireland and other countries are beginning to follow their example.

During the War, the Irish horse proved a great success, especially the "gunner", or light artillery type. F. D.

#### CATTLE

606 - **Frisian Cattle.** — GAUDOT, G., in *Journal d'Agriculture pratique*, Year 86, No. 12, pp 246-248, figs. 3. Paris, March 25, 1921.

The author gives reproductions of photographs of two fine Frisian cows sent to him by the Frisian Federation of Agriculture, at Lecuwarden, together with an account of the milk yield of the animals at different ages. For the first year, the figures were respectively as follows: duration of lactation at 2 - 9 - 10 years: 323 - 322 - 326 days; milk yield 4540 - 7377 - 8774 kg.; fat 3.46 - 3.35 - 3.05 %; butter production 170 - 267 - 287 kg. For the second year, duration of lactation at 5 and 11 years of age respectively: 330 and 327 days; milk yield 9012 and 9296 kg.; fat: 3.20 and 3.10 %; butter production 310 and 310 kg.

The author gives, in addition, some information respecting stock-breeding in the Province of Frisia.

Meadows cover two-thirds of its surface, only 50 000 hectares, or 15 % of the whole Province is arable land. The meadows occupy clayey tracts, or drained peat bogs, and are some of the most luxuriant in the Netherlands.

Stock-breeding is therefore the chief agricultural industry of Frisia.

The number of cattle is estimated at 300 000 head; this includes 200 000 cows and 100 000 young animals, bulls etc. This herd is composed of the Frisian variety of the Dutch Black Pied breed.

A special Herdbook for the Frisian variety was started in 1879; at the present time 3 500 breeders are members. No cows of bad conformation with poor milk yield, or giving milk with low fat content are registered. The milk yield of each separate cow is tested throughout the whole lactation period at intervals of 15 days at most.

During the summer, the cows are kept in the fields night and day and grass is their only food: in the winter, they are stall-fed and receive

hay as well as a small amount of concentrates, such as cakes, meals etc. They are milked twice in the 24 hours.

The average yield of the lactation period, 330 days at longest, is 4 500 kg. of milk with a fat content amounting to 3.3 %

Owing to the importance of the dairy industry, many pigs are reared. The number of head before the War was about 100 000. Breeding, which had decreased during the years 1917 and 1918 owing to lack of food, especially of cakes, has gradually acquired its former proportions. Two Herdbooks have been started, one for the old native breed and the other for the selected breed. The animals are registered at the stock-breeding Control Stations. The sheep kept are fewer in number than the pigs, they are estimated, before lambing, at about 90 000 head. The Frisian breed of sheep is noted for its milk-yielding capacity. A Flock-book was started in 1908. Sheep are mentioned which at the age of 3 years have given 658 and 734 kg. of milk with a high fat content. F. D.

607 - **The Dual Purpose Shorthorn Breed.** — ИОВЫС, R., in *The Journal of the Ministry of Agriculture*, Vol XXVIII, No 4, pp 302-305 London, 1921

The Dairy Shorthorn for beef and milk production, has been the breed reared by preference, for more than a century, by the small farmers of the United Kingdom; it continues to spread in new countries wherever increasing population necessitates the production of the largest possible amount of human food, a condition of affairs obtaining in the Eastern part of the United States, South America, South Africa, New Zealand, etc

In its own country, this breed has passed through crises threatening its existence. Of these the most serious was at the time when Argentina required beef-producing animals for breeding, which led to the crossing of good dairy Shorthorns with Cruickshank bulls, which are exclusively beef-animals.

Some far-seeing breeders succeeded in persuading the Shorthorn Society to award prizes at the chief Agricultural Shows of the United Kingdom to good Shorthorn milch cows. They subsequently founded the Dairy Shorthorn Association affiliated to the Shorthorn Society. It encouraged the testing of milk yield in herds of pure-bred animals and undertook the publication of the Register of Non-pedigree Dairy Shorthorns, animals whose descendants may gradually acquire the characters required for their registration in the Herdbook of the pure breed.

The Government Live Stock Improvement Schemes, which included prizes offered by the Ministry of Agriculture for the production of superior animals for the market, and special prizes given to Societies testing milk yield, have greatly encouraged the breeding of fine beef bulls, the offspring of excellent milch cows and, at no time has the importance of the dual-purpose animal and the Shorthorn milch cow been better appreciated.

In 1914, the Dairy Shorthorn Association boasted of 214 members, owning 55 herds; 337 milk yields were registered on its books. In 1920, the members had increased to 631, the herds to 332, and the milk yield

entries to 1194. In December 1918, this Association published the first volume of the Register of Non-pedigree Shorthorn Dairy Cows on which about a thousand tested and approved cows are entered as founders. One result has been the increased price of good registered milkers of mixed breed; these animals now realise from £107 to £114. An approved cow may be entered on the Dairy Shorthorn Register when its milk yield has reached 7000 lbs in one year, or 6000 lbs. in two successive years.

**608 - Comparative Study of Maize Silage and Sorghum Silage for Fattening Cattles. —**

I. WILSON, Y. W., and KUHLMAN, A. H., Corn and Millet Silage for Fattening Cattle, in *South Dakota State College of Agriculture and Mechanic Arts, Agricultural Experiment Station, Bulletin No 189*, pp. 205-220 Brookings, 1920 — GOOD, E. S., HORLACHER, L. J., and GRIMES, J. C., A Comparison of Corn Silage and Sorghum Silage for fattening Steers, in *Kentucky Agricultural Experiment Station, Bulletin, 233*, pp 61-89, figs. 8. Lexington, 1921.

I. The report is a description of two experiments in feeding cattle: the first was made with the purpose of comparing the silage of the sweet varieties of maize known as "Rainbow Flint", which are early and glutinous, and "Reed Yellow Dent". The data refer respectively to groups 1-2-3-4. In the second experiment, a comparison is instituted between silaged, ripe, White Dent; unripe, White Dent; and "proso", a variety of sorghum; the data refer to groups 2-3-4, while the first group serves as a control. The groups in the first experiment, which lasted 90 days, from February 1919, were composed of 5 steers each; those of the second, which lasted 120 days from January 1920, each consisted of 4 steers. Table I gives a summary of the most important results. The authors do not advise the use of sweet maize and proso for silage, and consider that green Dent should only be used for this purpose in cases of necessity.

Each steer that was completely fed, that is, given all the food it could consume, received in addition to silage, 1.36 kg. linseed cake extracted by compression.

During the last 3 months of the second experiment, oat straw was placed in the food racks, but the animals ate relatively little of it. Group I of the second experiment received maize grain, linseed cake, and meadow hay. The animals gained 118 kg. per head in live weight, which was more than was gained by the other 3 groups for which it served as a check. The increased weight did not however cover the higher cost of the ration without silage. This group consumed for every gain of 1 kg. in live weight: 3.6 kg. hay + 7.67 kg. maize grain + 1.09 kg. linseed cake + 0.99 kg. oat straw.

II. In the 3 experiments, the steers were fed maize + cottonseed cake + maize silage, or sorghum silage + straw. In one experiment, maize stalks (stover), were added to the ration. In all 3 experiments, the animals that had been given maize silage made a greater increase in live-weight, on an average 109 gm. per head and per day, than

TABLE I. — *Comparison of different kinds of maize silage and proso silage for fattening steers.*

Experi- ment and group	Composition of silage			Average initial weight per head	Daily increase in live-weight per head	Food consumed per kg. increase in live-weight		
	Water	Crude protein	Crude fibre			Silage	Linseed cake	
	%	%	%	kg	kg.	kg.	kg.

(1) Only the last 35 days — (2) The last 90 days. — (3) The last 105 days.

As compared with maize silage, sorghum silage contains less protein and a little more crude fibre, expressed as kg. of dry matter. The five-year average of forage per hectare was 241 quintals of maize silage and 376 quintals of sorghum silage. The amount of maize silage supplied by 1 hectare supplemented by the above-mentioned rations produced 1116 kg. of beef, whereas sorghum silage under the same conditions produced 1532 kg. The chief advantage in substituting sorghum for maize as a forage for silaging lies in the fact that sorghum is more resistant than maize to drought and frost. Taking everything into consideration, the value of sorghum silage (expressed as surface unit), is

92.2 % as compared with maize. At equal weights, the value of sorghum is 72.2 % that of maize silage. F. D.

609 - **Silaged Forages for Milch Cows, in Great Britain.** — I ROBERTSON, G. S. (Queen's University of Belfast) and PITCHER, F. J., Silage for Dairy Cows, in *The Journal of the Ministry of Agriculture*, Vol. XXVIII, No. 6, pp 506-515 London, 1921. — II WHITE, R. G. and ROBERTS, E. J., Silage for Milk Production, *Ibidem*, Vol. XXIX, No. 1, pp 34-37. April 1922.

In districts where the compact soil and scanty rainfall make it difficult to grow roots, the latter can advantageously be replaced as a stock feed by silaged forages. This is the case in Essex, the driest county of Great Britain, which has an annual rainfall of only 490 mm. The authors' experiments were carried out in that county, at Burnham-on-Crouch.

The forage grown there for silage was a mixture of vetch, oats and beans. The silo was made of planks of wood. About 13 tons per hectare of silaged forage were made of which the percentage composition was as follows: Water 70.84; fat 1.43; crude protein 4.86; carbohydrates 10.46; crude fibre 9.32; ash 3.09.

The following were the experimental rations.

A) fed during 91 days in 2 periods: 22.7 kg. of mangels + 4.5 kg. meadow hay + 8.2 kg. chopped oat straw + 1.8 kg. dry brewers' grains + 2.3 kg. concentrates.

B) fed during 81 days in 2 periods: 22.7 kg. silaged forage + 4.5 kg. of hay + 1.8 kg. dry brewers' grains + 1.4 kg. concentrates. The latter consisted of 3 parts decorticated cotton-seed cake + 2 parts bean meal.

Ration A contained about  $\frac{1}{3}$  more dry matter than ration B, and its starch value was higher (7 kg. as against 6.1 kg.). The method of alternate rations was adopted. During the periods when they were fed on mangels (ration A), the 11 cows yielded 3963 kg. of milk; when given silaged forage (ration B), the 11 cows yielded 4028 kg. of milk, therefore silaged forage gives the most satisfactory results from the point of view of production. As a rule, the milk obtained from feeding mangels contained 3.69 % of fat, but when the cows were given silaged forage the fat content rose to 4.60 %. It can thus safely be assumed that silage does not impair the quality of the milk, so that the prejudice shown in some quarters against using the milk of cows fed on such forage is not justified. The milk must be cooled slowly and kept where there is no strong odour of silage; if this is done milk will remain sweet and free from any unpleasant taint.

In the rations used in the experiments, 22.7 kg. of silaged forage replaced 22.7 kg. of mangels + 8.2 kg. of oat straw + 0.9 kg. of concentrates. As regards the latter at all events, the ration containing silage would appear to be more economical.

II. Experiments carried out on two farms near Denbigh (Wales), with 8 cows per lot which were fed with the two experimental rations alternately.

A) 183 kg silaged forage + 27 kg hay + 18 kg oat straw + 36 kg mangels + 09 peanut cake + 14 kg soy-bean cake + 07 kg oats + 035 kg barley,

B) 182 kg mangels + 68 kg hay + 18 kg oat straw + 09 kg peanut cake + 14 kg soy-bean cake + 05 kg barley

The two rations were calculated so as to supply equal quantities of starch values and of protein (57 kg and 123 kg per head and per day respectively) The silage was a mixture of oats and peas

On one farm, the average milk production per head and per day for all the cows was preliminary period 82 kg, ration with silaged forages 81 kg, transition period 69 kg, period with mangels + hay 66 kg, on the other farm 86, 78.5, 76, 76 kg respectively Thus, the milk yield was rather higher with the ration containing silage

610 - Studies made at the Maine Agricultural Station (United States), on the Lactic Secretion of different Breeds of Cattle. — I PEARL, R. GOWEN J W and MINER J R, Studies on Milk Secretion Transmuting Qualities of Jersey Sires for Milk Yield Butter Fat Percentage and Butter Lat in *Maine Agricultural Experiment Station Bulletin*, 281, pp 89 204 figs 3 Orono 1919 — II GOWEN J W Report of Progress on Animal Husbandry Investigations in 1919 *Ibidem Bulletin* 283 pp 49 284 figs 7 1919 — III GOWEN J W Studies in Milk Secretion On the Variations and Correlations of Butter Fat Percentage with Age in Jersey Cattle *Ibidem Bulletin* 84 pp 211 296, 1919 — IV GOWEN J W The Variation of Milk Secretion with Age in Jersey Cattle *Ibidem Bulletin* 286 pp 49 60 1920 — V GOWEN J W The Correlation between the Milk Yield of One Lactation and that of Succeeding Lactations *Ibidem Bulletin* 291 pp 121 132, 1920 — VI GOWEN, J W The Correlation between Butter Fat Percentage of one Lactation and Butter Fat Percentage of succeeding Lactations in Jersey Cattle, *Ibidem Bulletin* 291, pp 145 156, 1920 — VII GOWEN, J W Studies in Milk Secretion On the Influence of Age on Milk Yield and Butter Fat Percentage as determined from the 365 Days Records of Holstein Friesian Cattle, *Ibidem Bulletin* 293 pp 185 196, figs 2 1920 — VIII GOWEN, J W Inheritance in Crosses of Dairy and Beef Breeds of Cattle *Ibidem Bulletin* 295, pp 217 221 1920 — IX GOWEN J W, Report of Progress in Animal Husbandry Investigations in 1920 *Ibidem Bulletin* 299, pp 85 120, figs 7 1921

THE POWER OF JERSEY BULLS FOR THE TRANSMISSION OF GOOD QUALITIES OF MILK YIELD AND BUTTER PRODUCTION — The authors had at their disposal 225 Jersey bulls registered according to their transmitting qualities which had been ascertained in each case by the difference between the production of the animal's daughters and that of their dam Each bull was required to have at least 2 daughters entered on the Registry of Merit on which their dam was also recorded In order to be able to estimate the production, the milk yield was in every case brought up to that of the dam at 8 years of age, and the butter content of the milk when she was 2 years old A sire whose daughters are superior to their dam, both as regards milk yield and butter production is regarded as ranking above a bull, whose daughters are inferior to their dam in both these respects There were 28 "superior" and 40 "inferior" bulls These two groups were the object of the most careful study

It was found that the bulls of the "inferior" group were a little more closely related than those of the others and possessed fewer ancestors that had been imported directly from the Isle of Jersey.

The study of the genealogical tree of these two groups of bulls showed that all animals appearing more than 4 times on the male side, or more than 3 times on the female side of the tree of the "superior" bulls also appeared in the pedigree of bulls with an inferior power of transmission. This proves that the presence of one outstanding animal in the pedigree of a bull is not sufficient to guarantee value as a sire.

The authors have also studied the transmission of qualities from the bull to its male offspring as shown by the production of their daughters.

I. STOCK-BREEDING STUDIES MADE IN 1919 AT THE MAINE AGRICULTURAL STATION. — GOWEN used the Advanced Registry of the Holstein, Guernsey and Jersey breeds in order to determine the correlation between the age of the cows at the time of the milk yield test necessary for their entry on the register and the amount of milk they produced in 365 days. The average age for maximum milk yield was 8 years, 1 month and 13 days for Jerseys, 8 years 4 months and 29 days for Holsteins; 9 years, 8 months and 5 days for Guernseys.

The author examined statistically the registered milk yield of 88 Jersey cows with the object of discovering how far it was possible to determine exactly the milk yield of the first 5 lactation periods of a cow, from her milk yield during any one given lactation period. He took into account only the first 8 months of each lactation period. The results showed that the correlation between the total milk yield of 5 lactation periods and the milk given by a cow at 2 years of age is + 0.74, if the estimate is based on one lactation period; when the cow is older, the correlation is higher.

In the case of Holstein-Frisians, the average correlation coefficient between the yield of the 7 days test period and that of the 365 days period is + 0.57, if the 7 days are included in the 365 days, but it is only 0.55 when they are not so included (1).

(1) Another work on the same subject is W. W. YAPP's, Study of the Relative Reliability of Official Tests of Dairy Cows, in *Illinois Agric. Exp. Station Bulletin*, No. 215, pp. 323-339, figs. 7, 1919. The author institutes a comparison between the official tests (those lasting 7 days) of Holstein cows before entry on the Advanced Registry and those of the "semi-official" test, lasting for one year. In confirmation of the generally accepted opinion that the semi-official test gives an exact measure of the actual annual milk production, the author mentions the data obtained respecting the annual butter yield of 30 cows belonging to the herd of the Illinois University.

This is estimated by the semi-official method (the monthly percentage of the butter fat in the milk being based on that found in the milk of 2 days), was 185.4 kg  $\pm$  3.7, whereas the amount determined in the daily samples taken from the mixed milk of the 30 cows was 188.5 kg  $\pm$  3.7. Allowing for probable error, the difference is negligible.

With the assistance of the Holstein-Frisian Advanced Registry which he used until May 1, 1915, the author made a statistical study of the one year tests and of the 7 days tests. During the former, there was a continual uniform increase in the butter fat percentage, and

An examination of the points accredited by show judges for conformation and for actual milk yield during 365 days proves that frequently no correlation exists between them, although the correlation was negative in only one of the cases investigated by the author. The maximum correlation,  $+0.194$ , is found between the total points accredited and the actual milk yield. The external characters in clearly significant correlation with milk production are: the mammary veins, the size and condition of the udder; the size and shape of the posterior "quarters" of the udder, the shape and size of the body; the general appearance of the cow (1).

Crossing experiments between beef breeds (Aberdeen-Angus) and dairy breeds (Jersey and Holstein-Frisian) show that the low yield of the Aberdeen-Angus is recessive with regards to the higher yield of the Jersey, and the yield of the Jersey is in its turn recessive to the higher yield of the Holstein-Frisian.

III. VARIATIONS AND CORRELATIONS OF BUTTER-FAT PERCENTAGE WITH AGE IN JERSEY COWS — This article has also been published more in detail in *Genetics* Vol. V, No. 3, pp. 249-324, 1920. It is a biometric study of the fat-percentages in the milk during the first 8 months of 1713 lactations of a herd of Jersey cows with very fixed characters. This is the same herd that was employed in the researches described in the following section (IV).

It was found that the percentage of butter fat in milk slightly decreases with age, assuming that this diminution is uniform, this relation may be expressed by the formula:

$$f = 5.332 - 0.0191 x$$

where  $f$  = butter fat content of the milk and  $x$  = the age in years of the cow at the beginning of the lactation. In the case of older animals, the observed averages deviate considerably from the averages calculated according to the above formula, but this is explained by the few cases under consideration.

butter production, during the latter there was a uniform increase in the percentage as long as the weekly yield of butter (water-free) remained between 3.6 kg and 10.9 kg., but the increase was sudden and abnormal when the weekly yield was higher. The average percentage of fat in the weekly tests reached  $3.679 \pm 0.01$ , and in the annual tests, it was  $3.434 \pm 0.006$ . As the probable error is slight, this difference is certainly significant. The percentages obtained from the weekly tests were much more variable than those yielded by the annual tests, the typical variations being respectively  $0.526 \pm 0.007$  and  $0.317 \pm 0.004$ . The correlation between the milk yield during the 7 days test and that of the 365 days test was  $0.702 \pm 0.01$ . The correlation between the percentage of fat in the milk obtained during the 7 days test and the 365 days test was  $0.703 \pm 0.01$ . Although these figures are high, they are not high enough for correlations between two measures of the same product. The author deduces from all these data taken together that the 7 days' test does not give sufficiently satisfactory results to serve as a basis for estimating the annual butter production (Ed.)

(1) See *R* April 1922, No. 455, IV (Ed.)

GOWEN also gives a series of coefficients showing the connection between the percentages of the butter fat percentages of the different lactations taken singly, or in groups. These coefficients are of practical importance, inasmuch as they make it possible to estimate the effect of unfavourable conditions supervening during a given lactation.

IV. THE VARIATION OF MILK SECRETION WITH AGE IN JERSEY COWS. — This work was also published more in detail in *Genetics*, Vol. V, No. 2, pp. 111-188, figs. 9, 1920. It is a biometric study based on the data afforded by 1741 lactations, and the total milk yields for the first 8 months of each lactation of Jersey cows in a herd of which the production has been registered since 1897. The herd has always been kept in a uniform manner, no selection based on performance having been practised.

By the method of least squares the author has obtained the following formula to express the change in milk yield consequent upon age :

$$y = 3357.912 - 99.883 x - 0.487 x^2 + 2596.219 \log. 10 x.$$

where  $y$  is milk yield in pounds and the cow's age in years is  $1.25 + 0.5 x$ .

According to this formula, the age of maximum yield is 7 years and 2.4 months. As similar equations have been successfully used to represent changes due to development, the author suggests that the change in milk yield depending on age is due to the growth of the udder.

V AND VI. — These two articles are respectively summarised in *Bulletin* 286 (see § IV) and in *Bulletin* 284 (see § III).

VII. — ON THE INFLUENCE OF AGE ON MILK YIELD AND BUTTER-FAT PERCENTAGE AS DETERMINED BY THE 365 DAYS RECORDS OF HOLSTEIN-FRISIAN CATTLE. — The author has studied, by the help of the statistical method, the annual milk yield of 2586 cows ascertained for the Holstein-Frisian Advanced Registry. From the data thus obtained he plotted a curve showing the correlation between milk yield and age which may be expressed by the following formula :

$$y = 11351.5 + 873.07 x - 32.225 x^2 + 1548.36 \log. 10 x.$$

where  $y$  is the number of pounds of milk produced annually, and the age, in years, at the beginning of the test is expressed by  $1.25 + 0.5 x$ .

According to this formula, the maximum amount of milk is produced at the age of 8 years, 4 months and 29 days.

The butter-fat percentage of milk seems to decrease uniformly but slightly with the age of the cow. From the data obtained a graph was plotted forming a straight line corresponding with the formula :

$$\text{Percentage of butter-fat in milk} = 3.470 - 0.09 \times \text{age of cow in years.}$$

VIII. INHERITANCE IN CROSSES OF DAIRY AND BEEF BREEDS OF CATTLE (I). — *Transmission of milk production to the first generation.* — Graphic curves are given indicating milk production (corrected so as to apply

(1) This paper is the continuation of the article summarised in *R.* April 1919, No. 488. (Ed.)

to cows of 2 years of age) and the changes taking place in this production in the case of 12 cross-bred cows. Similar data are also given for the dams of these cows and for the potential, assumed milk producing capacity of their sires. These corrections were made according to the methods described in *Bulletin* 293. The author takes the mean milk production of the pure-breed cows as the hypothetical and potential milk production of the bull siring them. The cross-bred cows were: 3 Angus × Guernsey; 2 Jersey × Angus; 2 Jersey × Holstein; 2 Holstein × Guernsey; 1 Angus × Jersey; 1 Angus × Ayrshire; 1 Holstein × Angus. Their production was more or less the same as that of the sire with the highest production. Hence we may conclude that the character of high milk production is incompletely dominant.

*Transmission of butter-fat content of milk to the first generation.* Graphic curves shew the corrected percentages of the fat content of the milk given by the above-mentioned 12 cross-bred cows. The percentage of the milk produced by their dams and the hypothetical potential percentage for their sires are calculated by a method similar to that employed in estimating the hypothetical milk production. As a rule, the butter-fat percentage had a tendency to resemble that of the parent with the lowest butter-fat percentage. There was no sign of this character being sex-linked.

IX. ANIMAL HUSBANDRY INVESTIGATIONS CARRIED OUT IN 1920 AT THE MAINE EXPERIMENT STATION. — This is a report of work that has been summarised in *R.* April 1922, No. 455 (III) (1) and of data published in *Bulletin* 295 and summarised above. It further contains preliminary information regarding other kindred subjects, mostly relating to the physiology of milk production.

In the case of the Holstein-Frisian cows, a comparative study was made of the milk production for 7 days and 365 days respectively. It was found that the first was of great assistance in determining the value of a cow though the second was a more certain criterion of her future performance.

The author states that as milk production and the fat-content of milk vary with the age of the cow, the fat-content should be taken more into account than is done at present when entering cows in the Herd-book. The maximum butter-fat content is found in the milk of cows of about 8 years of age, whereas for admission to the Advanced Registry, the percentage required does not increase for animals above 5 years old. Generally, the conditions of admission are hardest for the youngest cows.

The study of twin births as shown by the Herd-books of the Holstein, Jersey, Guernsey, Shorthorn and Angus breeds in the United States, show that the sires of twin calves are generally younger than the sires of single calves, whereas the dams of twins are usually older than the cows dropping single calves.

The author has finished a study of the milk production of Holstein-Frisian bulls similar to previous studies relating to Guernsey and Jersey

(1) See also *R.* Oct. 1920, No. 1012. (*Ed.*)

cattle He states that the sire of cows with a milk production superior to that of their dams may be slightly more in-bred than the generality of bulls In any case, these results show that in-breeding, such as is usually practised in the case of the United States Holstein-Frisian breed, has no injurious effect so far as milk production is concerned

A Table gives the percentages of butter-fat and of total dry matter in the milk of the various breeds of cattle (1) F. D.

611 - The Period of Lactation as a Factor in the Variation of the Percentage of Fat in Cow's Milk (2). — RAGSDALE A C and TURNER, C W (University of Missouri), in *The Journal of Dairy Science*, Vol V, No 1, pp 22-26, 1 diagram, bibliography, of 6 works Baltimore, January 1922

A connection has often been observed between the period of lactation and the fat content of the milk The authors recall the results of the experiments made on this subject by PINGREE, VAN SLYKE, ECKLES and SHAW, THORNDIKE, and GRLDY (3) and give the results they themselves

(1) See *R* June 1920, No 670 (1d)

(2) Other important studies on the factors affecting the composition of milk, which were also made at the Missouri Experiment Station, are summarised in *R* April 1917, No 347, *R* July 1917, No 651 and *A* April 1918 No 445 *Bulletin* 151 (1917) and *Bulletin* 163 (1919) of this Station published in addition to an account of experiments on the effect produced upon the lactic secretion by the by products of cotton seed (summarised from another source in *R* July 1917 No 651), a description of experiments dealing with 1) the cause of the decrease in the fat of milk due to feeding maize silage with cotton seed cake to cows 2) the effect of the condition of the cow at the time of calving upon the composition of the milk and its fat content The authors (C H ICKLES, L S PARMER, and W W SPRUE) stated that this depressing effect of silaged forage is due to its lactic acid content the same effect was also produced by lucerne hay damped with a solution of lactic acid equivalent to the amount given with maize silage

The last part of the work deals with a cow that was under fed during its second year It yielded milk with about 3% of protein and a little under 3% of fat, the saponification and Reichert-Meissl indices were high and the iodine index was low After 90 days of lactation, the protein in the cow's daily ration was increased from a little over 400 gm to 900 gm approximately This caused a distinct improvement in the animal's physical condition, its live weight increased by some kg as did also the daily milk yield The protein content of the milk rose to 3.5% and the fat content to 5% the character of this fat was normal

In *Bulletin* 163, the same authors study the effect that the condition of the cow at the time of calving exerts upon the composition of the milk and of its fat content When the animal calved in August 1917 it weighed 11 kg more than in the preceding year, and the composition of its milk immediately after calving was quite normal During the two months the cow was fed a ration containing a minimum proportion of protein, the protein and fat percentages were lower than those previously observed The responses to changes in the amount of protein ingested were similar to those noticed in 1916 1917 (Fd)

(3) PINGREE (1916) concludes from a study of the milk yield of 18 cows entered on the Guernsey Advanced Register that the fat content of milk tends to rise during the whole lactation period, but that the increase is more marked during the first 5 months and the last month of lactation VAN SLYKE (1908) states that the fat and protein percentages decrease in the 2nd month of lactation as compared with the first, and then rise steadily until the end of the lactation period, the greatest increase taking place during the 11th and 12th months

obtained from the examination of 3763 samples of milk entered on the Guernsey Advanced Register, 299 entered on the Jersey Register of Merit and 95 entered on the Holstein Advanced Register. The summary of the

*Effect of the period of lactation on the fat percentage of cow's milk.*

Month of lactation	Guernsey	Jersey	Holstein
	Fat percentage	Fat percentage	Fat percentage
	%	%	%
1st . . . . .	4.63	4.98	3.24
2nd . . . . .	4.59	4.82	3.01
3rd . . . . .	4.71	4.88	2.99
4th . . . . .	4.85	5.10	3.02
5th . . . . .	4.97	5.13	3.01
6th . . . . .	5.08	5.26	3.08
7th . . . . .	5.16	5.40	3.11
8th . . . . .	5.22	5.43	3.16
9th . . . . .	5.29	5.50	3.19
10th . . . . .	5.39	5.58	3.27
11th . . . . .	5.49	5.60	3.32
12th . . . . .	5.60	5.73	3.49

results are given in the annexed Table. From them it is seen that under ordinary breeding conditions, and independently of the season and diet, the period of lactation has a distinct effect upon the fat percentage of cows' milk. This percentage decreases considerably from the first to the second month and in certain cases this diminution continues, though to a less marked extent, during three months at least. Later, the fat content gradually increase again, especially during the last month of lactation.

F. O

612 - **Butter Production Records for the different Breeds of Milch Cows in Kansas.** — FITCH, G. B., in *Agricultural Experiment Station, Kansas State Agricultural College, Manhattan, Circular 90*, pp. 32, figs. 13. Manhattan, 1921.

The author gives a short account of the breeding of milch cows in Kansas (935 000 in 1920), and the rules followed by the breeders, especially as regards choice of animals, rations and testing of milk yields. The

A summary of the work of ECCLES and SHAW (1913) is given in R. April 1913, No. 391. According to THORNDIKE (1918), the composition of milk during the different months of lactation tends to deviate from the general average for the whole lactation (brought up to 100), in the following manner: first months 89.6; second, 90.3; third 92.4; fourth 96.5; fifth 97.9, sixth 101.2; seventh 103.2; eighth 103; ninth 104.3; tenth 104.9; eleventh 105.3; twelfth 109.4. GRADY (1917) employed 10 Jerseys and 10 Holsteins in his study of the effect of the period of lactation on milk yield and butter production and on the percentage of fat in the milk. He found that the fat content of milk varies very little during the first four months of lactation, but increases gradually at a later period. (*Ed.*)

cows bred are Jerseys, Guernseys, Ayrshires, Holsteins (Dutch), Brown Swiss and Dairy Shorthorns. The following Table gives their milk yield and butter production for one year

Breed	Name of cow	Milk	Amount of fat in milk	Butter
		kg	%	kg

## SHEEP

613 — **The Herdwick Sheep, a good Breed for poor Mountain Lands.** — REID, E., in *The Journal of the Ministry of Agriculture*, Vol XXVIII, No 6, pp 501 505, London 1921

The author calls attention to the good qualities of this small but very hardy breed of sheep reared exclusively in the fell districts of Cumberland, Westmorland and Lancashire. He describes the animals, gives an account of the methods of breeding them and of their yield and finally discusses the question of their origin, which is probably Scandinavian.

At birth the lambs have a black head, legs and shoulders, the rest of the body being white. Later the dark parts become light grey. The ewes are hornless and a small percentage of the rams either have no horns, or they are rudimentary, 4.5 % in the 570 rams examined by the author.

The instinct which induces these sheep to return, even from very long distances, to the place of their birth and rearing, allows them to be kept in unenclosed fields, where they spend all, or most of the year. Lambing takes place before the end of April, 80 lambs per 100 sheep is regarded as fair, 90 as good, while a proportion of 10 % of twin births is highly satisfactory.

As a rule, the best ewes are kept for the production of pure-bred lambs, but where some extent of valley bottom is available, a certain number of these ewes are crossed with Leicester or Wensleydale rams in order to obtain grey-faced lambs. The Leicester hybrids mature earlier, and the Wensleydale are longer-sided. These lambs are sold to the shepherds of the plain.

The average weight of the carcass of an adult Herdwick ewe is about 5.5 kg. The mutton, especially in the case of four-year-old sheep, is of superior quality to that produced by any other English breed. The wool is coarse, and can be used for making carpets. An average fleece weighs about 4 kg.

All attempts at crossing Herdwick sheep with other breeds, with a

view to improving their wool or increasing their weight, have failed and the hardiness of the breed has to a great extent been lost in the process

**614 - Intensive Feeding of Ewes at Lambing Time and other Means of increasing the Production of Lambs.** — MARSHALL, F R., and POTTS, C G., in *United States Department of Agriculture, Bulletin No 969*, 14 pp Washington, 1921

Flushing, or the intensive feeding of ewes at lambing time, as a means of increasing the number of births and the production of twins has been tried for 5 years on a total of 302 ewes mated on the farm of the Bureau of Animal Industry at Beltsville, Maryland, and on the United States Morgan Horse Farm, at Middleburg, Vermont. On an average, 125 ewes that had not been subjected to intensive feeding produced 128.8 % lambs as against the 146.9 % dropped by 177 ewes that had been flushed. The first lot was put out to grass and given no ration, the second was grazed on richer meadows or else given a supplementary ration consisting respectively of oats, maize + oats, maize + oats + linseed-meal cake (14 5 1), or of maize + oats + linseed-meal cake + bran (4 4 2 1), at the rate of 225 to 340 gm per head and per day. The ewes were pure-bred Southdowns. The results of these experiments confirm the opinion that the number of births depends upon the age of the ewe. In the case of ewes from 2 to 9 years old at the time of lambing, the births were respectively 111.4 — 123.8 — 143.3 — 143.5 — 161.2 — 142.8 — 113.6 — 162.5 %. The number of twins depended on the breed, as is seen by the following data for 1919 to 1920 supplied by the Animal Husbandry Division of the Department of Agriculture of the United States

*Percentage of births in the case of sheep of different breeds  
(Average of 189 flocks)*

Breed	Two-year old ewes	Older ewes	Total number of ewes
Dorset . . . . .	146	163	158
Lincoln . . . . .	145	161	157
Oxford . . . . .	144	156	152
Southdown . . . . .	143	153	151
Hampshire . . . . .	139	148	144
Cotswold . . . . .	135	148	144
Shropshire . . . . .	134	154	149
Tunisian . . . . .	123	149	141
Rambouillet . . . . .	111	125	122

No correlation was observed between the age of the ram at the time of service and the number of twin births. The fact that the parents were not themselves twins appears to make no difference to the number of twins produced by them.

If both the twin lambs are suckled by their dam, they do not attain

the weight of the single lambs, but if each is reared by a separate ewe, they become as heavy or even heavier than the single lambs.

The average weight of ram and ewe lambs at the age of 6 months is 35.7 kg. per head; twin lambs suckled by the same ewe weigh 34.2 kg. and twin lambs each suckled by a different ewe, weigh 36.3 kg.

The largest percentage of twin births is met with in the case of the ewes which are in heat and mated soonest.

In order to produce the greatest number of twins, the ewes showed an increase in weight of at least 3 kg. during the service period.

When full-grown, there is little difference in the size of the young sheep whether twins or not

615 - **The Improved German Pig as a Means of improving Swine in the Province of Gorizia, Italy.** — ALDRIGHETTI, F., in *Bollettino Agrario, Organo dell'Ufficio provinciale e dei Consorzi agrari della Provincia di Gorizia*, Year III, No. 37, pp. 3-4, Gorizia, April 1, 1922

The improved German pig ("deutsches veredeltes Landschwein"), is characterised by its large size, thrift, early maturity, the fine quality of its meat, and its resistance to disease, this latter quality rendering it superior to other more susceptible breeds, such as the Yorkshire. It has been imported into the Province of Gorizia where animals of great weight have been bred, one German sow reared in the province weighed 3 quintals at the age of eighteen months, while another turned the scale at 4.5 quintals when 2 years old. Crossed with the Friulian breed, which is also reared in Gorizia, it produces offspring with such fixed characters that they can justly bear the breed-name and be called "Improved German Pigs." During the War, Gorizia not only lost 20,000 swine, but the quality of the remaining animals greatly deteriorated, for this reason, the author advises the introduction of new blood by means of importing from Germany boars and sows for breeding purposes.

616 - **The Influence of Age upon the Fertility of Sows (1).** — J. L. LINGG, T., in *Proceedings of the National Academy of Sciences of the United States of America*, Vol. VII, No. 5, pp. 134-138, bibliography of 16 works. Washington, 1921

The author carried out experiments in Denmark on 134 sows of the Danish breed and the results were communicated by PEARL to the National Academy of Sciences of the United States. Information as to their last 10 farrows was obtained from entries in the Danish Herdbook, Vols V and VI. All the sows bred and kept in breeding centres under State control under similar conditions, farrowed for the first time when about a year old and produced without any regard to the season, 2  $\frac{1}{4}$  litters annually. Thus, the successive litters should be in strict correlation with the age of the sows.

It seemed advisable to consider the number of young in each farrow,

(1) See R. July 1921, No. 744. (Fd.)

*Real and theoretical number of young per farrow for 10 successive farrows.*

Farrow		Average number of young per farrow (found)	Average number of young per farrow (calculated)
I		II	III
No 1 . . . . .		9.45	9.25
» 2 . . . . .		10.01	10.42
» 3 . . . . .		11.50	11.24
» 4 . . . . .		12.01	11.81
» 5 . . . . .		11.99	12.19
» 6 . . . . .		12.16	12.38
» 7 . . . . .		12.13	12.39
» 8 . . . . .		12.34	12.24
» 9 . . . . .		11.90	11.92
» 10 . . . . .		11.66	11.43
Averages. . . . .		11.52	11.53

which was 11.5 for the 10 successive litters of the 134 sows. The breed is thus very prolific.

By using MINER'S method (1), the author obtained with the help of the data given in this Table, the relation between fertility and age. The general form of the equation is  $y = a + bx + cx^2 + d \log. x$ , in which  $y$  represents the number of animals in the litter, and  $x$  the number of the farrow.

In the case in question, the equation is as follows :

$$y = 8.414 + 0.915x - 0.078x^2 + 1.627 \log. x.$$

The theoretic mean of the number of piglings in the successive litters is obtained by solving the equation and attributing successively to  $x$  the values 1-10. These values are given in column III of the Table.

Taking  $\frac{dy}{dx} = 0$  and finding the value of  $x$ , the largest litter is seen to be 6.56.

F. D.

617 - **Oats as a Pig Feed.** — PERKINS, A. J., in *Journal of Agriculture*, Vol. XXV, No. 5, p. 430. Adelaide, December 15, 1921.

The question whether oats should be fed to pigs depends entirely upon the difference in price between this oats and other pig-feeds, for physiologically it is well suited to pigs, although it is seldom given to them.

Oats ought not, however, to be the sole ration given to the animals, except perhaps in the case of old sows that are to be fattened. When fed to young pigs, they should be mixed with a protein food or combined

(1) MINER, J. R., Plotting Logarithmic Curves by the Method of Moments, in *Journal of Agricultural Research*, Vol. 3. Washington, 1915. (Author's note)

with grazing on leguminosae. The author, who is a Director of Agriculture, recommends the following rations for swine of different ages and sizes.

*For pigs weighing 18 kg.*: 1st ration, crushed oats 900 gm. + skim milk 1130 gm.; 2nd ration, crushed oats 900 gm + Abattoir's pig meal 110 gm.

*For pigs weighing 36 kg* · double the first and the second ration.

If oats are given alone, which is not so advisable, 1 to 2 kg should be fed daily, according to the size of the animals. The oats ought to be crushed, or preferably, covered with as much boiling water as they can absorb and left to soak for one night. They should be given in three meals. The above quantities are for grain of good quality, in the case of inferior qualities, the quantity must be increased in proportion.

*For pigs to be fattened weighing 54 kg.* · oats 2 25 kg + skim milk 3.6 kg.; or else oats 2 25 kg + tankage 0 340 kg

If oats are merely given to supplement grazing, 3 to 4 kg are fed per day, or else as large a quantity as the pig can assimilate, the latter being preferable

#### POULTRY

618 — **Four new Breeds of Fowls.** — I New Breeds seen at the Palace, in *The National Poultry Journal*, Vol II, No 77, p 322 Westminster, November 25, 1921 — II *La Revue avicole*, Year 32, No 2, p 50 Paris, February 1, 1922

At the last Poultry Show held at the Crystal Palace, London, in November 1921, four new breeds of fowls were entered that had never yet appeared at any Show in Europe 1) Black Marias, 2) Jersey Black Giants; 3) Marsh Daisies, 4) Australian Black Orpingtons. Their chief characters were as follows.

*Black Marias* — Shape intermediate between that of the Plymouth Rock and Rhode Island fowl. Single comb, black legs. The hens have black plumage and a hackle with silver-grey markings. The cocks have a black breast, but their necks and backs are silver grey. This breed was obtained in England and is recommended by the breeder for its relatively high general qualities.

*Jersey Black Giants* — This breed comes from the United States. The birds resemble Black Orpingtons, but are less compact, with a heavy frame and large head. The hens are too large to be good layers and seem chiefly adapted to the table.

*Marsh Daisies* — A small breed, slightly larger than the Buttercup or the Sicilian "Bottone d'Oro". Two varieties are to be recognised in future, the Wheaten and the Buff; thus they only differ in colour. This breed does not yet appear to be really fixed.

*Australian Black Orpington.* — A smaller bird than the Orpington and lacking the fine plumage which makes the Orpington such a conspicuous exhibit. The new breed recalls the primitive type of Black Orpington obtained by William Cook. It therefore deserves the attention of poultry breeders who are chiefly concerned with the utilitarian point of view.

F. D.

619 - **The Croad Langshan Breed of Fowl.** — HEAP, A. J. (Bittams Experimental Farm), in *The National Poultry Journal*, Vol. II, No 54, p 22 Westminster, 1921.

The Croad Langshan fowl, which is well-known for its hardiness and table qualities, is occasionally entered at Shows and sometimes appears in laying competitions. This is due to the fact that certain families have been carefully selected by clever breeders, but the bird has never been a general favourite, or widely kept. Its weak point is that it matures slowly. Although it may be said that the hens generally lay about the ninth month, there is great individual variation in this respect which makes it possible to select for quicker maturity. Indeed, Miss SIMMONS, who is engaged in breeding Croad Langshans, has obtained hens that begin laying at 4 ½ months to 6 months, that is to say, even too early, as a pullet is not sufficiently developed at 4 ½ months. The author has also begun selection experiments with this fine breed.

620 - **The Treatment of Contagious Entero-Hepatitis in Turkeys (1) with Ipecacuanha.** — BISSET, N (Midland Agricultural and Dairy College), in *The National Poultry Journal*, Vol II, No 92, p 534 Westminster, March 1, 1922.

The author reports the good results obtained in treating a flock of turkeys suffering from contagious entero-hepatitis, with ipecacuanha as advised by Dr. H. M. WEGFORTH and Dr. PAUL WEGFORTH of San Diego (California) (2). The healthy birds are at once separated from the diseased birds, the which are given 10 drops per head of fluid extract of ipecacuanha, 3 times a day for 3 days, then twice a day for 3 more days, and finally once a day for 3 days. Turkeys which were in good health, but had been in contact with infected birds, were given powdered ipecacuanha, the dose being 1 teaspoonful for every 20 turkeys, given in their food, until the flock showed no further symptoms of disease.

The treatment was completed by the thorough cleansing and disinfection of the poultry-house. F. D.

621 - **Inheritance of Silky Plumage in Fowls. Historic Account and Description of the Sporadic Appearance of Individuals with Silky Plumage among normal Birds and their genetic Relation.** — JONES, S V II in *The Journal of Heredity*. Vol XII, No 3, pp 117-128, figs 10 + tables 2 Washington, 1921

Individual fowls and breeds of poultry characterised by silky plumage have been described by ancient and modern authors amongst whom may certainly be included ALDROVANDI (1597), and perhaps, according to

(1) SMITH described this disease in 1895 under the name of contagious entero-hepatitis, later, it was studied in France by LUCET, who called it perityphlo-hepatitis. In the United States, it is known as "black head", on account of the dark colour assumed by the wart-like excrescences on the head and the wattles of infected turkeys. The disease is caused by *Amoeba meleagridis*, which passes from the intestine into the circulation and the liver, where it induces inflammation that is nearly always accompanied by intestinal inflammation. — A. PRÉSCE, *Le maladie des pouls*, pp 145-149 Milan, Hoepli, 1912. (Ed)

(2) The good results obtained with this method in California have been reported by A. SCHOFIELD, General Manager of the Poultrymen's Milling Association in California — *The National Poultry Journal*, Vol. II, No 66, p 165 London, Sept 9, 1921. (Ed)

DAVENPORT, even MARCO POLO (XIII century). BEECK (1) distinguishes 5 varieties: a) the "Siamese Silky" with red periosteum, red skin on the head, yellow beak and legs, yellowish plumage; b) the "Japanese Silky", with black skin and white plumage; c) the "Silky of Japan" with black skin; the "Chinese Silky" resembling the Siamese in the yellowish colour of its plumage, which is in reality more woolly than silky; e) the Negro Silky with black skin and plumage.

The author's review of different works, for the most part of recent date, shows that the silky plumage characterising the five above-mentioned varieties occurs sporadically in the following breeds that usually have normal feathering: *Cochin*, *Bantam Cochin*, *Rhode Island Red*, *Black Orpington*, *White Rock*, *White Wyandotte*, *Brown Leghorn*, *Grey Brahma*, and *Black Langshan*. No systematic studies have so far been made respecting the genetic behaviour of the plumage of these individuals, but many experiments have been carried out in crossing pure-bred silky individuals and individuals with normal plumage. The results of all these experiments show that silky feathering is recessive and occurs in the simple Mendelian ratio, as regards normal plumage.

The author, having by chance come into possession (1917) of a Brown Leghorn hen (referred to as 1A), with characteristic silky plumage, crossed this bird with a pure-bred White Leghorn cock. In the  $F_1$  generation only 3 individuals attained maturity, one cock and two hens, all of which had normal plumage. In the  $F_2$ , one pair of birds produced 40 individuals, 29 with normal plumage and 11 with silky plumage (theoretical ratio 30:10), while the other pair had only 5 offspring all with normal plumage. The total of 34 normal individuals and 11 silky gives a ratio very near to the theoretic ratio, of 33.75:11.25. In a similar manner, on mating the head fowl of the strain with the only cock of the  $F_1$ , the author obtained 5 normal and 6 silky individuals, equal numbers being expected theoretically. Thus, silky plumage that arises sporadically behaves as a simple Mendelian recessive.

In order to decide whether the sporadic appearance of birds with silky plumage was due to the same factor as that causing silky feathering in the pure breed, the author also made reciprocal crosses between pure Silkies and pure White Leghorns, as well as between the  $F_1$  individuals of these crosses with the  $F_1$  and  $F_2$  individuals resulting from the cross between hen 1A and the White Leghorn cock. The results proved that the character of silky in 1A is genetically the same as in the pure Silky fowl.

Silky plumage has been met with sporadically amongst domestic fowls for many centuries and perhaps dates back to the beginning of their domestication. It is probable therefore that this type of feathering appeared accidentally in the wild ancestors of the domestic fowl and that this character behaves in the same manner in the present wild breeds. It is impossible

(1) BEECK, *Die Federvuchsucht als Wirtschaftsweg und Liebhabererei*, vol. I. Verlag von R. Schmidt, 1908, pp. XIII-1880. (Authors' note)

to determine whether the sporadic cases are due to independent mutation, or are all produced by a single primitive mutation that has been transmitted through successive generations and through the present different varieties.

E. F.

622 - **The respective Influences of Cock and Hen in Egg Production.** — KAUPP, B. F. (North Carolina Experiment Station), in *The National Poultry Journal*, Vol. II, No. 74, p. 279-280. London, November 4, 1921.

Since 1914, the author and his collaborators have been occupied in the selection of poultry with a view to obtaining large egg production. They always used similar poultry-houses, of modern type with open front and tiled roof, and fed the birds on the same food; the only different factor for all the successive generations was the genetic.

**MATING OF ORDINARY FOWLS WITH ORDINARY COCKS** — The initial flock (No. 1), consisted of 90 hens of one year of age, the average number of eggs laid annually during 3 years was 80. On being mated with one-year-old cocks, they produced flock No. 2. No selection had been made in the case of either sex, all the birds were reared without exception, both with the object of studying individual variations, and in order that the conditions should be those obtaining in ordinary poultry-rearing.

In flock No. 1, only 8 hens each laid over 100 eggs during the 3 years of the experiment; only one laid 150, the second place was taken by a hen laying 128.

Flock No. 2, composed of unselected cocks and hens, produced an average of 88 eggs per fowl annually when the birds were in their second year, the three-years average per hen was 92 eggs.

The best layer gave 180 eggs and the second best 154; only two hens laid 150 eggs or more during one of the 3 years.

**MATING ORDINARY HENS WITH SELECTED COCKS** — The second year, the hens of flock No. 1 were mated with 3 cocks (brothers), the performance of their ancestors being as follows: mother laid 207 eggs annually; paternal grandmother 229 eggs, maternal grandmother 175 eggs; pedigree of grandparents unknown (selected during 3 generations). In this way was flock No. 3, obtained was composed of 100 fowls of which 96 had completed their first year. The three years' average of eggs per hen was 135, that is to say, 46 hens, or 48 %, laid 150 eggs or more in a year, and 5 laid 200 or over. It is thus clear that their laying capacity was transmitted by the cock.

**TRANSMISSION OF FERTILITY FROM GRANDFATHER TO FATHER AND FROM FATHER TO DAUGHTER** — Flock No. 4, was obtained by mating flock No. 2, with 3 cocks (brothers). The father of these 3 cocks is one of the three birds whose ancestors' performance is given above; their mother had laid 128 eggs a year. The hens of flock No. 2, like their mothers were not good layers, their three years average being only 92 eggs. The increased fertility of flock No. 4 was therefore undoubtedly due to the influence of the father and the paternal grand-father. During two years of laying, flock No. 4 produced an average of 138 eggs per hen and per year;

the best layer, a hen obtained after 6 years selection, belonged to this flock. This hen laid 232 eggs in one year; 23 hens, or 56 %, laid 150 eggs or over; 11, or 27 % laid 175, and 4 laid over 200 eggs in one year.

**MATING SELECTED HENS WITH SELECTED COCKS.** — Flock No. 5 was obtained by mating the 12 best layers of flock No. 3 with a cock whose paternal grandmother laid 242 eggs annually, his maternal grandmother laying 234. The 12 hens of this flock laid 6129 eggs in 3 years, or 510 each in 3 years, and 170 per hen and per year. The three years' average of the best layer was 223 eggs

Of the hens composing flock No. 5, 46 laid on an average 162.2 eggs; 28, or 60 % 150 or more eggs; 15, or 32 %, laid 175 or more eggs.

*Results obtained in 6 years.*

Ordinary hens (unselected white Leghorns) . . . . .	89 eggs annually
Progeny of ordinary hens × ordinary cocks . . . . .	96 " "
Progeny of ordinary hens × selected cocks . . . . .	135 " "
Progeny of ordinary hens × sons of selected cocks . . . . .	138 " "
Progeny of selected hens × selected cocks . . . . .	163 " "

The capacity of laying a large number of eggs is thus transmitted from mother to son and through the latter to his male and female offspring alike.

If the hens do not belong to a good breed, a large production of eggs is not to be expected, no matter how much attention is given to the feeding of the birds, or the hygiene of the poultry-house, etc; on the other hand if the breed is good, success depends upon observing carefully the rules for rearing and keeping domestic poultry. F. D.

623 - **The Dryden Method of choosing Laying Hens.** — *The National Poultry Journal* Vol II, No 56, p 42 Westminster, 1921

Prof JAMES DRYDEN has devised a method for the classification of hens as good, fair and bad layers. This method is based on the egg production ascertained by the use of trap-nests and by the study of the characters of the fowl.

Hens that cease laying and moult in July-August are not good layers, the same may be said of pullets laying few eggs their first year; such birds will not improve later and are therefore better eliminated.

Should nest-traps not be available, omission of laying is shown by: 1) shrivelling of the comb, wattles and auricles; 2) the narrow pelvis; 3) the contraction or induration of the abdomen; 4) in breeds having naturally yellow skin and legs, like the Leghorns and Plymouth Rocks, the brilliant hue of the legs and beak show that the hen has not laid for some weeks; 5) moulting.

In July, August and the beginning of September all fowls should be weeded out that: a) are in an advanced stage of moulting, the comb

and wattles being shrivelled ; *b*) have a contracted abdomen, or dry and wrinkled cloaca ; *c*) have yellow legs and beak. As a rule, symptom *a* is sufficient guide, but it is sometimes necessary to find it combined with *b*, in order to be quite certain ; *c* alone is not enough and this symptom must be associated with either *a* or *b*.

By adopting this method it is possible to reduce by 20 % a flock of average fowls without lessening the egg production.

The better the feeding and general conditions, the more certain are the results obtained, for scarcity of food or a change in diet or environment may cause laying to cease, and make even a good layer begin to moult.

If it is desired to make a still more rigorous selection and to keep only fowls able to lay 200 eggs a year, hens must be chosen, from October 15 to November 15, which have not completed moulting, and possess : 1) bright red wattles and comb, and quick eyes ; 2) very broad pelvic bones, and elastic caruncle and abdomen ; 3) pale legs, beak and cloaca, if the breed is one in which the skin and legs are naturally yellow. The present higher price of food renders the rigorous selection of the best laying hens more necessary and more profitable than before the War.

624 - **The Duck as an Egg-Layer.** — PINARD, V, *La Production des œufs de canes in La Revue avicole*, Year 32 No 5, pp 155 156 Paris, May 1, 1922 - The National Laying Test in *The National Poultry Journal* Vol II, No 99, p 639 Westminster, April 28, 1922

The value of the duck as a great egg layer capable of producing as many and even more, than the fowl, has only been clearly shown of recent years.

The results of the first egg-laying competition for ducks which took place in 1920-1921, at Bentley, England, and lasted for 48 weeks dating from October 22, are given in the following Table :

No. of ducks at begin- ning	Ducks that died	Breed	Eggs laid		Totals	Average
			size 1	size 2		
115	4	White Indian Runner	16 774	48	16 822	148.52
70	2	Brown Runner . . .	11 493	60	11 553	168.11
10	0	Magpie . . . . .	1 543	4	1 547	154.70
15	0	Buff Orpington . . . .	2 538	10	2 548	169.85
10	2	Khaki Campbell . . .	1 987	8	1 995	204.49
220	8	<i>Totals . . .</i>	34 335	130	34 465	
		Eggs laid out of nest .	229	1	230	
			34 564	131	34 695	160.24

The lot of 5 Khaki Campbell ranks first with 1211 eggs, or an average of 242. The second place was allotted to a group of brown and white

Runners with 1075 eggs. The duck that had laid most eggs (269), was a White Indian Runner. 26 ducks laid more than 200 eggs.

The Khaki Campbells take their name from a lady who bred them, at Uley, Gloucestershire. They are the result of crossing Runners, Rouens and Orpingtons. The fact that there is also Runner blood in the two latter breeds explains why both are celebrated for large egg production.

In the competition of 1921-1922, which began on October 21 and is still in progress, all the competitors belonging to the Coaley Fawn, Khaki Campbell, Orpington and White and Fawn Runner breeds laid a great number of eggs, the average being 75.73 per head for the 20 winter months.

#### BFF-KFFPING

625 - **Bee-Keeping in Rhodesia** (1). — ROSS, J. W. in *The British Bee Journal* Vol. 4, No. 2072, pp. 106-107. London, 1 March 1922.

The author alludes to the prevalence of wild bees in Rhodesia and describes his successful attempts at keeping and breeding them in a systematic manner.

The native bee much resembles the black bee of Scotland, but swarms without forming a cluster. The insect is very active and is a good honey maker and defends its hive with much energy. It is, however, very aggressive and is not affected by smoke. If disturbed during the day the insect becomes furious and stings everyone in the vicinity, and in consequence bee-keeping operations can be carried out only towards sunset. No bee disease is known in Rhodesia. The importation of queen-bees, wax, etc. is prohibited by Government.

F D

626 - **Experimental Centre in the Shetland Isles for rearing the Pure-Bred, Black, Scottish Bee.** — *The British Bee Journal* Vol. XLIX, No. 2058, p. 563. London, December 1, 1921.

In view of the great difficulty in obtaining a pure breed of the native black bee, the Scottish Board of Agriculture has installed an apiary in the Shetland Isles, far from any other centre of bee-keeping. Experiments are being made there, and it is hoped that the Shetlands will in time become a breeding centre for the supply of pure-bred, vigorous queen-bees.

627 - **The Melilot as Honey-Bearing Plants.** — CHAPMAN, P. W., in *The British Bee Journal*, Vol. 4, No. 2064, pp. 10-11. London, January 12, 1922.

The Melilot (*Melilotus Officinalis* with yellow flowers, *M. alba* with white flowers, and the variety recently isolated in the United States called Hubam clover, which is characterised by its extraordinary growth), are much valued as useful forage plants that will grow on any type of soil. The author has grown Hubam clover as an experiment at Wykeham Ranch, Enderby, British Columbia. This plant was sown on April 1, and on July 15 had attained the height of 1.20 m., it was at that date in full flower. Towards

(1) See R. February 1922, No. 195 (Ed.)

2) See R. April 1922, No. 415 (Fd.)

the end of September, it had grown to 2.40 m and was still in flower and loaded with seed, having experienced no bad effects from the first light frosts

The flowers were continually visited by bees F D

628 - **Bee Diseases in Michigan.** — KILTY, B H, in *Agricultural Experiment Station Michigan, Agricultural College, Special Bulletin No 107*, 16 pp, figs 5 East Lansing, 1921

This article gives a brief account, intended for the use of practical bee-keepers and the general public, of the diseases to which bees are subject and of the best means for their control. The following diseases are studied: American foulbrood due to *Bacillus larvae*; European foulbrood caused by *B. pluton*; sac-brood, an infectious disease of the larvae due to a filtrate virus; nosema disease produced by *Nosema apis*; dysentery, spring dwindling (high mortality occurring in the spring in old hives that have passed the winter under bad conditions), paralysis, Isle of Wight Disease (1) F D

629 - **The Rearing of Reindeer in Canada (2).** — WARSON, T A in *The Agricultural Gazette of Canada*, Vol IX No 2 pp 93-96 figs 2 Ottawa March-April 1922

VARIOUS  
ANIMALS

Towards the end of October 1921, a herd of some 600 Norwegian domestic reindeer, was landed at Amadnak (Baffin Island). The consignment had been sent by the Hudson Bay Reindeer Co., who intended to despatch more of these animals in order to establish reindeer depôts at various places in the territory of North Canada where they are to be reared for the butcher. Reindeer seem very suitable for breeding in large numbers in the great unproductive tracts of North Canada. They can be employed as draught animals and thus supply a need that has hitherto prevented the exploitation of these regions.

Many successful attempts have already been made in the same direction. In 1898, reindeer were introduced by the United States into the Yukon territory, and later into Alaska F D

## FARM ENGINEERING

630 - **Co-operative Societies for the Use of Machinery and Materials used in Mechanical Tillages, for the assistance of German Agriculture.** — SCHWANECKE, in *Deutsche Landw. Presse*, No 60, pp 444-445 Berlin, 30th July, 1921, No. 61 pp 452-453, Aug 3 1921, No 62, p 453, Aug 6 1921

AGRICULTURAL  
MACHINERY  
AND  
IMPLEMENTS

Even before the war agricultural specialists agreed that the product from the soil could be increased without much effort.

In the present state of things it becomes a duty to increase production, but this will be attained by individual effort only in exceptional cases.

Table I compares the working expenses and capital required for a farm

(1) See R July 1921, No 748; R April 1922, No 463 (Ed)

(2) See R Oct 1913, No 1185, R Oct 1914, No 931 (Fd)

of 400 hectares (of which 56 % is under cereals, 18 % under root-crops, 13 % under vegetables and fodder crops, 10 % under pasture and 3 % fallow)

ical traction ploughs, things have not improved during the war. The high price of machinery at present render its extended use very difficult. In Table III a comparison is made between the prices of machinery, coal, oil and other accessories in 1914 and 1920.

In spite of the high price of machinery, every farmer can use it extensively thanks to the cooperative society. It is especially advantageous in the case of special machinery or that used in extensive production, as, for instance, mechanical traction ploughs, threshing-machines, provincial railways, etc.

Simple machinery and that in ordinary use, such as horse-ploughs, harrows, rollers, clod-crushers, etc. may be acquired by each farmer. The other machines: fertilising, seed-drill, binders, but especially horse-ploughs, steam-threshers, live-stock weighing-machines, provincial railways, etc. will be used advantageously by co-operative societies.

The author compares the cost-price of the work done by several machines on a farm of 20 hectares and on one of 400 ha.; from which he concludes that for small farms it is necessary to co-operate for the use of machinery.

The author especially deals with co-operative societies for the use of threshing-machines and of mechanical traction ploughs. Up to the 1st January, 1919, 667 societies were registered in Germany for the use of threshing-machines and mechanical traction machinery and ploughs.

Benzol, per 100 kg. . . . .	22.00	550.00
Lubricating liquids, per 100. kg. . . . .	50.00	1 500.00
Garniture, per kg. . . . .	1.10	22.00
Driving-belts . . . . .	8.00	320.00
Electric current per HP per hour, for power . . . . .	0.18	1.35
Electric light current per HP per hour . . . . .	0.50	2.85

The threshing-societies have been established longer than the other. The steam-ploughing associations come next, their number in 1919 being 52.

Ploughing by mechanical traction, tractor, or motor-plough, has scarcely developed under the form of co-operative societies, for the first results were not very satisfactory. The author attributes this to lack of organisation and defective exploitation; and considers that the societies might succeed if established on a sound and firm basis and managed by a capable staff.

632 - **Apparatus for extracting Oily Matter by Ethyl Trichloride.** — BONNET, J (Professor of oleoculture at Marseilles), in *Bulletin trimestriel de l'Office régional agricole du Midi*, No 1, pp 11-23. Marseilles, January 1922

The author uses non-inflammable, incombustible and inexplusive ethyl trichloride. He gives the characteristic qualities of this products and its current market price. As it is sensitive to light it should always be stored in metal receptacles underground, care being taken to cover it with a layer of water 0.25 m. to 0.40 m. to prevent evaporation.

On being brought into contact with a substance containing oil when the substance is almost dry and at a favourable temperature, the ethyl trichloride after two or three hours absorbs all the oil contained in the substance.

The mixture of oil and solvent is conveyed into an apparatus called the « distiller », into which dry, superheated steam is introduced; the trichloride distils at 85° and, after passing through a refrigerator, is collected in a receptacle intended for that purpose. When the oil has been extracted from the substance, the latter is subjected to a jet of steam which drives out the remaining solvent, all of which is thus recovered.

The oil is collected from below.

The process is simple and may be carried out by one operator.

The apparatus includes: 1) a fruit-stone crusher (2 toothed rollers); 2) a dryer; 3) a boiler of 15 to 20 sq. m. capacity to supply the steam; 4) two extractors of 500 to 600 kg. each. the substance is placed on a grating covered with a thick mesh and is fed from above; underneath is an opening for ejecting the waste substance; 5) the distiller with its accessories (levels, projectors, etc.); 6) a multiple refrigerator connected with the 2 extractors and the distiller. As soon as one of the extractors is full, the solvent is introduced; the other extractor will not be filled with solvent until the oil has been extracted from the substances in the first.

After 2 to 3 hours, fresh solvent is introduced into the first extractor. This, being denser than the mixture of oil and solvent, forces the latter into the distiller, steam is brought into action and the distiller is then emptied; it will be refilled from the extractor while the process of extraction is going on in the latter. Fresh solvent is then introduced into the first extractor and the solvent is driven into extractor No. 2; in this way, any oil still remaining in the substance cannot be lost. The solvent in contact with the exhausted substance is ejected directly into the solvent receptacle.

To recover the traces of solvent in extractor No. 1, it is connected with the boiler; the steam carries off all the trichloride remaining. At the same time, the operation already described recommences with extractor No. 2.

The apparatus (1) can extract oil from 2500 to 3000 kg. of matter per day, the loss of solvent being 15 litres per 3000 kg. 2 HP are necessary for the solvent pump, the crusher and the dryer. The apparatus is strongly put together and can be placed anywhere. It may be used equally well for extracting oil from olive-stones as from grape-seeds. In the latter case a seed crusher is necessary.

633 - **Relation between the Nitrogenous Substances in Barley and the Value of Barley in Brewing.** — HULTON, H. E., in *The Institute of Brewing, Research Scheme*, v XXVIII, supp to No 1, pp 33-112, Bibliography London, 1922.

Critical review of the scientific literature extant on the question of the nitrogenous substances in barley as related to its value in brewing from the following points of view :

- 1) Connection between the percentage of nitrogen and the size of the grain ;
- 2) Connection between this percentage and the quantity of extract of malt ;
- 3) Connection between this percentage and the nature of the extract of malt ;
- 4) To what extent is the presence of nitrogenous matter in barley connected with the properties of this cereal for brewing ?
- 5) Up to what point is the nature of nitrogenous matter related to the value of barley as raw material used in brewing ?

In summarising the results arrived at in this review, the following points become evident

*Factors which contribute to the production of barley containing a high percentage of nitrogen* ripening too quickly or too slowly ; warm, dry season ; sowing too thinly, resulting in insufficient root competition soil too rich or heavy ; excessive use of nitrogenous fertilisers, separate or mixed ; large, heavy grain ; genetic character of richness in nitrogen. Some of these factors may be eliminated, others, such as those dependent on the weather, for instance, cannot be avoided.

*Properties usually inherent in barley containing a high percentage of nitrogen.* abundant shoots ; small quantity of extract of malt ; defective ripening ; grain hard ; weight per volume low ; tendency to heating and heavy loss during malting ; slowness in malting ; high percentage of nitrogen in the malt produced high percentage of non-coagulating proteins in the must ; tendency of the beer after brewing to be cloudy ; tendency to permanent froth on the beer ; low proportion of grain as compared with straw.

All these characteristics, are, generally speaking, undesirable, and might justify one in taking as a criterion, the nitrogen content of barley when estimating its value, and this rather from the malster's than the brewer's point of view. But the method to be followed in cultivation is that of selection after determining

- 1) The desirable qualities in barley for malting and brewing ;
- 2) which among these qualities are definitely mendelian, so as to permit of selection by means of pure growths and by crossing.

In any case, all research on this subject should be directed towards quantity of output

G. A. B.

634 - **Utilisation of Tobacco Waste in the Manufacture of Nicotine Extracts and for Fertilising Purposes. Experiments in South Africa.** — SMIT, [B J, in *Journal of the Department of Agriculture, Union of South Africa*, Vol IV, No 3, pp 267-271. Pretoria, March 1922

At the present time, tobacco growers in South Africa are much concerned with the profitable disposal of their crops and have consequently turned their attention to the question of the utilisation of tobacco waste i. e. tobacco unsuitable for pipe and cigarette.

The author has made a series of detailed analyses of 36 samples of tobacco obtained from different localities, and the tables demonstrate the percentages of nicotine content and fertiliser constituents covering a wide range, also the quantity of tobacco required per gallon of extract and the value of the fertilisers per ton.

The analysis shows that the nicotine content in the air-dried samples varies from 0.41 % (lowest grade Vredefort) to 5.98 % (strong good leaf Nelspruit), with an average value for the 36 samples of 2.52 %, and from the fertilising standpoint, the potash content varies from 0.15 to 7.36 % (light Vredefort leaf) light strength, average 4.66 % 2nd crop Piet Retief

From the analyses taken as a whole the following interesting deductions have been made

One gallon of tobacco extract with specific gravity 1.35 weighs 13.5 lb and contains 1.08 lb nicotine. In order to obtain say 1.08 lb from a sample containing 2.20 % nicotine, 49.09 lb of tobacco will be required and at 3d a lb the cost of tobacco will be 12s 3d. The cost of extraction increases as the nicotine content of the tobacco decreases. For instance with extract containing 7 1/2 % nicotine, retailed at from 26s. 6d. to 28s. 6d. per gallon the cost of tobacco varied from 2s. 5d., (requiring 38.3 lb. per gall. of extract) to as much as 48s. 6d. (requiring 77.1 lb. per gall.) This calculation is based on the assumption that all the nicotine in the tobacco is removed, although in practice, allowance should be made for the small quantity which probably remains in the leaves.

With regard to the fertilising value of tobacco waste, it is considered that this material should prove to be of excellent value to such crops as potatoes, the potash content is exceptionally high. It will be necessary, however, to establish a new process of extract manufacture, as at present the extraction of the nicotine with hot water, results in the removal of most of the fertiliser constituents and the residue has little value. It should be considered, however, that the tobacco plant removes comparatively large amounts of plant nutrients from the soil (100 lb. potash, 50 lb. nitrogen and 6 lb. phosphoric oxide), and whenever possible, therefore, it is distinctly advisable to utilise the tobacco offal on the land. The analyses of the samples taken show the advantage attached to this proceeding and an economically sound solution as to the extraction of nicotine without detriment to the plant constituents would undoubtedly prove of great benefit to tobacco growers. An analysis was made of a sample of tobacco before and after extraction by the present hot water method, and the loss is striking viz. potash 93.3 %, phosphoric oxide 53.6 and nitrogen 20.3 %.

It would certainly be unwise to grow the plant solely for use as a fertiliser, but the information furnished with regard to the evident value attached to the offal, combined with the analyses recorded, throw light on a question having an important bearing on the industry. M. L. V.

635 - **Some Factors affecting the Quality of ripe Olives sterilised at high Temperatures.** — CRUESS, W. V., in *College of Agriculture Agricultural Experiment Station, Berkeley, California, Bulletin No. 333*, pp. 221-230, figs. 2. Berkeley, Oct. 1921.

At the beginning of the olive canning season in California (1920-21) it was found that the olives had become softened and had acquired a disagreeable scorched flavour as a result of sterilisation at 240-250° F. There was a distinct variation in behaviour in different cases. The investigations reported were undertaken in an attempt to determine the causes of the observed differences and extended over two canning seasons.

From the experiments conducted, it was concluded that the development of scorched flavour, bitter almond odour, and excessive softening was due to a certain extent to insufficient lye treatment or excess alkali in the fruit. It was found, however, that properly pickled olives retain their superior qualities when sterilised at 240° F for 60 minutes. The California State Board of Health has recently inaugurated a regulation demanding that this method be adopted. Rapid chilling of the can and contents to room temperature immediately after sterilisation is considered desirable in order to prevent prolonged action of the heat. On the other hand about 10 % of the fruit softened to a marked degree when heated at 250° F for 40-60 min. and to 240° F for 60 min., and olives heated to 250° F for 15, 30, 40 and 60 min. and to 240° F for 30-60 min. had a marked scorched flavour. However, after one month's storage the scorched flavour appeared to be greatly diminished.

The Manzanillo olive especially when very ripe was more subject to damage in flavour and texture at 240° F than the Mission, Sevillano and Ascolano varieties. Brine of 5 % salt (20° salometer) is recommended for shipment purposes, and one of 10 % salt (40° salometer) for conservation in the factory for long periods. Long storage in dilute brine should be avoided, although it appears that storage in strong brine for several days followed by canning in very dilute brine or water, makes the texture of the fruit more resistant.

Olives retained their colour more satisfactorily in lacquered cans than in plain tin cans which had a distinct tendency to bleach the fruit.

Acidification of the brines is not advised as it causes more serious changes in the quality than occur when the non-acidified pickled fruit is sterilised at 240° F for 60 minutes. M. L. V.

636 - **Rubber Latex for Paper Making.** — KAYE, I. (College of Technology, Manchester) in *The Rubber Age*, Vol. II, No. 9, p. 465, and Vol. III, No. 2, pp. 67-68. London, Nov. 1921, and April 1922.

The possibilities of the utilisation of rubber latex for the manufacture of paper has aroused considerable interest. The author has invented a process for mixing the latex as it comes from the tree with the pulp from

which paper is made, and has experimented with several kinds of fibre, the results indicating that the hydration of fibre is modified and stimulated by the action of the latex. Both the material condition and physical qualities of the fibres are improved and strengthened.

After thoroughly mixing the latex with the pulp, which may be done in the beater, a coagulative agent is then added (acetic acid, formic acid, etc. may be used). The nature and quantity of this agent will vary with the nature of the latex employed. Following the coagulation, the ordinary system of paper making is adopted.

According to reports received, a very satisfactory paper has been manufactured by this process, using the latex of *Hevea brasiliensis*, and containing from 0.5 % to 5 % of rubber to the weight of dried paper ; much more resinous latices have been successfully used to produce papers for special purposes, containing as much as 10 % coagulative material. As the quality of the paper is evidently improved by this process, the time of beating, may, in many cases, be considerably shortened, thus reducing the cost of manufacture.

An interesting table gives comparisons of papers produced from fibres without and with rubber latex. Amongst the list are noted :

Fibra	Without latex		With latex	
	Folding resistance	Bursting strength	Folding resistance	Bursting strength
		lb.		lb.
Cotton waste . . . . .	220	31	1 300	40
Cotton linters fibre . . . . .	99	30	6 625	53
Sisal hemp . . . . .	700	32	8 000	40
Id. . . . .	927	41	3 100	52
Manilla hemp (old rope) . . . . .	726	41	24 000	60
Jute (waste) . . . . .	330	30	2 125	54
Waste flax . . . . .	38	25	800	40

Bursting strength = lb. per sq. inch. calculated to a thickness of 0.1 mm.

The rubber does not appear to have any deleterious effect upon the colour of the finished material. Experiments with cotton linen, bleached, sulphite, bleached esparto, bleached straw, and bleached bamboo have proved this statement. In addition to this, the texture is improved. It has been found also that paper containing rubber latex is rendered more waterproof, and is likely to prove very suitable for loading purposes. Experiments are being conducted in this respect. In any case it appears certain that latex paper will be valuable for many purposes.

As regards the economic value and costs attached to this process, the practical commercial experiments made up till the present have shown that the labour costs etc. are negligible. Till the latex is more or less standardised on the plantations, the amount of rubber in the latex in each

delivery can be determined by pouring a limited quantity of the latex into methylated spirit or acetone and then drying and weighing the solid coagulum. The actual cost of latex will naturally be controlled by the current price of rubber, freightage, etc. but it is estimated that the cost of the latex for a paper to contain 0.5 % of rubber would be 12 to 18s. per ton of paper made.

By using very strong fibres, such as Manila hemp, sisal hemp, jute, etc. and using higher percentages of rubber, say up to 20 % or more, the author considers that products can be made to take the place of leather for many purposes. Linoleum substitutes can be made cheaply and abundantly on a paper making machine by using mechanical wood, waste paper and various other fibres, with loading material and increasing the quantity of rubber latex. Recent experiments have shown also that many kinds of asbestos goods, such as high pressure packing can be made more cheaply.

Experiments on a commercial scale have been made already in certain paper mills in England and further tests are to be made shortly with a view to the importation and utilisation in the near future of large supplies of latex for use in the paper industry

- 637 - **Investigations on Milking Machines: their Efficacy, Advantages in Labour Saving, and their Sterilisation.** — I WOLL, F W, Investigations with Milking Machines, in *California University Agricultural Experiment Station, Bulletin*, 311, pp. 31-34, 3 fig., Berkeley, 1919 — II RIDDFI, F F, Machine versus Hand Milking, in *Michigan Agricultural Experiment Station, Quarterly Bulletin*, v 1, No 1, pp 163-164 East Lansing, 1919 — III BRADFORD, R S, Methods of Caring for Milking Machine Tubes, in *Journal of Dairy Science*, v V, No 1, pp 102-109, bibliography of 15 works Baltimore, Jan 1922

I — EFFICACY OF MILKING MACHINES — Part of the herd of the "College of Agriculture" of the California University was milked by hand and a part by machine and on correcting the figures of the actual yield so as to make them correspond to that given entirely by 5 year old cows, 153 kg  $29 \pm 3.68$  was shown as the average annual production of butter for cows milked by machine and 160.07  $\pm 4.67$  for those milked by hand.

As the probable error in calculation, must have been comparatively great, the difference cannot be attributed to methods of milking.

The correction of the figures of the actual yield was made by increasing the yield by cows of less than 2  $\frac{1}{2}$  years at the beginning of the milking period, by 30 % ; that of cows between 2  $\frac{1}{2}$  and 3 years by 24 % ; and for each successive increase in age of 6 months by progressively decreasing percentages (18 — 15 — 8 — 5).

II. — LABOUR EMPLOYED IN MACHINE, AS COMPARED WITH THAT IN HAND MILKING — The data relating to the labour required in hand and in machine milking are taken from 93 farms in the Michigan districts where the condensed milk industry is very important. These data are summarised in the annexed Table

*Labour needed for machine as compared with that for hand milking*

	Number of herds	Average number of cows per herd	Work per cow per year			Work per quintal of milk		
			Milking	Care of milk and utensils	Total	Milking	Care of milk and utensils	Total
			hours	hours	hours	hours	hours	hours
<i>Machine milking:</i>								
Average for all the herds . . . . .	51	18.2	57.9	13.4	71.3	2.11	0.46	2.57
Average for the herds containing up to 15 cows. . . . .	17	13.1	65.2	14.7	79.9	2.30	0.48	2.78
Average for the herds of more than 15 cows . . . . .	34	20.8	55.6	13.0	68.6	2.05	0.46	2.51
and Milking: All the herds . . . . .	42	13.6	89.2	11.2	100.4	2.78	0.35	3.13

III — STERILISATION OF THE MILKING MACHINES — Owing to the fact that those who use mechanical milkers often do not know exactly how to sterilise them, and the neglect of the makers to give instructions on this subject for the machines they sell, large quantities of milk have been produced in the United States containing an excessive number of micro organisms. Partly for this reason and partly on account of the return to the country of more abundant labour, hand milking is again competing seriously with machine milking in the States.

It has been absolutely proved that the chief source of the bacterial contamination of milk is the dairy utensils with which it is brought into direct contact (1). The best means of avoiding this is to carry out thorough sterilisation of all parts of the apparatus. These methods have been proposed, *a*) by heat; *b*) by chemical agents; *c*) by cooling.

The first is very efficacious, provided it is done with boiling water or steam, but has the disadvantage of spoiling the rubber parts of the ma-

(1) M. Y. PRUCHA and H. A. HARDING (Elimination of Germs from Dairy Utensils (1) by Rinsing; (2) by Drying in Sun and Air, in *Illinois Agricultural Experiment Station Bulletin* 230, pp 139-168, Urbana, 1920) have proved by experiment that the chief causes of the bacterial contamination of milk are the dairy utensils and not the air, the construction of the stable, or the way in which the ordinary work of the stable and the dairy is carried out. Washing the cans in hot water and drying them in the sun bottom upward is a very effectual means of destroying germs especially when done by machinery. A hot solution of soda quickly loses its germicidal power through neutralisation and cooling, if passed from one can to the other. — J. J. HOOPER and J. W. NUTTER (The Production of Cream Milk at the Kentucky Agricultural Experiment Station, in *Kentucky Agric. Exp. Sta. Circular*, 24, 15 pp 12 fig Lexington, 1920) report that at the Kentucky Agricultural Experiment Station unboiled milk containing only a very small number of bacteria has been produced and sold, by means of: cooling the milk just taken from the cow, carefully sterilising the utensils after washing and again before using them; simple, but not primitive apparatus, and the elimination of milk coming from inflamed mammals. (Ed.)

chine. This has been remedied by making rubber tubes which remain unharmed by this mode of sterilisation, but only with partial success as regards those parts which must necessarily be "estampées" of solid material.

As chemical agents the following have been suggested : A solution of boric acid, slaked lime, formaldehyde, a solution of common salt, soap powder, etc. It has been observed that the most effective of these is common salt, but it has the disadvantage of corroding certain metallic parts. RUEHLE, BREED and SMITH (*New York Agricultural Experiment Station, Bulletin* 450, 198) have proved that the micro-organisms which live in brine cannot thrive in milk and vice-versa. WING (*Cornell University Agricultural Experiment Station, Circular* 18, 1913) has proved that brine can be easily and efficaciously sterilised by the addition of hypochlorite ; the mixture, solution of common salt + hypochlorite, therefore, will be found to be a really effective means of chemically sterilising those parts of the milking machine which are not proof against heat.

The third method has been used with success by several breeders of New York State, where cold springs abound. It is rather a preventive measure, and consists in rinsing, between two milkings, the tubes and receptacles of the milking machine by passing cold water through and over them. To be effective, the water should be at a temperature below 10° C.

Y., 1919. — IV. CUSICK, J. T., Phosphorus in Butter, *Ibid*, *Memoir* 30, pp. 159-187, 1920. — V. HEPBURN, N. W., A Modified BABCOCK, Method for Determining Fat in Butter, *Ibid*; *Memoir* 37, pp. 669-690, 1920. — VI. SUPPLEE, G. C. and BELLIS, B., Fat Analysis of Milk Powder in *Journal of Dairy Science*, v V, No. 1, pp. 39-50, bibliogr. of 8 works. Baltimore, Jan. 1922.

I. — **THE PRESERVATION OF MILK FOR CHEMICAL ANALYSES.** — Detailed investigation as to the effect of various factors on the preservation of milk for chemical analyses ; it treats of : quality and quantity of the preservative ; temperature during preservation, development of micro-organisms before the addition of the preservative ; quantity of air in contact with the milk ; relative importance of bacteria and enzymes in the decomposition of milk ; minimum quantity of best preservative to use.

Of the antiseptics tested (formaldehyde, corrosive sublimate, bichromate of potassium, sulphate of copper, thymol, toluol), formaldehyde is the best because it causes the fewest alterations in the milk constituents. The author has devised the following method, which permits of the milk being preserved unaltered for analysis for several weeks.

Carefully stir the sample of milk which has just been taken from the

cow ; measure out exactly 1 litre and then to 1.5 to 2 cm of formalin (containing approximately 40 % of formaldehyde), place in a bottle, preferably sealed, sufficient to fill about  $\frac{9}{10}$  of the bottle ; cool rapidly to 8-10° C or under and keep the milk at this temperature until it is analysed.

II. — THE CHEMISTRY OF CHURNING — The microscopic examination of butter made from cream coloured with Sudan III and fuchsin confirms FISCHER's theory that churning is the transformation of an emulsion of fatty matter contained in a hydrated colloid (cream) into an emulsion of hydrated colloid contained in fatty matter (butter)

III — THE LECITHIN CONTENT OF BUTTER AND ITS POSSIBLE RELATIONSHIP TO THE FISHY FLAVOUR — If trimethylamine be added to cream or to butter before preparation, the butter when made has a fishy flavour (See R. Sept 1913, No 1087) In commercial butters having a fishy flavour, the author has noticed (by means of a special micro-reaction) the presence of trimethylamine The hypothesis that the characteristic flavour caused by this alteration is due to the presence of trimethylamine arising from the decomposition of lecithin is therefore correct The presence of the latter has been observed by the author and by J T CUSICK

In order to ascertain the biological conditions which produce the fishy flavour, samples of cream are inoculated with micro-organisms isolated from butter having a fishy flavour, especially when *Bacterium ichtyosmius* Hammer or some other micro-organism not identified had been inoculated *B. ichtyosmius* decomposes the choline (a lecithinic base) and sets free trimethylamine. The action of specific bacteria is therefore sufficient, if not necessary, to produce trimethylamine in butter

IV. — PHOSPHORUS IN BUTTER — The pasteurisation of cream renders the organic components of phosphorus more soluble, so that they are lost in churning This loss (in freshly made butter) is greater in the case of ripe creams than in that of fresh creams, whether pasteurized or not. After storage for 15 months the greater part of the soluble organic phosphorus is transformed into inorganic phosphorus. Butters made from ripe cream, pasteurised or otherwise, had a tendency to retain more soluble organic phosphorus than the others About  $\frac{2}{3}$  of the total amount of phosphorus in the cream remains in the buttermilk and only 25 % passes into the butter ; the difference is lost in the water used in washing and in that which drains from the salted butter.

V. — A MODIFIED BABCOCK METHOD FOR DETERMINING FAT IN BUTTER — HEPBURN has compared the BABCOCK container for samples of 6 gm and that for samples of 9 gm for determining fat in butter. The difference observed in the results thus obtained is slight and quite negligible in practice. For this reason the author advises the use of a container for 9 gm. on the grounds of convenience.

VI. — FAT ANALYSIS OF MILK POWDER. — The Association of Official Agricultural Chemists has not yet indicated an official method for determining fat in milk powder. The ROESE-GOTTLIEB method however, is generally considered to be the best for this purpose, though numerous

modifications of existing methods have been proposed SUPPLEE and BELLIS have submitted several to comparative tests and have obtained results from which they draw the following conclusions

1) Normal variations in results obtained should not exceed 15 % of the powder analysed

2) The diminution of fat content ( % of the powder analysed) in old powders is only apparent it is due to moisture absorbed by them

3) The method by simple extraction with ether gives results 25 % inferior, on an average, to those obtained with the ROESE-GOTTLIEB (MO-JONNIER) method

4) The RIMMOND modification of the BABCOCK method by centrifuging, does not give reliable results

5) The ROESL-GOTTLIEB method modified by making the extraction with an acid instead of an alkaline medium generally gives better results

I - RELATION BETWEEN LACTIC ACID PRODUCTION AND BACTERIAL GROWTHS IN THE SOURING OF MILK - Two samples of pasteurized skimmed milk containing a small number of bacteria, and from the same cow, were

(1) See I H ECKHART, Valuable Bulletins and Circulars for the Dairy Farmer and the Manufacturer of Dairy Products in *University of Minnesota, Agricultural Extension Division, Spec Circular* 2, 4 pp St Paul, 1919 - Bibliogr including especially the works of the Department of Agriculture and Agricultural Experiment Stations in the United States (Ed)

inoculated each with a different culture of *Streptococcus lacticus* and incubated at 25° C. The estimations of sourness and the bacterial count were performed at half hour or one hour intervals 15 hours after inoculation. In one case there was approximately the expected increase in the number of bacteria (double for each generation) but in the others the speed of multiplication was much slower and remained fairly constant during the whole period of systematic observation. The quantity of acid produced was approximately in proportion to the number of bacteria present. In a vigorous culture a single cell produced 5, 10- and  $10^{10} \times 10^{-10}$  milligrams of lactic acid per hour.

II — THE ACCURACY OF BACTERIAL COUNTS FROM MILK SAMPLES — By means of 3 parallel series of bacteriological analyses of milk the authors have observed a close agreement between the number of isolated groups of micro-organisms (clumps) of one or several species counted directly under the microscope or on the agar plate.

In the isolated groups the average number of individuals generally varied between 2 and 6 but sometimes when there were streptococci it was much higher.

The bacterial count on the plate does not represent the total number of bacteria present in the isolated groups of micro-organisms (clumps) are very incompletely broken up in the process usually employed for diluting liquids.

III — THE LACTIC ACID BACTERIA — Monograph in which the cultural character and source of energy and food used by the species in question are especially shown. It is based on 10 year work and on the culture of 330 stocks isolated from milk and dairy products, excrements and vegetable matter.

The lactic acid bacteria are considered by the author to be a group of non-motile rod-shaped or spherical forms producing no spores, gram positive, deprived of catalase and which ferment producing chiefly lactic acid. The dextrorotary or levorotary optic activity constitute an important diagnostic character as the optic properties are not influenced by the quality of the sugar fermented. Five genera (*Thermobacterium*, *Streptobacterium*, *Betabacterium*, *Streptococcus* and *Betacoccus*) comprising 22 species, are known to be true bacteria producing lactic acid, and two genera (*Microbacterium* and *Tetracoccus*) are very analogous forms.

The true lactic acid bacteria are incapable of decomposing amino acids not in combination and comparatively few have a marked proteolytic action. The coccus which decomposes casein, does this slowly and forms peptones, these are then broken down into amino-acids, but the rod-like forms which decompose casein set free the mono-amino acids from the casein molecule without a preliminary formation of peptone. From the peptones, the lactic acid bacteria form a quantity of polypeptides which are not precipitated by phosphotungstic acid.

The author observed that a number of lactic acid bacteria, if cultivated in milk, produce, especially at a low temperature a saliva, due to the swelling of the capsules, more or less distinct, which surround the cells.

at certain phases of the culture *Streptococcus cremoris* (a new name), which is the typical micro-organism of the starter, *i. e.*, the inoculation cultures used in making butter, also produceropy milk. The best stocks of *S. cremoris* for making butter have, it seems, the lowest power to ferment saccharose, maltose and dextrin.

The author, as an experiment made some cheeses with milk practically germ-free and inoculated with pure cultures of lactic acid bacteria. In every case putrid fermentation was greatly reduced.

*Streptobacterium casei* (= *Bacterium casei* α) was the most satisfactory when high temperatures were not used in the process of making the cheeses. The second place is held by *Streptococcus lactis* (= *S. lacticus*) and the third by *L. cremoris*. *Tetracoccus liquefaciens* (= *Micrococcus casei liquefaciens*) renders the cheese rather soft and imparts to it an odour and flavour similar to those of Swiss cheese and cheese from the Russian steppes. The value of *Thermobacterium helveticum* (= *Bacterium casei* ε) is confirmed for cooked cheeses.

IV — NOTES ON ABNORMAL EVAPORATED MILK — A description of the morphological, cultural and biochemical characters of *Bacillus amarus*, a new micro-organism isolated from evaporated milk having a bitter flavour and abnormal odour. Evaporated sterilised milk, inoculated with this bacillus curdles after some months and the bacillus almost entirely disappears.

V — NOTES ON FORMATION OF GAS IN SWEETENED CONDENSED MILK — A sweetened condensed milk after the closing of the tins, undergoes gaseous fermentation. A new yeast *Torula lactis-condensi*, has been isolated from it and observed to be the cause of this alteration.

VI — THE VOLATILE ACID PRODUCTION OF STARTERS AND ORGANISMS ISOLATED FROM MILK — None of the micro-organisms isolated from a "starter" and cultivated in milk produce strong acidity, whereas the mixed cultures of *Bacterium lactis acidum* and some of these micro-organisms (incapable alone of curdling the milk) produce a volatile acidity approximately equal to the characteristic acidity of good "starters." It must be concluded that the combined action of the micro-organisms present in the "starter" is necessary to obtain the desired volatile acidity.

VII — BACTERIOLOGICAL RESULTS OBTAINED IN PRACTICE WITH MILK PASTEURISED BEFORE AND AFTER BOTTLING — Milk sterilised after bottling gave a smaller number of samples with a high percentage of bacteria than milk sterilised in the vat and then bottled.

VIII — RESEARCH IN DAIRY PRODUCTS AT THE WISCONSIN AGRICULTURAL EXPERIMENTAL STATION — Cheddar cheese made with sterilised milk has no flavour. To remedy this defect, E. G. HASTINGS and J. L. SAMMIS have used a special "starter" containing, besides lactic acid bacteria, micro-organisms isolated from the ground and from excrements.

H. H. SOMMER has observed that milk sufficiently acid to be capable of titration, does not imply that it will curdle after sterilisation, condensed milk factories therefore have no reason for refusing very acid milk.

Curdling is principally due to an excess of soluble salts of calcium and the tendency to curdle may easily be corrected by the addition of the proper citrates or phosphates

**IX — EFFECT OF ENZYMES AND MICRO-ORGANISMS ON THE KEEPING QUALITY OF BUTTER** — As a result of researches made at the Minnesota Agricultural Experiment Station 1) butter made from cream pasteurized at 80° C (a temperature which destroys the enzymes) keeps better than that made from the same cream heated to the ordinary temperature of 63° C (enzymes still active), 2) by placing a small quantity of "starter" in the churn, butter made from fresh cream has a better odour and flavour than that obtained by the old system of letting the cream ripen in the pan before churning

**X and XI — EXPERIMENTS ON DAIRY PRODUCTS MADE AT THE CALIFORNIA AGRICULTURAL EXPERIMENT STATION (I) — L. S. DENNING** has observed that butter cut into blocks weighing 900 gm wrapped in parchment paper, covered with a solution at 20 % of common salt and kept at 10° C were still in a good state of preservation after 8 months

The following conclusions arrived at on the use and bacterial composition of the "starter" are chiefly based on the works of A. S. BAIRD

1) The use of a "starter" containing *Bacillus bulgaricus* produces a thin cheese of good quality from skimmed milk,

2) Pasteurised milk ripened with *B. bulgaricus* produces a rather firm Cheddar cheese,

3) A pure culture of *B. bulgaricus* used as a 'starter' is more effective than a culture of *Streptococcus lacticus* (*B. lactis acidus*) for preventing gaseous fermentation in cow-paste cheese ("California cheese"), but the odour and flavour are not uniform

Regarding researches on the possible substitutes for rennet, it was observed that pepsin makes a tough cheese, and thus, it seems, should be attributed to the fact that, to cause curdling, pepsin needs more acidity than rennet. A mixture of equal parts of pepsin and rennet, on the other hand gives satisfactory results

II. S. BAIRD has investigated the use of 'starters' for making Cheddar cheese from pasteurised milk, he has observed that no culture

---

(1) Other interesting studies, described in the 1920 Report, deal with the keeping of milk and butter — C. L. ROADHOUSE and J. C. MARQUARDT have examined milk kept in refrigerators cooled by a current of water and have observed that bottled and pasteurized milk can be kept in them without becoming sour for at least 24 hours. Of these refrigerators, those with linen partitions are as efficacious as those of cement. In an experiment made by S. L. DENNING, a certain quantity of butter was kept at the room temperature, from 13th June, in brine of different strengths. On 22nd July, the best preserved sample was that which had remained in a solution of 30 %. The sample in a saturated solution (at 40 %) took the second place, while that in a 20 % solution was in a worse condition than the sample wrapped in paper which had not been in brine. On 14th October, none of the samples kept at a natural temperature were in good condition, those kept in the refrigerator, on the contrary had not deteriorated (Fd)

gives favourable results with pasteurised milk at 75° C by the continuous heating process.

Some of the cultures give more favourable results with milk kept at 63° for 20 minutes and then cooled to 30° C. The cultures were obtained from milk in its natural state.

XII. — THE MICROSCOPIC STUDY OF BACTERIA IN CHEESE. — HUCKER quotes the works of several authors (JOHAN-OLSEN, TROILI-PETERSON, GORINI, RODELLA) who formerly used the process of direct microscopic examination of microtomic sections of cheese, and describes the technical method which he himself has used in this process, and the results he has obtained in applying it to the study of bacterial flora in Cheddar cheese.

He cuts the sample under consideration into small cubes which are imbedded in paraffin wax and then cut into sections 5  $\mu$  in thickness with the Minot rotary microtome. The sections are then stained by the Gram method, followed by methylene blue.

The number of micro-organisms determined by this direct examination was much greater than that obtained by the ordinary cultural method. The two methods together give much more satisfactory results than those obtained with one alone.

XIII. — THE DETERMINATION OF YEASTS AND OIDIUM IN CREAM AND BUTTER. — Among the various factors which determine the preservation of butter, several authors have attached importance to yeasts and *Oidium lactis*. REDFIELD has devised a special method of investigation to enquire into the matter. The results obtained, which he sets out in tabular form, show that the actual number of micro-organisms present in butter recently made is of little importance. The addition of "starter" introduces bacteria of the pure acidifying type in such quantities as to predominate in the bacterial count at this phase. The other groups represented only occasionally show an insignificant number of micro-organisms. The micro-organisms of the peptonising group abound only in butters of very inferior quality. On the whole, butters of inferior quality contain a large number of yeasts and *Oidium lactis*, but there are sufficient divergences to indicate that the deterioration of the butter is also caused by other agencies as yeasts and oidium are present both in inferior qualities of cream and of butter. It is possible that in the final product their number is in correlation with the condition of the cream treated (1). F. D.

(1) Ice cream may be included in the category of dairy products (see: W. W. FISK, *The Book of Ice Cream*, p. XVIII, + 302, 88 fig. New York, Macmillan Co., 1919). The following may be cited as bacteriological studies on this subject: 1) HAMMER, B. W. and SAUNDERS, L. R., A Bacteriological Study of the Method of Pasteurizing and Homogenizing the Ice Cream Mix, in *Iowa Agricultural Experiment Station, Bulletin* 186, pp. 17-26. Ames, 1919; 2) ELLENBERG, H. B., A Study of Bacteria in Ice Cream during Storage, in *Cornell University Agricultural Experiment Station, Ithaca, N. Y.*, 1919. From the results of his researches the author declares that: 1) with agar plates the number of bacteria is greater than with those of gelatine; 2) the use of tournsol slightly increase this number in either case; 3) incubation at 20° C for 7 days gave the best results of all those tested for the

640 - **Influence of Surroundings and Temperature of Incubation on the Bacterial Count of Milk.** - SUPPLÉ, G. C., WHITING, W. A., and DOWNS, P. A., in *Memoir 43, Cornell University, Agricultural Experiment Station and The Creamery and Milk Plant Monthly*, v. XI, No. 2, pp. 25-26. Chicago, Feb. 1922.

The present methods of counting bacteria in milk give only approximate results which cannot be used for purposes of comparison. They are undoubtedly of great use in safeguarding the interests of consumers in large towns as is shown by the report (1917) of the "Committee on Statistics of Milk and Cream Regulations of the Official Dairy Instructor Association". This Committee has brought together all the regulations concerning the sale of milk in 409 towns of large and medium size, in the United States, and has observed that 189 of these towns impose a legal limit for the number of bacteria in milk sold in the municipality. The limits allowed vary for the different towns from 50,000 to 5,000,000 per cubic cm; about half the number of towns adopt the limit of 500,000. The necessity of fixing legal limits for the bacteria in cream has not seemed so urgent, for 30 only of the 409 towns have done so; these limits range from 50,000 to 1,000,000 organisms per cub. cm.

The inaccuracies inseparable from the present methods of counting bacteria are too great to allow of attaining that degree of accuracy which would seem to be guaranteed by the fact that typical numerical limits have been adopted.

The American Public Health Association, recognising the enormous variations observed in the results furnished by the ordinary method of plate counting, drew up in 1915 a method of counting micro-organisms in milk called "The Standard Method of Bacterial Analyses of Milk", which includes the use of pure agar plates and incubation for 48 hours at 37° C.

The general use of this method has the advantage of giving results more easily compared, but still far from uniform, as COVY found in 1915 by having the same milk examined by four different laboratories.

The reasons for disagreement in the results of plate counts are numerous. 1) certain species do not produce colonies visible among their surroundings and at the incubation temperature employed, 2) tendency of several spe-

growth of ice-cream bacteria on agar plates. In the bacterial count by the plate method, the most serious errors are caused by the inequality of distribution in the final dilution with water. The various ingredients used in the manufacture of ice cream -- milk, cream and condensed milk -- are the most fruitful sources of bacteria. By subjecting them to thorough pasteurization, a small number of bacteria only will be found in the ice cream. In addition to the contamination due to the apparatus used, there is generally an increase in the number of bacteria caused by the freezing process, which might be attributed to the breaking up of clumps of micro-organisms.

There is no radical change in the total number of micro-organisms in ice cream during storage. But there seems to be a slight decrease during the first 2 to 4 days, followed by a greater increase and then again by a corresponding decrease between the 4th and 21st days, after which there is a very slow decrease. The bacterial groups do not appreciably change during storage. The acidifiers predominate throughout the period of storage, and several of them, it appears, belong to the *Bacterium lactis acidii* group. (Fd.)

cies to exist in groups of 2 or 3 individuals more or less completely broken up during the preparation of the plate ; 3) too few or too many colonies on the plate ; 4) hindrance or beneficial effect of the diffusion of the sub-products of the growth of certain species on others within the radius of diffusion ; 5) personal error, etc.

The " Standard Method " has fixed the minimum number of colonies at 30, and the maximum at 200, per plate ; according to Messrs BREED and DOTTERIER (1916), the limits 30-400 give equally satisfactory results.

Several authors have noticed that the use of agar plates to which have been added carbohydrates, and a longer period of incubation at a lower temperature, have several advantages ; the authors have therefore examined the variations in bacterial counts effected at different incubation temperatures, and with agar disks with or without the addition of carbohydrates.

The samples used in these experiments were taken indiscriminately from the market at Ithaca at frequent intervals during a period of 18 months. With the same dilution of each sample 27 plates were made : 9 of agar, 9 of agar + 1 % of dextrose, 9 of agar + 1 % of lactose. The agar was all of the same quality. In each group of 9 plates 3 were incubated at 37° for 48 hours, 3 at 30° for 5 days, and 3 at 20° for 5 days. For all the rest the authors adhered strictly to the " Standard Method " process.

From the results, arranged in tabular form, the following conclusions may be drawn.

The great differences observed in the counts made on different substrata and at different incubation temperatures, clearly show the insufficiency of any combination of temperature and substratum to determine the maximum number of bacteria in the different samples of milk. Pure agar at 37° for 48 hours is certainly the least adequate combination for the purpose ; the use of agar with galactose at the same temperature has few or no advantages over agar used alone, the majority of the results given by it are inferior to those obtained by incubation at 30-20° for 5 days.

To obtain the largest numbers of bacteria, agar with dextrose at 30° for 5 days appears to be superior to all other combinations treated in this work.

The numbers of bacteria obtained at 37° after 48 hours, are probably subject to greater divergencies than those obtained at lower temperatures with longer periods of incubation. It has been proved that normal variations of temperature in a large number of plates in close proximity, are sufficient to cause in the same sample of milk, a possible 50 times greater number of bacteria ; whereas if the plates are sufficiently wide apart to enable the air to circulate freely between them, a variation of not more than three times the number is obtained. When experimenting at a temperature of 35°, therefore, the incubator must be sufficiently ventilated to permit of all the plates being equally heated.

The possible variations in the numbers of bacteria due to the present method of counting do not imply that this method is useless ; but its limitations should be recognised and the grading of milk into various

classe of purity and keeping quality should not be based exclusively on it.

To harmonize these variations with the typical methods of examination, all factors which tend to cause variation and disagreement should be reduced to a minimum.

- 641 - **Variations of certain Characters of the Fatty Matter in Buffalo and Cow-Milk, corresponding with Change of Season and Feeding.** — PLYMPER, F. J., and AIYER, A. R. P., in *Memoirs of the Department of Agriculture in India, Chemical Series*, v. VI, No. 4, pp. 187-208, tab. 5, Calcutta, 1921

For the purposes of inspection and determination of the degree of purity and of the other characters of butter and of dairy products, numerous States have adopted technical methods based on the chemical properties of the fats contained in these foods, such methods are those of REICHERT-MEISSL (which reveals the relative quantity of volatile fatty acids) — POLENSKE (which differentiates the volatile fatty acids soluble in water from those which are insoluble) — AVELLEMENT (which is of practical importance because it enables the purity or adulteration of butter to be ascertained by means of the relative solubility in water of the barium salt contained in the fatty acids), etc

Very few researches have been made on this subject in British India, and the authors proposed to remedy this by making a series of investigations based on the above methods, to determine the physical and chemical properties of pure butter made from the milk of cows and buffaloes fed under well-defined conditions.

These investigations completed, both in the case of isolated animals and herds, and set forth in detail in 5 tables, gave the following chief results: a) from each animal butter may be produced with characters widely differing from those of the total produce of a herd; b) in the case of the total product from a herd, the divergence of the characters considered to be normal is more accentuated during the months in which warm and dry weather prevails; c) the ordinary chemical and physical determinations do not permit of distinguishing the fat of cow butter from that of buffalo butter; d) if the numerical indices adopted in other countries be considered as minimums of purity, a great part of the fatty matter of butter produced from the milch-cattle of India must be taken as altered

E. F.

- 642 - **The Reciprocal Application of the Numerical Indices of the Characters of the Fat in Cow Butter and in "Ghee" (clarified Buffalo Butter).** — PLYMERS, F. J. and AIYER, A. R. P., in *Memoirs of the Department of Agriculture in India, Chemical Series*, vol. VI, No. 5, pp. 209-214, 4 diagr. Calcutta, Oct. 1921

The fatty matter of butter reaches the market after passing through numerous and varied processes, according to circumstances, and in consequence the numerical indices usually employed to estimate the degree of purity cannot always be compared. Especially is this the case when the comparison is made between ordinary butter (from the cows), which is prepared at a low temperature, and clarified buffalo butter (the "ghee")

of the Hindoos), which is subjected to a high temperature during its preparation.

In the researches made on this subject, the authors have used butter and "ghee", each prepared from the same sample of milk (both cow and buffalo), and have subjected the cream to the different processes generally employed in India in the preparation of butter for the market. The results obtained clearly show that the different methods of ripening cream and preparing cow-butter at a low temperature or "ghee" at a high temperature have no appreciable effect on the numerical indices usually employed in estimating their purity.

Investigations were also made with samples of the fatty matter of butter and "ghee" kept from 3 to 5 years, and it was proved that the fact of heating butter fat to a high temperature, as is done in the manufacture of "ghee", does not modify the numerical indices of its characters, nor the conclusions which may be drawn therefrom.

In conclusion, the indices relating to butter fat may also be applied to "ghee", and *vice-versa* E. F.

(43) - **Manufacture of Cheese of the Roquefort Type with Cows Milk in the United States.** — MATHESON, K. I., in *United States Department of Agriculture, Bulletin* 970, pp. 28, figs. 11. Washington, 1921.

Detailed rules are given for the manufacture of the Roquefort type of cheese from cow's milk. These rules are based on the experience gained in cheese-making in the Dairy Division of the Department of Agriculture of the United States at Grove City, Pennsylvania. The care necessary during ripening is especially studied, and manufacture of this type of cheese is not advised in cheese factories which have not the necessary apparatus for ripening well.

The Roquefort cheese produced in France is made from ewe's milk and is one of the earliest of which mention is made. The average composition of a good Roquefort cheese is approximately as follows: Water 38%; fat 32%; protein 20%; minerals 6%, including 4% of sodium chloride.

Ewe's milk differs both physically and chemically from that of the cow. The relation between fats and protein, however, is almost the same.

The use of clean, fresh milk is essential. From 3 to 4% of "starter" (which sets up fermentation) is used and the milk is given an acidity of 20-23% before being curdled. It is heated to 28-29°C and curdled with rennet in the proportion of 190 to 250 gms. per 1000 gms. of milk. The curd is allowed to stand for 1 hour or 1½ hours and then broken, and ten minutes afterwards thrown into a cloth and left to drain for about twenty minutes. When the curd is put into the mould, it is sprinkled three or four times with *Penicillium glaucum* powder. The cheese is turned three or four times the first day and afterwards at least twice a day until the salting. The temperature of the room in which the cheeses are ripened should be from 18 to 20°C and the moisture from 85° to 90°. In this room the cheeses are washed daily for four or five days, after which they

are salted in a special room in which the temperature is kept at 9° and the moisture between 80° and 90°.

The salting lasts from 8 to 10 days. Special apparatus is necessary to ensure the right temperature, moisture and ventilation. The cheeses are then pierced thirty or forty times and placed on shelves edgewise and not on their flat surfaces.

By the use of a refrigerator and special apparatus, the cheeses ripen at 7-10° C with slight ventilation. During the salting and wrapping in tin-foil, the air should be dry and fresh.

The cheeses are left to ripen two or three months, during which time, they are scraped every three or four weeks; the total loss from the scraping is 7-8 %.

After ripening, the cheeses are wrapped in tin-foil and stored for at least one or two months.

At Grove City the cost price of the Roquefort type of cheese was estimated at 46 cents per pound. With milk containing 4% of fat, the production of cheese should be from 10 to 11 kg. per 100 kg. of milk.

The cheeses when finished are wrapped in tin-foil lined with parchment paper and packed in cotton wool, in cases, 12 in each case.

With proper apparatus and skilful labour, the Roquefort type of cheese may be successfully prepared from cows milk. F. D.

## GENERAL INFORMATION

LEGISLATIVE  
AND  
ADMINISTRATIVE  
MEASURES  
FOR THE  
PROTECTION  
OF CROPS

644 - Decree of December 21, 1921, No. 15198 Sanctioning the Regulations relating to Plant Diseases in Brazil. — *Diario official*, No 14, January 18, 1922 (cf. International Institute of Agriculture, *Textes législatifs de l'année 1922*, No. 2 (1).

This Decree describes the regulations in force in Brazil respecting the trade in plants, or parts of plants, their importation, transit, and exportation.

Throughout the national territory all trade importation or transit is forbidden in the case of . 1) living plants, or parts of plants, infected with diseases or parasites recognised to be dangerous, 2) injurious live insects in every stage of their development; 3) cultures of bacteria or fungi injurious to plants; 4) soil and mould that may contain (in any stage of development), fungi, insects or other plant enemies, even if such soil or mould should form an integral part of the said living plants, 5) cases, sacks or other packing material having been used in the transport of the above-mentioned products.

The Ministry of Agriculture, Industry and Commerce shall also be empowered to forbid the importation of any plant product coming from countries suffering from the ravages of diseases or animal parasites, and hence constituting a source of danger to native crops. G. T.

645 - Decree of January 26, 1922, prescribing the Measures of Control of Diseases and Animal Parasites of Plants in the Regency of Tunis. — *Journal officiel tunisien*, No. 20, March 11, 1922 (cf. *Textes législatifs etc* No. 3)

When the injuries caused to cultivated plants by animal or plant, parasites are, or seem likely to become, widespread or to assume serious proportions, the Director General of Agriculture, Commerce and Colonisation passes decrees delimiting the infected areas, and prescribes the necessary measures to destroy the pests and to regulate the transport of plants and parts of plants capable of propagating such parasites.

All owners, including the State, Communes and Public Administrations, or tenants of urban or rural landed property, are required to carry out the measures prescribed by the decrees. For this purpose they may, if belonging to the same or a neighbouring *circondario*, form themselves into co-operative Societies which in some cases may receive a grant.

---

(1) Sec R April 1922, No 504 (Pd)

Should the owners or occupiers of the property omit to carry out the regulations in force, the work of destruction may be performed by the authorities at the expense of the interested parties, and without prejudice to the penalties entailed by such omission.

In the case of any infringement of the rules laid down for the transport of plants, the sender as well as the forwarder are jointly responsible. Any plants transported fraudulently are seized and destroyed together with their packing material. If not detected until planted, they will be destroyed at the expense of the offender, who is liable to the same penalties as the sender and forwarder.

G. T.

| 651 - <i>Bacterium flaccumfaciens</i> n. sp. injurious to Beans in South Dakota. — HEDGES, F., in <i>Science, New Series</i> , Vol. LV, No. 1425, pp. 433-434. Utica N. J., April 21, 1922. | DISEASES<br>OF VARIOUS<br>CROPS |

A new form of bacteriosis has been reported as attacking the ordinary haricot bean in South Dakota. The agriculturist on the estate where the disease was discovered estimates that it caused the loss of 90 % of this crop in 1920. In 1921, he sowed seed taken from the plants that had survived and lost about 25 % of the yield. Some of the seed from the crop obtained at Dakota in 1920 was sown at Arlington (Virginia), and produced a large number of diseased plants many of which never grew beyond the seedling stage.

The disease is characterised by the withering of the leaves of the young plants sometimes accompanied by change of colour and stunted growth, reduced yield, and the death of some of the shoots if the plant has passed the first stages of its development.

Samples of beans from South Dakota were received on August 6, 1921, at the Phytopathological Laboratory at the Bureau of Plant Industry, Washington. It was then discovered that bacteria were present in the vessels of the stem, and that the vascular ring was often of a brownish colour. A yellow micro-organism was isolated from the infected stems

which when inoculated into young, vigorous specimens of the variety of bean known as King of the Mountain, immediately caused withering. This micro-organism, when again isolated from these infected plants, induced withering in beans of the Great Northern variety. King of the Garden, a variety of *Phaseolus lunatus*, and Ito San, a variety of *Glycine Soja* were also infected by inoculation with a pure culture of the bacteria. The same micro-organism has been isolated from bean plants grown at Arlington and was found to reproduce the disease.

The change of colour, sometimes observed in infected bean plants appears as a pale-green, brownish-green, greenish-brown, or reddish-brown area occasionally bordered with yellow. This area is at first flaccid, but afterwards becomes dry and assumes the consistency of paper. In many cases the whole blade and petiole become flaccid and drooping, without undergoing any change of colour; sometimes part of the leaf-blade becomes soft and changes colour, while the rest of the lamina and the petiole remains turgid for a time.

The micro-organism inducing the disease is regarded as a species new to science and has been given the name of *Bacterium flaccumfaciens*. The author gives a very detailed account of the many characters distinguishing it from *Bact. Phaseoli* Erw. Smith. G. T.

652 - **Potato Diseases in Argentina.** GIROLA C. D., in *Boletín del Ministerio de Agricultura de la Nación* Vol XXVI, No 3, pp 260-264, 2 pl. Buenos Ayres, 1921.

Potato disease appears to be spreading in Argentina. In addition to "potato mould" (*Phytophthora infestans*), which has long prevailed there, causing very considerable damage, and "dry-rot of the tubers," (*Fusarium Solani*), a fairly common malady, a disease due to *Corticium vagum* var *Solani* has been reported for some years from the neighbourhood of Buenos Ayres. During the agricultural year 1920-1921, Potato scab *Oospora Scabies*, was observed for the first time on potatoes coming from Balcarce.

The author describes the characters of the two last mentioned parasites and the means of their control.

The beetle, *Epicantha adspersa* sometimes causes serious injury to the potato. G. T.

653 - ***Peronospora Trifoliorum* found in Italy on Lucerne of Argentina Origin.** — CAMPBELL, C., in *Annuale di Botanica*, Vol XV, Part 4, pp 283-284. Rome, 1922.

In the course of comparative cultural experiments carried out with lucerne seed from different parts of Italy, France and Argentina, the plot sown with Argentina seed was found, for several years in succession to be severely attacked by *Peronospora Trifolium* De Bary, whereas the other plots of lucerne, as well as those sown with species of *Medicago*, clover, *Lorus* etc., were entirely free from the fungus.

The germinating capacity of the Argentina lucerne seed when previously tested in the laboratory, did not differ from that of the seed from the other countries. G. T.

- 654 - ***Botrydiplodia Theobromae*, a Deuteromycete injurious to the Cotton Plant (*Gossypium punctatum*) in Dahomey.** — PATOULLARD, N., in *Revue de Botanique appliquée et d'Agriculture Coloniale*, Year II, No. 6, pp. 41-42. Le Mans, February 28, 1922.

Cotton plants belonging to the species *Gossypium punctatum* Schum. and Thonn (= *G. barbadense* L.) and native to Dahomey have been seriously injured by *Botrydiplodia Theobromae* Pat.

The diseased plants were stunted, bore few and malformed leaves, while the incompletely developed, shrivelled, black pods did not open. The cotton was tangled into a shapeless mass, and was often quite black and always useless.

The wood of the stem and root and also the cortex assumed an abnormal grey colour, caused by the brownish filaments of the mycelium which connect the cells.

The parasite was seen externally, on the lower part of the stem, near the root-collar, and on an oval swelling several centimetres in length, where it formed small, scattered, black tubercles which penetrated the epidermis. These tubercles are also met with on the largest branches, and cover the surface of the bolls. They become fewer and smaller as they ascend the stem, and are composed of pycnidia united by a stroma.

Should *Botr. Theobromae* continue to spread on cotton plants, it might become a dangerous pest. The disease being a wound parasite probably penetrates into the stems through the lesions produced by insects in the growing tissues. G. T.

- 655 - **Diseases and Pests of Cinnamon in Ceylon.** - - See No. 577 of this *Review*

- 656 - **The Mucedineae, *Botrytis vulgaris* on the ornamental Liliaceae, *Funkia ovata* and *F. Subcordata*, and in its latent form on Rose Bushes in Italy.** — FERRARIS T. and CIFERRI, R., in *Costa Azzurra Agricola-Istoriale*, Year II, No. 1, pp. 7-8, San Remo, January 1, 1922.

Plants of *Funkia ovata* Spreng. and of *F. subcordata* Spreng. growing in two different places have been found to be attacked by *Botrytis vulgaris* Fr.

The disease first made its appearance on the floral axes in the form of a white cotton like mould, which almost covered the axes and then spread to the leaves. The floral axes are disorganised by the mycelium, bend back on themselves and frequently become useless. The parasite then descends to the root-collar, which turns yellow and the plant dies. Slender sclerotia are seen afterwards on all the affected parts, especially of the floral axes.

Where the surrounding conditions are favourable, the mycelium spreads over the surface of the ground, and passes from plant to plant.

A latent form of the same fungus has been observed on the rose-bush. The buds of the infected plant do not fully develop, but wither and fall without the plant showing any sign of disease. The presence of the fungus was discovered by placing the buds peduncle downwards in damp sterilised sand, and keeping them under glass for some time.

The best means of preventing this disease in greenhouses is to provide good ventilation. In the case of rose-bushes grown out of doors, fairly resistant varieties should be chosen, and the permanent moisture of the soil lessened by a moderate application of mineral fertilisers. The disease having once appeared, an attempt may be made to check it by spraying with 1-2 % bisulphite of lime, alternating with the application of powdered lime (80 %) and powdered alum (20 %). It would be better, however, to burn all diseased plants immediately and to isolate infested plots.

G. T.

657 - *Cytosporina citriperda* n. sp. a Deuteromycete destructive to Mandarin Oranges, in Italy. — CAMPANILE, G., in *Le Stazioni sperimentali agrarie italiane*, Vol. IV, Part. 14, pp. 512, figs. 4. Modena, 1922

In 1922, most of the mandarin oranges offered for sale in Rome were infected with a disease characterised by the presence on the skin of a single round patch (occasionally two or three patches occurred) of a maximum diameter of one and a half centimetres. This was at first brownish-red, and later black. The spot was depressed and in the endocarp under it there developed a laminated, irregular, sinuous, almost cartilaginous formation. This formation which microscopic examination showed to be a stroma, bore on both surfaces a large number of pycnidia of a Deuteromycete belonging to the genus *Cytosporina*, said by the author to be a type new to science, to which he gave the name of *Cyt. citriperda*. From its position, and as a result of inoculation made with it, the author considers this fungus to be the cause of the disease.

Pycnidia of *Cit. citriperda* have also been observed, although rarely, on the patches appearing upon the bark.

The parasite spreads subsequently in the endocarp, where it forms new stromata, it may penetrate even as far as the centre of the fruit, sometimes actually attacking the seed.

Mandarin oranges thus affected naturally lose much of their value, especially if the patches are numerous, and the diseased portion acquires a bitter, rather disagreeable taste.

It is probable that this disease is related to that produced on citrus fruits in America by *Phomopsis Citri* Fawcett.

G. T.

658 - *Trichothecium candidum*, a Mucedinea injurious to Apples in Italy. — CIFERRI, R., in *L'Italia Agricola*, Year LIX, No. 1, pp. 16-17. Piacenza, January 15, 1922.

During the summer of 1921, the author observed that many of the ripe apples on a tree of the Reinette variety in the Marches, were covered with small round spots with a blackish-brown border bearing a whitish efflorescence in the centre. Examination under the microscope proved this to be formed by conidia of *Trichothecium candidum*, a Mucedinea well-known as a saprophyte, but apparently capable, as in the present case, of assuming the rôle of a facultative parasite. From the superficial patches, the fungus mycelium penetrated into the pulp of the fruit which resulted in a brownish rot. As a rule, the decomposition though progressive,

stopped short of the loculi; when it reached this point, the apple already brown and shrivelled, soon became mummified by the summer heat if left in its natural surroundings. In a moist chamber, on the other hand, it was speedily reduced to a soft putrescent mass of pulp which was soon invaded by moulds.

In order to prevent the possible spread of the disease, it is advisable to destroy all fruits showing any signs of this infection, to which the author has given the name of "white apple-blotch" G. T.

659 - *Dothiorella Sanninii* n. sp. a Deuteromycete causing Scab ("Rogna") on Pomegranates in Italy. — CILERRI, R. in *Il Coltivatore*, Year LVII, No. 36, pp. 569-570. Casale Monferrato, 1921.

The surfaces of some fruits of *Punica Granatum* on sale at Alba (Prov. of Cuneo), were completely covered with small black patches caused in the opinion of the author, by a Deuteromycete, *Dothiorella Sanninii* n. sp. This fungus was found to spread from one fruit to another wherever there were slight lesions of the epidermis.

It does not seem to injure the interior of the pomegranates, but as the fruit is greatly disfigured by the presence of the patches, they lose their commercial value.

Care must be taken not to store the fruits in piles, and to remove any that are affected. G. T.

660 - Fungi injurious to the American Grape in Sicily. — See No. 586 of this Review.

## WEEDS AND PARASITIC FLOWERING PLANTS

661 - The Macrolepidopteron, *Papilio leratii*, as a natural Means of controlling *Asclepias curassavica*, a Weed growing in New Caledonia. PALADINI, I. (Senoi), in *Revue agricole* No. 77, pp. 3-4 Noumea, Feb. 1922.

The seeds of *Asclepias curassavica* were introduced into New Caledonia from Tahiti about 1860 and the weed spread with such rapidity, especially in the valleys, that it infested nearly all the soil.

Some years later, the parasite had almost entirely disappeared from New Caledonia owing to the attacks of a Macrolepidopteron, called by the author *Papilio leratii*. The larvae destroy the leaves and stem of the *Asclepidiæ* upon which *Asclepias curassavica* carries out all its metamorphoses.

The author considers that the extirpation of the plant, even had it been possible, would never have given such a satisfactory result. G. T.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS

662 - Biological Observations on the Larvæ of the Coleopteron, *Tenebrioides mauritanicus*. — MIGNONE, A. in *Nuovi Annali del Ministero per l'Agricoltura*, Year II, No. 1, pp. 136-141. Rome, March 31, 1922.

GENERAL

An account is given in this paper of experiments made from 1915 to 1917 with a view to determining the habits of the larvæ of *Tenebrioides mauritanicus* L. (= *Trogosita mauritanica* L.), with respect to the caryop-

sides of wheat and other cereals, which according to many authorities, are seriously attacked by these parasites. The experiments have proved that the larva, like the adult beetle is carnivorous and does not injure wheat, the larvae of phytophagous insects forming its favourite food.

G. T.

663 - **Scale Insects Observed on Orchidaceae in Colorado.** — COCKFRELL, T. D. A., in *Entomological News*, Vol XXXIII, No 5, p 140 Philadelphia, May 1922

The following scale-insects have been found at Boulder (Colorado), on *Orchidaceae* grown in greenhouses.

1) *Aonidia pseudaspidiotus* (Lindinger), on the stems of *Vanda teres* Lindley the host-plant comes from India and the scale-insect no doubt belongs to an eastern species;

2) *Chrysomphalus dictyospermi* (Moigan) infesting the leaves of *Coclogyne cristata* Lindley;

3) *Diaspis boisduvali* Signoret, on *Lachnocattleya hybr. Victoriae* (Queen Victoria Hort), and on *Odontoglossum Rossi* Lindley.

All three of these scale insects are interesting owing to the place where they were found, *Chrys dictyospermi* and *D. boisduvali* being reported for the first time as occurring on their respective hosts.

G. T.

664 - **Insects injurious to Crops in Brazil.** MORTIRA, C., in *Ministerio da Agricultura, Industria e Commercio, Instituto Biologico de Defesa Agricola, Boletim No 1* (Serie de divulgação), 152 pp., figs 25, pl 60. Rio de Janeiro, 1921.

In the above publication the author first gives a few data regarding the anatomy and physiology of insects and then mentions the principal species of agricultural pests in Brazil. The matter is subdivided into as many chapters as there are plants or plant products under discussion, e. g. citrus trees, fig-trees, *Anona reticulata* and other *Anonaceae*; sugar-cane; cacao plant, coco-nut palms and other palms; caryopides of maize and rice; beans, and coffee berries, tobacco; rice (plant); cotton plant, guava plants and other *Myrtaceae*; kitchen-garden plants, vines and coffee; shrubs and those of commercial value ornamental trees. There are also special chapters dealing with locusts, fruit-flies, Forficulidae, the two beetles popularly known as "vaquinhas," which destroy fruit trees (*Macroductylus suturalis* Mannh. and *Epicaula atomaria* Germ), with aphides and scale insects, and with control measures, especially insecticides.

The author describes the stages of development and the habits of the most important insects considered in each chapter, and gives an account of the methods of control which may be used against them.

G. T.

665 - **The Introduction into Italy of the Hymenopteron, *Aspidiotiphagus lounsburyi*, an endophagous Parasite of the "bianca-rossa" of Citrus Trees (*Chrysomphalus dictyospermi*)** (1). — PAOLI, G., in *Il Coltivatore*, Year LXVIII, No 15, pp 451-455, figs 2 Casale Monferrato, May 30, 1922.

The chalcid hymenopteron, *Aspidiotiphagus lounsburyi* Berl. and

(1) See also R Jan 1918, No 118 (Fd)

Paoli is well-known in Madeira. This insect is an endophagous parasite of the Coccid, *Chrysomphalus dictyspermi* Morg ("bianca-rossa" of citrus trees), which is also very common in the island, and is found on many widely differing species of plants.

In March 1922 the author was sent to Madeira by the Italian Ministry of Agriculture to collect leaves attacked by "bianca-rossa." This insect was infested by the internal parasite, *Ispidiotiphagus lounsburyi*. These leaves were taken to Italy, some were placed in gardens at Chiavari (Prov. of Genoa) and others in Sicily where the coccid occurs in great numbers.

Part of the material was kept in the laboratory, and the insects which hatched out daily in hundreds from the leaves under observation, were at once set at liberty in the various gardens.

The author is of opinion that *I. lounsburyi* will become acclimated in Italy without any difficulty.

G A

666 - **South African Maize Pests.** See No. 565 of this Review.

INSECTS, ETC.  
INJURIOUS  
TO VARIOUS  
CROPS

667 - **Pests of *Sorghum vulgare*, in India.** See No. 566 of this Review.

668 - **Insects injurious to Sainfoin in Sicily and Tunisia.** — DI STEFANI, I. in *Annali mensili* Year III, Part 3, pp. 85-86 (Palermo, March 1921).

In Sicily and Tunisia during the past few years the crops of sainfoin (*Hedysarum coronarium*), have been attacked by *Sphinctoplera lineata* Fabr. and *Sph. laticollis* Oliv.

The author gives a short account of the life cycle of the former which is entirely passed within the host plant. Both the Buprestid beetles, when in the larval stage excavate a deep gallery in the tap-root of *Hedys. coronarium*, and do irreparable damage to the plant.

The individuals that are attacked can be easily recognised as their leaves first wilt, and afterward wither. Both the beetles have increased to a greater extent in each successive year. The injury done recently by *Sph. lineata* in the territory of Monreale (Prov. of Palermo) was so serious that the young sainfoin seedling were entirely withered throughout wide areas, while the colonists in Tunisia fear that they will have to give up growing this crop owing to the attacks of *Sph. laticollis*.

*Hedysarum coronarium* is not only injured by the above two Buprestids, but also by the larva of a Macrolepidopteron, *Sesia ichneumoniformis* S. V., which likewise infests the tap-root of the Leguminosa.

In the control of these insects good results could be obtained, according to the author, by uprooting and burning in February, March and April all unhealthy looking plants of sainfoin, as their diseased condition is most probably due to the mining of the tap-root by the larvae.

G T

669 - ***Heliothis armigera* (Cotton boll-worm) a Macrolepidopteron causing Damage in ratooned Cotton fields in South Africa.** - See No. 572 of this Review.

670 - *Homalonotus coriaceus*, a Coleopteron injurious to the Coconut Palm in Brazil (1). — BONDAR, G., in *Chacaras e Quintaes*, Vol XXV, No 3, pp 205-208, figs 5  
São Paulo, March 15, 1922

In Brazil there are large numbers of coconut palms bearing crops much below the normal minimum, which instead of producing over fifty nuts per annum yield only from ten to twenty. In place of the twelve annual bunches each containing ten to twenty nuts, four or five bunches only with three to four nuts each, attain maturity. The others either die prematurely before the fruit sets, or lose the greater number of their nuts before they are fully developed or ripe.

The abortion of the fruit is due to a Curculionid beetle, *Homalonotus coriaceus* Gyll.

The adult individuals hide themselves in the axils of the leaves near the inflorescences, and live on the internal tissues of the palm.

In order to reach the flowers that have not yet unfolded, the insect actually perforates the spathe enveloping them. Many of the flowers thus attacked die, and when the spathe is perforated in ten or fifteen places, all the blossoms it contains perish. This is, however, exceptional, as a rule only some of the flowers are destroyed by the attacks of the Coleopteron.

When the surviving flowers produce fruits, these are perforated by the insect which sucks out their contents. This causes the abortion and fall of the young nuts. Frequently 4 to 5 holes are to be seen in the fallen nuts, usually at the extremity of the fruit.

The beetle lays its eggs on the palm, choosing by preference the spathes where it finds its food supply. Each egg is deposited in a cavity made for its reception in the median part of the spathe, which acts as a sheath to the peduncle of the inflorescence.

The larvae live on the tissues of the spathes and then pass to the more tender and succulent peduncle of the inflorescence excavating a groove as they descend the stipe. The nutrition of the flower and fruits is thus hindered, and in consequence the nuts fall. Often the whole peduncle of the inflorescence is attacked, so that it dies and all the nuts are lost. When the larva attains its full development before reaching the base of the peduncle, it weaves a cocoon in the cavity of the spathe, using the tissues of the plant itself for this purpose. In this cocoon the beetle pupates and remains until it attains its adult form.

When several larvae descend into the peduncle, or if the peduncle dies before the enclosed larva has completed its development, the grub passes into the stipe, which is still covered with leaves, and there bores a gallery 20 to 30 mm in diameter.

The best means of controlling the insect is to catch the adults that usually hide in the axils of the leaves, all dead or injured inflorescences should be cut back as far as possible, and the insects found on them must be destroyed.

671 - **Pests of the Cacao in Grenada.** — See No 576 of this Review.

672 - ***Glyphodes unionalis*, a Microlepidopteron destroying Jasmine in the Department of Var.** — BERLAND, L., and SEGUY, E., in *Bulletin de la Société entomologique de France*, No 7, pp 95-96, fig. 1. Paris, 1922

In September 1921, at Callian in the Department of Var, much damage was done by a caterpillar to the plantations of jasmine, a flower grown on a large scale for the extraction of perfume.

The caterpillar feeds upon the leaves of the plant, and also bores a hole about half-way down the corolla tube of the flower, generally causing the flower thus attacked to wither quickly.

Some of the caterpillars collected on the spot were reared; they pupated from the 8th to the 10th of September. On the 10th of the same month, there emerged from them a fairly common Microlepidopteron, *Glyphodes unionalis* Hübner, better known owing to the injury it does to the olive-tree, but also occurring as a parasite of the jasmine, *Ligustrum* sp. and *arbutus*.

Some apparently healthy caterpillars did not make chrysalides, but produced pupae found beside the contracted body of the caterpillars. From each of these pupae on September 19th there emerged the adult form of a parasite of the Microlepidopteron, the tachnid *Zenillia roseanae* B. B. of which the authors give a description.

It is probable that in the territory of Callian this tachnid will act as a sufficient check upon the Microlepidopteron, but it may not prove as efficacious in the neighbourhood of Grasse, where the complaints of the horticulturists are continually increasing. G. T.

673 - ***Eriophyes* spp., Mites injurious to the Fruits of the Fig-Tree and of *Rubus*, new to California.** — ESSIG, E. O., and SMITH, E. H., in *Monthly Bulletin of the Department of Agriculture, State of California*, Vol XI, No 1, p. 63. Sacramento, California, January 1922

Two new *Eriophyes* injurious to cultivated plants were discovered in California during the summer of 1921.

The first was a species of *Eriophyes* which appeared to be common in the valleys of the interior of California. It lives on the fruits of the different varieties of fig-tree, "Dottato" or "Kadota," "Calimyrna" and "White Adriatic"

The mites are found in all stages of the unripe fruit and their presence is shown by a whitening of the bracts and pulp in the neighbourhood of the apical opening. On cutting open one of the figs there are seen in the pulp certain spots and striae, radiating from the apical opening. These are often translucent and prematurely pink or brown, according to the degree of ripeness the fruit has attained. Large numbers of mites are always present in these spots and on the yellowing bracts, as well as in the normal pulp. They are most numerous in the half-grown, or nearly full-grown figs. As the figs ripen, the mites gradually change their position and are to be found only under the small bracts at the apical opening, when the fruit is quite mature.

How far this mite is responsible for the changes described is not yet known. According to the authors this Eriophyde had never before been met with on fig-trees either in California or elsewhere.

The second species of *Eriophyes* occurs on the green and the ripening fruits of *Rubus* var. Himalaya. This mite produces a definite change in the fruit which prevents it ripening, or else causes the drupels to ripen irregularly, so that some may be still green while others are quite ripe and black. The mites cluster chiefly round the centre of the fig and at the base of the drupels. This species of *Eriophyes* had never been seen before, although the damage done to the fruits of *Rubus* Himalaya (the only variety that appears to be attacked) had been noticed for many years and attributed to animal agency of another kind.

G. T.

674 - Pests of the Date-palm in Mesopotamia. Sec No 554 of this *Revue*

675 - Observations on an Affection of the Date Palm known under the name of "Doud" in North Africa. SURCOUT J M R, in *Bulletin de la Societe d'Histoire naturelle de l'Afrique du Nord* Vol XIII, No 2 pp 31 35 Algiers, February 15, 1922

The affection of the date-palm known as "doud" has spread to the knowledge of the author, from the district of Figuig in Morocco, to El Goléa and Touggourt, it is well-known to the natives who attribute it to the attack of beetle larvae

Some authorities do not consider that "doud" is entirely due to the agency of these insects but the author's researches carried out in various parts of Algeria from 1917 to 1921, have shown it to be coincident with the presence of beetles in the leaf-crown of the palm. The species which occur in the largest number are *Phyllognathus vlenus* and *Oryctes bispinosus*

In the author's opinion, the affection is due to lesions produced both by the adult beetle and the larva, but chiefly by the latter

G. T.

676 - The Fir-Needle Beetle (*Polydrosus pilosus*), in Switzerland. — BARBEY, A., in *Journal forestier suisse* Year LXXII, Nos 10 11, pp 186 189, 1 pl Berne, 1921.

The curculionid beetle, *Polydrosus pilosus* Gredl., was observed for the first time at the end of May and early in June 1921, in the forests of the Canton of Vaud on the White Pine, as well as upon the Spruce and certain deciduous shrubs. In the case of the White Pine, naturally sown seedlings were attacked when four years of age when they had attained the height of ten centimetres, as well as trees three to four metres high. The beetle wandered over the branches, eating the scarcely developed leaves, those near the tip being preferred

There is good reason to believe that the insect had appeared the preceding year, but in such small numbers that its depredation escaped notice

The spikes and terminal buds seem immune from attacks of the beetle, though the growth of the tree is arrested to some extent as a result of the partial stripping of the leaves.

G. T.

677 - The Grey Pyralis of the Larch (*Steganoptycha pinicolana*), injurious to the Siberian Pine and the Mountain Pine, in Switzerland. — BADOUX, H., in *Journal forestier suisse*, year LXXIII, No 1, pp 1-6, 1 pl. Berne, January 1922.

Since 1858, *Steganoptycha pinicolana* Zll. (= *St dimiana* Gn.), has periodically attacked larches in the plantations of Grisons and Valais. It in its larval stage this insect devours the leaves in larch stands of all ages, and arrests the growth of the trees to a very considerable extent.

Although this Microlepidopteron lives chiefly on the larch, it is not strictly monophagous. Most authors however regard its presence on other forest trees as exceptional. COAZ, NÜSSLIN and BARBIY seem to consider that the Spruce, Siberian Pine and Mountain Pine are attacked only by *St pinicolana* when growing in a plantation of infected larches.

Observations made during the summer of 1921 have shown that the larch pyralis is injurious to other trees besides *Larix*.

In several parts of Grisons, both the Siberian and the Mountain Pines, generally regarded as vigorous and immune to insect attack, were found to be infested over a large area by a caterpillar recognised as being the larva of *St. pinicolana*, while nearly all the larches in the same neighbourhood were free from the pest.

G. T.

678 - Damage caused by the "White Fir Beetle" (*Pissodes piceae*) in Switzerland. — BADOUX H., in *Journal forestier suisse*, Year LXXIII No 4, pp 68-69. Berne, April 1922.

*Pissodes piceae* Ill. occurs frequently in Switzerland, but seldom does any appreciable damage.

In 1921, this Curculionid beetle made its appearance in the forest of Engelberg (Aargau) in a plantation of firs that had been greatly injured by the attacks of *Dreyfusia nüsslini* C. B.

The appearance of the beetle has recently been reported in a forest belonging to the Commune of Lichtensteig (St. Gall). About twenty average sized timber fir trees have been attacked and it has been necessary to fell them. An examination of the wood has shows the presence of *Sirex gigas* L. as well as of *Pissodes piceae*.

In order to prevent the propagation of both the Coleopteron and the Hymenopteron, all trees harbouring any of the beetles should be felled at once and the bark stripped off. All fragments of bark in which the insect has deposited its eggs must be burnt.

AND PRACTICE OF AGRICULTURE

MONTHLY BULLETIN  
OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION

679 - **Report of the California Department of Agriculture for the Period ending December 31, 1921.** — HECKE, G. H., in *The Monthly Bulletin, Department of Agriculture, State of California*, Vol. X, Nos. 11-12, pp. 559-569. Sacramento, Ca., Nov-Dec 1921

DEVELOPMENT  
OF  
AGRICULTURE  
IN DIFFERENT  
COUNTRIES

The general agricultural depression following the war has probably been felt to a lesser extent in California than in most parts of America, this being due largely to the excellent organisation of the co-operative marketing associations and of the prominent independent commercial concerns. The year 1921 has been exceedingly important from the point of view of agricultural and horticultural legislation. Some of the decrees established have meant the addition of entirely new activities to the work of the Department, for example the Pure Seed Law authorises a much needed standardisation of agricultural seeds and a Seed Testing Laboratory is now established in co-operation with the United States Bureau of Plant Industry.

As regards the new laws affecting the livestock industry, the most important are the co-operative systems relating to tuberculosis which are under control of the Federal State.

The centralisation plan has now been completed and the diagram illustrates the present organisation of the State Department of Agriculture. The recent addition of the Department of Weights and Measures and the State Market Commission and Fish Exchange has resulted in broadening the scope and activities of the Department. The important steps taken with reference to Standardisation, Pest control and quarantine etc. are dealt with under the various sections. These reports of

[Abstract No. 679]

the different division leaders demonstrate the marked development, in every case attributed to the loyal co-operation of the various agencies concerned.

#### DIVISION OF PLANT INDUSTRY.

*Bureau of Pest Control* — Activities have been continued along the following lines:

a) Regulation of traffic in walnuts to control the spread of codling moth (1);

b) Investigation of the possible improvement in the treatment of nursery stock to prevent the transport of certain insect pests. Work carried on by the Bureau includes treatment of apple, pear, peach, plum, almond, apricot, cherry, olive, orange, grapefruit and lemon. A number of standard liquid insecticides and fumigants were used, applied under vacuum conditions. Results have furnished a basis for the development of methods which should prove very helpful with reference to a number of present day problems. Special work has been undertaken with citrus nursery stock, which was first defoliated, then treated with hydrocyanic gas for 1 hour under reduced-pressure conditions (ratio 1.03. sodium cyanide to 100 cub ft. in a 27 inch vacuum) This method proved very successful in the destruction of red scale (2),

c) Control of insects affecting dried fruits. Satisfactory reports have been received from fig, date and raisin packers after their installation of fumigators. Experiments have been made with a view to ascertaining the value of fumigation of dates in vacuum with sulphur dioxide and their resistance to such treatment without commercial injury. In various experiments gas was generated by the utilisation of pure liquid carbon bisulphide at varying strengths. No injury was evolved from the standpoint of excess residue.

Reports as to the designs put forward for the fumigating apparatus are given, but all work of this kind should be considered of a preliminary nature.

d) Investigation as to the possibility of a satisfactory treatment of potatoes to destroy tuber moth (3). Complete details of the work done will be presented in a special report.

e) Work with the California Almond Growers' Exchange, in connection with the control of insect pests of almonds. The Indian moth (4) has been a constant source of trouble in the packing houses. A successful treatment has been effected to eradicate this pest, namely the application of heat to the infested part of the building. The details of the procedure are given.

f) Sterilisation of picking boxes. The treatment by steam to destroy pests has met with considerable success.

g) Grasshopper poison.

(1) *Carpocapsa pomonella* — (2) *Chrysomphalus aurantii*. — (3) *Phthorimaea operculella* Zell — (4) *Plodia interpunctella* Hbn (Fd)

*Field work in Insect control.* — Attention has been turned especially to the control of the following pests : — Strawberry root weevil (*Otiorynchus rugifrons*) ; strawberry leaf weevil (*Paria canella*) ; pear thrips (*Euthrips pyri*) ; pear mealybug (*Pseudococcus maritimus*), etc.

The introduction of the South African black scale parasite (*Aphiscus lounsburyi*) is very evident, and a systematic distribution as well as the development of further quantities of this parasite has been in progress. Other beneficial insects are also reported, amongst them the Citrus feeding mealybugs, *Cryptolæmus montrouzieri*, the Sicilian internal parasite, *Tanaomastix abnormis*, the Cotton cushion scale predator, *Vedalia cardinalis*. Experiments are also in progress in connection with red scale parasites and the Coleopteron steely-blue ladybird (*Orcus chalybeus*), *Rhizobius lophanthrac* and *Chilocorus bimaculatus* have already given good results. The Chalcid, *Aphelinus diaspidis* is also under close observation. Rodent control work has been prosecuted vigorously throughout the State and an intensive campaign against coyotes and other predatory animals has been inaugurated. Full details relative to these points are given.

#### BUREAU OF STANDARDISATION

a) *Fruit and Vegetable Service* -- At present this Bureau is engaged in the determination of workable standards for grapes and other deciduous fruits.

b) *Port inspection service of fruits and vegetables.* — This service places at the disposal of growers and shippers of perishable products, expert, disinterested, official inspectors from the Department of Agriculture who issue certificates covering the carload as a unit.

The seed potato certification service has been extended and enlarged during 1921, and also the grain and warehouse inspection service and the seed standardisation and inspection service.

**BUREAU OF PLANT QUARANTINE.** — In addition to the maritime port inspection, activities have been extended to the inspection of automobile traffic, a new field in quarantine work and one which should be given full consideration in the future. Quarantine orders have been revised so as conform to changing conditions brought about by the spread of pests and diseases in other States.

**REPORT OF THE VITICULTURAL SERVICE.** — Details are already published in the Annual Grape Report and data relative to economic returns will shortly be published by the California Crop Reporting Service of the State Department of Agriculture.

Data is given relative to the frost damage to the 1921 grape yield.

No further progress has been made as regards control of diseases and pests. The nematode *Heterodera radicum* (potato eelworm) has caused serious damage lately.

Grape phylloxera (*Phylloxera vastatrix*) is prevalent and widespread throughout the State, and the most effective methods adopted are : 1) the grafting on resistant roots when the soil is susceptible to phylloxera infestation ; 2) planting in very sandy soils or loams not susceptible

to infestation. All other practices offer little guarantee of longevity. The hot water treatment of rooted vines and cuttings when applied with care is effective as an agent of disinfection and if universally adopted would undoubtedly retard attack and restrict the spread of this disease. The Federal quarantine regulations although causing inconvenience to vine growers by barring the use of rooted vines and consequently delaying the planting of vineyards, is an advantageous institution in that it is a safe measure of protection against the introduction of pests and vine diseases which if once acclimatised would be so costly to control that vine cultivation would be restricted to the more highly profitable localities.

**DIVISION OF CHEMISTRY.** — A comprehensive inspection service has been inaugurated relative to the manufacture and sale of materials used in the control of diseases and pests, weeds and rodents, the last two of which have not hitherto been covered by any law.

A co-operative arrangement has been effected with the Division of Animal Industry and the Division of Chemistry for the equipment and operation of a laboratory for the bacteriological and chemical examination of dairy products.

An inspection service has also been at work for the administration of the Fertiliser Law. Briefly stated, the activities of the Division are now as follows :

1) Administration of Fertiliser Law : — a) Registration and licensing of manufacturers and dealers ; b) collection of tonnage taxes ; c) sampling and analysing of all brands of commercial fertilisers offered for sale, and publication of the results ; d) prosecution of those who sell commercial fertilisers without license or payment of tonnage taxes ; e) prosecution of those who sell labelled commercial fertilisers below the guaranteed analysis ; and of those who sell animal manures containing added sand or water.

2) Administration of the Economic Poison law : — a) Registration and licensing of manufacturers and dealers sampling and analysing substances offered for sale in the State to be used for the control of insects, fungi, weeds and rodents and publication the results ; c) prosecution of those who sell economic poisons without license ; d) prosecution of those who sell adulterated or misbranded economic poisons.

3) Chemical and bacteriological examination of dairy products as required by the Dairy Service of the Division of Animal Industry.

4) Testing and certification of all instruments used by creameries to determine the percentage of butter fat in milk and cream.

5) Analysis of miscellaneous substances required by other Divisions of the Department

This has included the analysis of fruits for the Bureau of Standardisation, and toxicological examinations of stomach contents of various organs of cattle and other live stock, feed and water, in suspected cases of poisoning.

6) Testing of instruments and supplying standard solutions for

all County Horticultural Commissioners, test determination for the ripeness of oranges, and instruction of officials and their deputies and inspectors in the technique of making the so-called 8 to 1 test.

7) Public service: a) Official and private analyses of economic poisons, fertilisers and allied substances, such as agricultural lime, gypsum and so called soil stimulants.

b) Analysis of milk and cream for industrials.

c) Correspondence, personal visits and conferences pertaining to the above-mentioned activities.

d) Investigations: — a) Chemical and bacteriological investigations to improve the quality of dairy products and to prevent and detect fraud.

b) Chemical investigations to obtain information when needed for the enforcement of the various laws.

**DIVISION OF ANIMAL INDUSTRY.** — In addition to the important laws affecting the live stock industry concerning tuberculosis eradication, disease investigations have been in progress and certain diseases such as the Texas fever tick and sheep scab have been reduced to a minimum. A list is given of the various diseases investigated and the eradication results.

Data are given concerning Dairy Inspection work, cattle protection service and cattle statistics, and the newly-established meat inspection law.

**DIVISION OF WEIGHTS AND MEASURES.** Inspections have been made in the various counties, cities and towns of the State in respect to weights and measures, to the sale of goods, wares, merchandise, commodities and foodstuffs in containers. These inspections are made in the various localities during their busiest seasons. Each state institution is inspected at least once annually and all scales, weights and measures are tested and corrected, which enables an accurate check to be made on incoming supplies. Further details are given with reference to the work of the "public weighmasters", the Net Container Law, *i. e.* the marking of containers with net quantity of contents; the gasoline and oil measuring devices; bread standardisation etc.

**DIVISION OF MARKETS.** — The efforts of this division have been concentrated largely on the proper and equitable distribution of the food supply. A survey of activities during the latter part of 1921 is made.

*Crop Report for 1921, and final estimates of acreage production and value of the principal crops of the State of California* — The tables in this report summarise the production of the various crops. Revised figures on acreage and production for 1919 and 1920 are included for comparative purposes.

680 — **Review of the Agricultural Situation in North West Morocco.** — SAULNIER, J., in *Revue Agricole de l'Afrique du Nord* Year 19, No 75, pp 10 13 1 map Algiers, 1921

The "Gharb" area under discussion, occupies the whole of the North Wets of French Morocco. Bounded on the north by the Klott, on the south by the Béni-Hassen area, on the east by Djebala and Riata and on the

west by the Atlantic Ocean, this region forms an immense plain with the Chatba Mountains as a central ridge running from west to east.

Three types of soil quite distinct from each other are to be found, namely: — 1) Sandy soils ("rimet"); 2) black soils ("tirse"); 3) white soils ("desse"). The sandy soils are prevalent in the northern section of the area. Beneath the surface soil is found a layer of blue clay containing traces of glauconite, and below this, sand again, and then gravel. It therefore belongs to the Upper Pliocene group, and is especially noticeable in the Maarif and Anabsa plains. The comparatively pure sand extends as far as Oued Bon Harira, but further south the colour changes to black, perhaps owing to the abundance of humus. Here and there in the sand, if the clay layer is at all deep, marsh ("merdja") formation is obvious, and this formation is associated with almost the entire coastal area (*merdja rassed daoura*) and in certain portions inland (*merdja marktane*). The marshes are to a large extent dried up in the summer.

Further South, in the mountainous region of Chatba and Djebel Dail, there is a variation of black, sandy, whitish and greyish soil. At Aïn-el-Gsob, certain molluscs have been observed, and varieties of *Pecten jacobus* and *Ostrea* spp. (Pliocene). Dwarf palms are to be found over a limited area.

On the mountain spurs, the black soil extends to within 2 or 3 km of Oued Sebou, where it is replaced by white soil of a very colloidal nature.

CLIMATE. — The temperature of the 'Gharb' is very mild, snow is scarcely ever seen in spite of the neighbouring high altitudes (Dj. Alem. 2300 m.; Dj. Iziren. 2500 m.) The rainfall is fairly regular, and the atmosphere comparatively moist, as a result of the situation of the country near the sea and the N. W. winds.

AGRICULTURE. — The soil in the extreme north is unsuitable for cultivation and only small quantities of barley and sorghum are grown for local consumption. Wheat is cultivated only on the border of small oueds, where alluvium deposits occur. In the Maaref and Anabsa plain, where humus is combined with the sand, melons, water melons, and gourds are grown.

On the Chatba Mts. cultivation is met with only in the hollows of the foothills. On black soils of the Souk-el-Arba and Daouia plain, the chief crop is wheat, and the native activity is more marked. Further south on the Sebou white soil areas, very large tracts are covered with wheat and barley.

As regards the quality of the crops, it is noted that the wheat is frequently very fine on the black soils; durum wheat is rarely seen; the barley is also of good quality but not equal to the wheat. Fungous diseases are rare, rust and smut have been noted in a few instances.

LIVESTOCK. — The chief interest of the native from the agricultural standpoint is bound up in stock raising, more especially in the north. Special attention is paid to cattle raising, and then to horses, sheep and pigs.

*Cattle.* — These are of medium size ; certain remarkably fine specimens exist, particularly amongst the bulls. The colour varies, generally from red to deep black. Stock raisers concentrate their attention both on butcher's stock and working animals ; the first remain inactive in herds. At about 2 years old, the natives proceed to castrate, following a somewhat crude method (" *martelage* ") (doug): they beat the testicles of the animal with a switch, until they are reduced to pulp. The animal becomes feverish for a few days after the operation, and then recovers its equilibrium and fattens rapidly. Only on a few occasions has death occurred as a result of this method. No shelter is given to the animals ; they are merely enclosed in a large dug out (" *asses* "), made in the form of a regular trapezium to prevent escape.

Up to the present, stock raising has been left entirely in the hands of the natives, the Europeans merely purchase the animals and leave them in the care of the natives and take no further responsibility. The following form of contract is in vogue.

" The native takes  $\frac{1}{3}$  of the profits, is responsible for stolen beasts, and if one dies has no right to cut up the animal before the European owner has seen and investigated the cause of death etc. (This latter condition has scarcely ever been included in the contracts between the natives themselves) The European takes  $\frac{2}{3}$  of the profits.

*Milk cows.* — These are of superior quality, and give from 4-5 litres of milk per day. Cows from Southern Morocco are not often transferred to the North, as the change of conditions has a deleterious effect on such animals, the death rate amounting to 60 %. Some difficulty is found in distinguishing northern and southern animals on the market. The natives consider that they can distinguish them by the teeth, but this is doubtful. Certainly on the Gharb markets, these animals are extremely thin.

*Sheep.* — Sheep raising is especially developed on the banks of the Sebou. The animals are well made and stand high, resembling closely the merino sheep, but the wool is much less waved. The wool is generally of quite good quality. When improved, the Gharb breed should prove more profitable even than it is at the present time.

*Horses.* — The animals are of medium size, the colour varies, and no particular colour can be said to dominate. The natives completely misunderstand the castration of horses. Horse breeding is not extensively practised, but following ancient custom all who can afford to do so buy a single horse or mare, and breeding is confined to these strictly limited lines.

In Souk-el-Arba, a remount dépôt exists consisting of 10 Algerian stallions. The native horse is feeble and resembles more the draught-horse than the Algerian type. It is known by the natives as " *caïdai* " or pack-saddle horse.

Further exploitation in horse rearing will certainly be forthcoming, owing to the extensive pasture land in the Gharb area.

*Pigs.* — It appears that even before French influence existed in

the Gharb, pig rearing was a native custom. At present the same method is adopted of confiding the care of the animals to the natives as is with cattle, and a similar division of profits between European and natives. At present, two or three large exploitation schemes are being carried out and pigs are being raised in large numbers, and the future looks decidedly promising.

**TRADE** — Trade has reached a comparatively advanced stage. The chief markets are situated in Lala Mimouna or Jemao and Souk-el-Arba. The cattle trade is most important, although sheep are to a certain extent dealt with. Development in trade is dependent on stock breeding.

**INDUSTRY** — This is almost non-existent in the Gharb. The only purely local industry lies in the manufacture of the *gelabas*.

**POLICE AND LAW** — Two military posts are in existence, at Sebou and Arbaona, situated near Klott. These contain information bureaux from which officials are sent to inspect and control the local "caids", which form the native law courts.

In conclusion, the author expresses the opinion that there is a great future for the Gharb region especially on the completion of the Tangei Fez line as it is one of the most interesting districts in Morocco. Agriculture which up till now has not made any distinct progress should shortly make decided advances provided that energy is shown in the introduction of modern methods.

M L Y

**681 - Agriculture in Sergipe (Brazil). Note from the President, Dr. Jose Joaquim Pereira Lobo (1).** *Mensagem apresentada à Assembléa Legislativa, em 7 de setembro de 1921 ao installar-se a 1ª Sessão ordinária de 1ª legislatura, pelo Coronel Dr. José Joaquim Pereira Lobo, Presidente do Estado* pp 17 + tables 21 (besides text) Aracajú, Imprensa Official 1921.

Note from the President of Sergipe, Dr J J PEREIRA LOBO addressed on September 7, 1921 to the Legislative Assembly, on the occasion of the opening of the 2nd Session of the 14th Legislature, which is concerned especially with the political and economic situation. Certain extracts have here been made of outstanding importance and giving a general idea of the agricultural conditions and hygienic arrangements in this State.

**AGRICULTURE AND STOCK RAISING** — The evident importance attached to agriculture in Sergipe is demonstrated by the export data which chiefly concern farm products.

(1) For Development of Agriculture in Brazil see R June 1921, No 592 R July 1921, No 700 R Nov 1921 No. 1078, R Feb 1922 No 135. Also *International Institute of Agriculture, International Review of Agricultural Economics* Yr XII, Nos 1-2, Rome, Jan Feb 1921, containing an important bibliographical record. The following references are worthy of note. Armand LEDENT *Organisation Agricole au Brésil*, Antwerp Laporte and Doussard 1913 — Notes on institutions established by the Federal Government, in support of agriculture stock raising and agricultural industries — Dr Idelfonso SIMÕES LOPES, *Economical Notes on Brazil* Ministry of Agriculture, Industry and Commerce, Rio de Janeiro, Villas Boas V C 1921 (1d).

In 1918, the exports amounted in round figures to 22 million *milreis* (1 *milreis* = 2 $\frac{1}{2}$  at par); in 1919, 21.3 millions; in 1920, 10.4 millions.

In 1920, 93 % consisted of the following products: sugar (14 625 tons); cotton yarns (1501 t), cotton (770 t); rice (3374 t); salt (17 127 t); skins, salted or dried (245.4 t), sugar comprised 53 % and cotton yarns 31 % of the total value of exports.

Several sugar factories are in existence, the most important being the "Engenho Central de Riachuelo", the third largest in Brazil; — others are stationed at Aracajú, Estancia, San Christovan, Villanova, Propriá, and in addition to these are several other less important concerns.

The Government endeavours to encourage cotton growing (1) by the distribution of selected seed, etc., this crop however owing to the existing cotton crisis, is on the downward grade, and in 1921, the estimated yield showed a decrease of 40 000 bales of 75 kg below the preceding year, that is a ratio of 1 : 3.

The recent visit of the Cotton Commission under the direction of Mr. A. S. PEARSE (2), brought into evidence the excellent quality of the Sergipe cotton, attributed to the length of the fibre. According to the report of the Commission, the "Riqueza" or "Veidão" is the best quality cotton in the State: the fibre is 38 mm in length, strong and superior texture, very resistant to the "lagasta rosea" (*Pectinophora gossypiella*). Seed sorting is practised as a preventive measure against this pest. At present there are 72 ginneries containing in all, 48 sorters and 28 gins for cleaning purposes.

In 1920, 8 cotton fabric factories in the State had utilised 80 % of

(2) See R. Dec. 1921, No 1220 (Ed.)

the production, i. e. some 48 000 bales of 75 kg. To encourage cotton growing, the President has put forward the following propositions: 1) To fix by decree the official types of cotton, handing over the classification to the care of a competent expert, and charging the Inspection of Agriculture with the taxation, the grading and the selection; 2) to exempt for ten years from the tax on manufactures where municipal authorities have installed a first quality hydraulic press capable of reducing a bale of 180 kg to a maximum volume of 0.35 cub. m.; 3) to extend this exemption also for 10 years, and from the export tax for 5 years to the first factory which shall be established in the State for: fine thread (no. 24 and above); English thread, the weaver adapted to these threads, bleaching, tinting, preparation etc., the threading machine, weaver or other up to date method suitable for the manufacture of flannel; the Government being obliged to contribute 20 % towards the expense of installation, and to exempt from the tax on manufactures for 10 years the ginneries which are employed for seed sorting and commercial grading.

*Rice cultivation* is still limited to very primitive methods, and consequently the yield varies from year to year.

*Tobacco, maize and coconuts* hold an important place, and the export of these products steadily increases. It may be estimated that as much as 2647 hl. of vegetable oils were exported in 1920.

The Government encourages the farmer, by the distribution of imported machines and agricultural implements, at cost price and free from customs charges. At the "Centro-Agricola", several crops are on trial: manioc, maize, forage crops, etc. and also at the "Horto botânico". The "Zootechnological Postes" has received a subsidy of 50 000 *milreis* (1920) for improvement purposes, this "posto" is an important asset in connection with stock raising, and is a recognised resort of animal breeders. The export of hides and skins has been on the increase for several years.

*Lines of communication.* — The lack of communication continues to render stationary the economic situation. It appears probable that once the obstructions at the mouth of the river Japarutuba are removed, the immense valley, where the land is particularly fertile, could be utilised; already several factories are established there. This scheme, which has been submitted for approval to the Chamber of Deputies, would render the river navigable, and would keep back the floods, which each year, cause destruction over a wide area planted with sugar cane, and would permit the cultivation of immense areas.

*Education.* — Sergipe State possesses at the present time not counting the numerous free establishments — 271 institutions: the "Athenas Sergipense" a secondary school for boys; the "Escola normal" for teachers providing a course covering a period of 4 years; 7 evening schools for adults. The State Primary schools are increasing slowly; in 1921, in the whole State there were 7855 pupils of both sexes. The illiterate are in the majority. The President proposes to add to the girls' section of the schools, a second year for children who do not

pass on to the normal school for teachers, and who have the wish to qualify in domestic management typewriting, needle work music, etc

*Sanitary conditions* — The population is on the decrease due chiefly to emigration

The sanitary arrangements are still open to much improvement Even in the Capitol itself the drainage system is incomplete and the drinking water arrangements are poor The unfavourable season from the hygienic standpoint is the winter when the marsh fever influenza small pox etc play havoc

In Seigipe as is the case in the whole of Brazil steps are being taken to improve conditions

The President draws attention to the high infant mortality due chiefly to the ignorance of the mothers

I. D

682 — **Notes on the Agricultural Conditions in the Italian Colonies** *Minister delle Colonie Ufficio Affari Economici e Industriali Informazioni Year X No 1 pp 116, plates 6* Rome Jan Feb 1

**TRIPOLITANIA** The Mediterranean has a remarkable influence on the coastal region which possesses a typical maritime climate in the area adjacent to the desert the forces which influence the maritime climate are in opposition with those of the desert climate and a certain modification results Inland it is quite hot and typically desert

Annual average rainfall to 4 mm The fauna is very varied livestock occupy an important position and tunny fishing and the sponge industry are given much attention and are remunerative

The flora is characterised by 1) The date palm and some 5400 plants young and fully developed to be found in the oasis on the coast of Tripoli 2) *Tagura Guita* and *Croguense* 3) the olive which is the sole fruit grown in the non irrigated area now under cultivation Several wild plants either aromatic or with oleaginous seeds or barks utilisable for tannins and dyes are also to be found

Agriculture is the chief industry and the small holder leads the way Cereals table grapes henna, which is largely exported to Algeria the central market for this crop, and olives grown in the coastal plains and in the Djebel are all recognised crops The progress made in olive cultivation the attention given to new plantations and the improved methods of oil extraction have all contributed to increased yield during recent years and the oil production will in future be estimated as sufficient for local consumption The extension of plantations and the further improvement of industrial methods should make it possible in the near future to have a reserve which may be utilised for export purposes

The decree issued by the Government on November 15 1911 provides land concessions under certain regulations Up till now taking into account the minor importance of such land which can be certified is available about 10 concessions have been made of limited area comprising 3000 hectares

Facilities of various kinds are agreed upon by the Colonial Government authorities

Tripoli is the tobacco factory centre and large plantations exist in the neighbourhood

**CYRENAICA** — Temperate climate which permits settlers to enjoy living conditions not unlike those of Southern Italy The average annual rainfall varies from 20 to 6 mm

As in Tripolitana, the fauna is distinctly varied. The livestock is, however, of finer quality, especially the sheep which possess superior wool. The sponge industry is most important, as regards both quantity and quality.

The flora is very rich, and includes all types characteristic of Italian plants especially on the upper plateaux. The plants most abundant are the broom, *Pistacia Lentiscus*, cypress, wild olive, carob and oak. The date palm, except in the oasis of Derna and the palm grove at Bengasi, is less luxuriant than in Tripolitana. The cultivated olive covers a very large area but is not so widely spread as the wild olive to which attention might be given.

Farming is the leading industry in Cyrenaica. The production of cereals is important, particularly barley. In 1919-1920, the yield was about 1 000 000 quintals, of which about 160 000 qx were imported into Italy, for food purposes and for malt, which has taken the place, to a certain extent, of malt previously imported from other countries. Some 150 000 qx were exported elsewhere.

Very few land concessions are granted by the Government in view of the small amount available for the purpose. On the other hand the farmers, either in groups or as Co-operative Societies are in conjunction with the native owners facing the problem of putting to useful purposes the large tracts of first rate cultivable land with easy access to the coast, which is now in possession of the native tribes.

The collaboration of the native tribes with the settlers indicates that the results will be satisfactory.

The facilities and premiums have been arranged and competitions organised in accordance with existing conditions by the Colonial Government with a view to agricultural development and stock raising.

In the north of Gasi el Mugtar on the Tripoli borderland in Butic extensive sulphur deposits are found which are easy to work although situated the surface. The sulphur obtained is usually transported to Bengasi and sold in the local markets. Considerable quantities are exported to Egypt, and employed in the tanning of 'gale' of camels.

**ERITREA** In the plain on the sea level the climate is tropical. In the Upper plateau, the climate resembles that found in temperate regions, with marked differences between the warm and the cooler hours of the day. In the intermediate area, between the plateau and the sea, wide variations in temperature are met with according to the seasons; the days may be subject to torrid heat and the nights are almost as cool as in the upper plateau. On the inland lower plateau the day temperature is equal to and sometimes higher than that on the coastal lower plateau, and the nights are comparatively cool. The lowest average annual rainfall is recorded at Assab viz 25.8 mm, the highest at Addi Ugri, 788.5 mm.

The fauna and flora are very rich and very varied. The doum palm, the broom and even aloes, *Sansevieria* sp. are remarkable for their abundance. Cattle and sheep are numerous, a large majority of the native population devote their attention to stock raising.

The most important industry of Eritrea from the economic standpoint is agriculture, and the flora has great possibilities, considering the geographic situation of this region, and the evident advantages of having both a temperate and a tropical climate. The river reservoirs of Mt Belesa, the irrigation barrages of Zula and Haut-Falcet, are intended to raise the value of land which when irrigated will render these almost arid regions available for valuable tropical crops.

A well-planned exploitation of wild and cultivated fibre plants (agave and *Sansevieria*), camphor, aloes and tan bark plants is being undertaken. Plantations of tobacco and coffee are beginning to give satisfactory results.

The yields from the doum palm which grows wild and vigorously in the Barca valley and its tributaries and in the valleys of the Gasc and the Setit, are exploited to a large extent. The nut from the fruit is utilised in the ivory button industry in conjunction with the American corozo. Agordat and Cheren are the chief trade centres for this article.

The first machinery installations for the stripping of the agave and dealing with the fibre have given excellent results.

There is considerable amount of State Land available especially in the Lower Plateau. Land concession is regulated by special provisions introduced by the Land Organisation approved by Royal decree on January 31 1901 No 376.

All concessions are subject to yearly dues which may be redeemed on certain conditions. Exemptions are allowed to farmers on special conditions.

There have been up till now 176 concessions referring to 17 350 hectares in all.

Sheep and cattle are numerous and constitute an important part in trade of this Colony. The much-valued skins represent alone one of the chief export articles. The preserved meat and slaughter house by-products are dealt with at Sembel (Asmara).

As regards hunting elephants are found in Cunamo and Licazze lions in Assaouta and in Barka. Megrich leopards and panthers hyenas and jackals everywhere hippopotami in Gasc and Setit alligators in several rivers and in the pools of torrents. Large numbers of apes of all kinds and species especially noticeable owing to the damage done to doum palm fruits and tamarisks antelopes wild boars and various types of birds. All these animals are of commercial value in connection with Zoological Gardens in other countries.

Indications of pho phoric and potassic salt formations have been noted in Damabris. **SOMATII AND** On the coastal region the monsoon winds tends to maintain an almost uniform climate throughout the year the daily temperature varies between 22 and 32°C but inland where the effect of the wind is less and the atmospheric humidity low the temperature varies from 15°C during the night to 35°C and even to 40°C during the day.

The average annual rainfall in the more favoured regions of Benadir does not exceed 350 mm. The factor which influences the vegetative development is not the temperature which is equally distributed during the seasons but the water supply dependent on the rains coming from Ubi Chebeli and Djouba and which represents the most valuable asset of the Colony.

The fauna and flora are uniform throughout the region except in the very fertile areas along the Djouba and to a certain extent on the banks of the Chebeli where the splendour of the tropical vegetation is a source of admiration during the whole year. The most common plants are the doum palm the baobab and resinous acacias.

Livestock is the most important industry and half the population almost exclusively composed of natives is thus occupied. The region best adapted to stock raising is in Benadir where the pasture land is luxuriant, and the stock generally allowed to remain in the wild state, except in the district round Ubi Chebeli, starting from Andegle, where only semi-wild. A census taken on February 1 1920, demonstrates that in Benadir only, were 2 101 176 camels 124 461 cattle 1 666 308 sheep.

Native agriculture is of poor quality, and the economic results are characterised essentially, except perhaps in the case of cotton by the production for local consumption rather than for export. The cultiva-

tion of dourah, typical of arid zones, of "uembe", of native cotton, of maize, of sesame of haricots, occupies a good half of the population grouped in villages, on the bank of the rivers Djouba and Chébeli, or in fairly scattered groups in Dafet, Baïdoa, and round Itala.

In Somaliland, the two great rivers should play a considerable part in the improvement of land values, permitting the introduction of tropical crops important from the industrial standpoint, especially cotton, sugar cane, tobacco, sesame and kapok; this however, naturally entails capital and European technical direction, with manual labour supplied by natives, accustomed to the climatic conditions. White men cannot do heavy, outdoor work owing to the climate and to obtain this manual labour without difficulty a successful step has been taken in securing the collaboration of the native element with Italian settlers. In this way, the "Società Agricola Italo-Somali" has found no difficulty in the carrying out of important barrage schemes and utilisation of the waters of Uebi Chébeli for the irrigation of newly exploited areas in the Sidle-Moyen, and plantations will shortly be laid out.

There is plenty of State land available. The concessions are regulated by special provision contained in the Colonial Land Organisation approved by royal decree on June 8, 1911, No. 520. The concession costs demand only the payment of a modest annual rent which may be redeemed. Exceptions are made for certain small holders, who are exempted from payment.

The concessions so far accorded, include just over 5000 hectares. Apart from this, there are numerous tracts of land, belonging to natives, which have already been developed by the Italian settlers.

Just as in Eritrea, the land is rich in wild beasts. Elephants, rhinoceros, buffaloes, are found near the two great rivers, especially the Djouba, also hippopotami, and a large number of crocodiles, numbers of lions and leopards are found in the Balli region, antelopes, gazelles, wild boars everywhere, all of commercial value for parks, circuses, zoological gardens, as well as for their skins.

Fish appear to be abundant and help to feed the coastal population, and after pickling in brine serve as a valuable export product, and afford by products.

G. A. B.

#### EXPERIMENTAL WORK

683 - **Importance of Technical Supervision on Sugar Plantations.** ROSENFELD, A. H., in *The International Sugar Journal*, Vol. XXIV, No. 270, pp. 140-143. London, March 1922.

With a view to securing better yields by ascertaining, under technical supervision, the maximum potential yield, fertilisers, irrigation and drainage requirements etc. of each acre, the Sugar Planters' Association in Honolulu has conducted a very interesting demonstration, and one pregnant with possibilities of super-intensive sugar production. The most outstanding result has been that for the last two years, the cane and long ratoons in this test have averaged 12 tons of sugar per acre, some areas yielding more than 15 tons per acre.

Assurance has been given that these results are neither accidental, nor are impracticable methods employed. These are enumerated as follows: 1) extraordinarily close technical supervision of each acre; 2) in-

tensive fertilisation, through ascertaining the *practical limit* and then applying required amount of fertiliser; 3) very careful irrigation, but no excessive quantities of water; 4) careful decision as to the proper time for cessation of irrigation and ripening the cane before harvesting. The last three on every sugar plantation are to a large extent contingent upon the first, a fact which hitherto has been too much overlooked. Apart from some of the most progressive countries such as Hawaii and Java, real technical supervision of sugar cane plantations has been almost unknown. The reported results in Honolulu should, however, demonstrate clearly the utility of technical care applied to production.

M. L. Y.

684 - The "Office Régional Agricole" in the South of France. — *Bulletin Trimestriel de l'Office régional agricole du Midi*, pp. 1-10. Marseilles, Jan 1922

AGRICULTURAL  
INSTITUTIONS

The agricultural bureaux consisting of a Department Office and an "Office régional" (District Office) were inaugurated on Jan. 6, 1919 (1) for the intensification of agricultural production.

The "Office régional" in the South of France covers the following area: Basse Provence (Bouches-du-Rhône, Var, Alpes-Maritimes); Lower valley of the Rhone, and of Durance (Drôme, Ardèche, Vaucluse and Basses-Alpes); the Southern vineyards (Gard, Hérault, Pyrénées-Orientales) and la Corse, which all together constitute the 8th district.

Headquarter- are established at Marseilles, temporarily at the Hôtel de la Préfecture (Direction des Services agricoles).

The directing committee consists of:— Inspector general of agriculture for the district concerned, two delegates from each of the departmental offices. The Directors of the Agricultural Service assist at the meetings for consultation purposes.

The agricultural offices are corporate bodies and have financial liability.

(1) The law of January 6, 1919 inaugurated the district agricultural offices and the department offices. The former represent each agricultural inspection centre. All possess a single organisation consisting of a council which is expected to meet at least twice each year; before December 15, propositions etc. are put before the Ministry of Agriculture, and further schemes are subject to the decision of the Ministry. Every year, the district office submits a written report concerning all work undertaken and also that carried out by the departmental offices. The Inspector General of Agriculture sees that the decisions made by the various Offices are carried out and surveys the work of the various experiment stations.

The council, in each department, consists of 5 members, 2 at the most occupy the position of "conseiller général", the others represent the principal agricultural groups. The reunion of the Council is held on the convocation of the Prefect. The Council revises its line of activity in accordance with the suggestions made by Agricultural associations. The programme is examined by the Office régional and definite arrangements are made only in conjunction with the ministerial decision. Every year, the Departmental Office presents a detailed report on the work and this is transmitted through the Office régional to the Ministry of Agriculture. Departmental inspection is made by the Director of Agricultural Services in conjunction with the decisions of the Departmental and district Offices.

They have the right to take the initiative as regards improvements in the departments or in the district.

**ACTIVITIES OF THE OFFICE RÉGIONAL AGRICOLE IN SOUTHERN FRANCE.** — The activities of the Office are concentrated on: 1) the co-ordination of the work of the departmental offices, 2) the organisation of district experimental stations, 3) the co-ordination of scientific research etc. in the interests of agricultural progress and the protection of crops in the district concerned

*Co-operation of different branches of work of the Departmental Land Offices.* — Definite steps are taken at the General Assemblies where each of the Departmental Committees present an account of the work undertaken and the schemes in view. The Office régional has up till now directed the Departmental offices along the following lines: organisation of seed testing establishments, distribution of seeds and plants of pure types and well selected, joint control of diseases and pests, inoculation of herds; institution of itinerant lectures (wheat, livestock); reimbursement of losses of animal breeders, participation at competitions and demonstrations with a view to implement improvement etc.

*District Experiment Stations* — The existing number of stations is not less than 30, and they absorb a considerable part of the credits of the Office régional. The work of this Office is therefore clearly differentiated from that of the Departmental Office which concentrates its attention on popularisation of information supplied by the Office régional the experimental work being carried out on a uniform plan though under different conditions. These Stations are concerned with crop production of especial interest in southern France, and with stock raising, particularly sheep and pigs. Their schemes of work are checked by the Office régional after submitting to Committees consisting of 2 members of the Departmental Office interested, the President of this Office, the Director of Agricultural Service, the President of the Agricultural Association, an expert eminently suited to study the question, and the General Inspector of Agriculture for the District.

*Crops.* — Olive-growing in 5 centres: Villeneuve-Loubet (Alpes Maritimes), Le Luc (Var), La Fare (Bouches-du-Rhône), Lédénon (Gard), Pilacanal, Piscialetto and Ajaccio (Corse). M. BONNET, chief of the olive-growing association at Marseilles is appointed as director of this work. The programme is the same everywhere, the study of the best pruning methods, the effect of ploughing and treatment of surface soil, control of collar rot, pests (olive fly etc.), propagation of interesting varieties, treatment of old trees, use of fertilisers, and should the occasion arise, the improvement of machinery etc. in the neighbouring oil mill. Nurseries have been started at Ajaccio, Antibes and Aix.

Fruit growing:— at Solliès-Pont and Fréjus (Var), St. Vallier, Albon and Leveyron (Drôme), Prades (Pyrénées-Orientales), Cabannes (Bouches-du-Rhône) and Ajaccio (Corse). Experiments are in progress to ascertain the variety best adapted to local cultivation, the best manure,

the treatment of both plant and animal pests. Attention is also given to packing, transport and utilisation of the products.

Vine growing:— A National Experiment Station has been established at Montpellier. Stations have also been set up at Saint Marcel d'Ardèche (Ardèche), Sallèles d'Aude, Lafond de Long, Carcassonne (Aude), Gineaux en Camargue, Berre (Bouches-du-Rhône), Roquebrune (Var), le Gard and Ajaccio. A further station will shortly be established at Perpignan (Pyrénées-Orientales). Tests are being made with various stocks for local varieties, grafting, direct production, manure, control of pests.

Market gardening and flower growing — at Avignon (Vaucluse) and Perpignan, and probably shortly at Hyères (Var). Experiments are being made on the best varieties, manures, new varieties, control of pests.

Flower growing is specialised at Antibes. It is intended to establish a centre for aromatic flowers such as lavender in the Basses-Alpes.

Potatoes: at Alboussière (Ardèche) and Volx (Basses-Alpes).

Cereals: — at Maninet near Valence where (Drôme), very interesting results have already been obtained. Experiments are also in progress at Aix (Bouches-du-Rhône), Cuxac-Cabardès, and St. Michel de Lanes (Aude).

*Livestock.* — Sheep: In order to maintain a pure race in Southern France, the Office grants a subsidy for stock upkeep in the special sheepfolds at St. André-en-Quint, for the Quint breed, and in La Bâtie Verdun (Drôme), for the Corse breed and at Ajaccio for the production of Roquefort Cheese. A centre for the Larzac breed is proposed in Hérault.

Pigs.— the Marseillaise breed is being improved at Aix-en-Provence.

Silkworms: At Oraison (Basse-Alpes), experiments are being made in the feeding of silkworms owing to the efforts of M. GRAMER.

The Office régional also undertakes research work of general interest and contributes to the popularisation of motor ploughs, etc., and has brought to the public notice a machine adapted to the oil industry, etc.

As regards propaganda, the Office régional has assisted in the publication of several pamphlets dealing with the district, and intends to organise agricultural conferences illustrated by cinematograph. A central information bureau will shortly be established in Marseilles which should be useful also to the Departmental Offices, etc.

In addition, it has been decided to publish a quarterly Review dealing with the more interesting work in hand, with a summary of the various branches of newly-started work in other districts. P. C.

685 — **The National Agricultural Conference in the United States.** — *Journal of Farm Economics*, Vol. IV, N. 1, p. 61-63. Lancaster, Pa., Jan., 1922.

The National Agricultural Conference, called at President HARDING's request by Secretary of Agriculture WALLACE during the week beginning January 23, served to focus attention of the country on the agricultural situation.

A total of 336 delegates were in attendance, comprising representa-

EXHIBITIONS,  
MEETINGS,  
CONFERENCES

tives of farm organisations, agricultural journals, State agricultural colleges and departments, the seed, fertilizer, machinery, and allied business interests, and agricultural interests generally throughout the country. The intention, as expressed by Secretary WALLACE, was to bring together a group thoroughly capable of passing on the many phases of problems affecting agricultural production and marketing.

The Conference was addressed upon opening by President HARDING.

The first two days were mainly devoted to addresses by agricultural leaders from many sections of the country, presenting the facts as to current conditions and outlining some of the most important needs and problems before the country.

Following this the Conference broke up into twelve committees. For three days committees met, reported, and their reports were debated by the main body.

While the Conference presented a clear-cut picture of the depression which has affected agriculture for the past year, its recommendations were not directed entirely to relief of an emergency as such. Perhaps its most significant work lay in presentation of fundamental economic relationships between agriculture and other elements in the country, and in attempts to formulate some constructive lines of policy with regard to the national welfare.

A considerable number of resolutions were presented in committee reports and passed. In general, however, the outstanding action of the Conference revolved about four main propositions, namely More adequate financing for agriculture ; insistence on cheaper transportation and distribution costs , development of cooperative organization and freedom from legislative restraints thereon , recognition and fair adjustment of the farmer's economic status relative to other groups.

Some of the chief resolutions passed included :—

Enactment of laws, state and national, authorising cooperative marketing

Amendment to warehouse act facilitating the financing of stored crops and better protection of such crops

Better enforcement of State cold-storage laws and the enactment of a Federal Law

Establishment of more Federal standards for farm products

Passage of laws prohibiting inter-state traffic and manufacture of filled milk

Legislation compelling truthful labeling of raw and manufactured products such as truth in fabric bill now pending

Investigation by the inter-state Commerce Commission of the advisability of extending preferential rates to agricultural products for the purpose of promoting foreign trade.

Extension of the provision of the Webb Pomerene Act which provides for combination of concerns for export trade in order to meet competition of consolidated purchasing of other countries

Tariff protection for agriculture equal to that extended to other industries, establishment of tariff board to administer a permanent flexible tariff law with an anti-dumping provision

Importation of potash free of tariff.

Increased support of the International Agricultural Institute at Rome and appointment of agricultural attachés to foreign embassies.

Improved and greatly extended market reports on crops and live stock and the taking of census every fifth year.

Congressional legislation to meet the need for agricultural credit running from six months to three years such as is provided in the recommendations of the Congressional Joint Agricultural Commission; if this form of credits be not made available, the War Finance Corporation should continue to function until such time as may seem necessary and proper.

Amendment of the Federal Reserve Act so as to give Federal Reserve Banks authority to buy and sell notes secured by warehouse receipts covering readily marketable, non-perishable, agricultural staples or live stock, of the kinds and maturity now eligible for rediscount.

Recognition of agriculture, merchandising and manufacturing in the selection of the Federal Reserve Board and directors of Federal Reserve Banks.

Increasing the individual borrowing limit from Federal Farm Loans from \$10 000 to \$25 000

Congressional amendment to the joint-stock land banks so the banks may issue bonds to amount of twenty times their capital.

Extension of the activities of the Federal Farm Loan System so it may include all the commodities which the farmer usually puts up as collateral

Reduction of freight rates immediately to rates effective August 25, 1922.

Federal aid in highway building and farm-to-market roads and continuation of this policy for a definite period, so States may plan adequate cooperation;

The acceptance of HENRY FORD's offer to lease dam at Muscle Shoals, Alabama, and manufacture fertiliser

Retaining all bureaux of Department of Agriculture in that department.

Establishment of a National Agricultural Advisory Council

Appointment of a National and Commission to classify land areas. Determination of a policy of reclamation which shall be coordinate with the need for agricultural land and further economic conditions.

Effective legislation for stopping devastation of forests and a national consciousness of forest problems.

Extension of research work and increase of area devoted to forests

Improvement of rural conditions and farm home life

More research and agricultural educational activities, particularly an enlargement of agencies for gathering and disseminating accurate statistics on production, marketing and economic phases of agriculture in general

G A B.

686 - **The Smithfield Club Show in London and its Lessons.** — I. *Live Stock Journal*, Vol. XCIV, No. 248, pp. 583-593. London, December 9, 1921. — II. VOITELLIER, CH. and GRAN, A., in *Revue de Zootechnie*, No. 4, pp. 299-321. Paris, January 1922.

I. — A comparison between the Cattle Show organised by the Smithfield Club in London, in December 1921, and the preceding shows held there during the last century reveals the great changes that have taken place in English stock-breeding in that period.

According to the reports of the earlier Shows, most of the cattle exhibited were from 10 to 12 years of age, for the breeders found that the animals after having been worked for several years, could be fattened quickly at grass and sold to the butcher at a profit. On the other hand, the cattle exhibited of late years, have been much younger, as it has become customary to slaughter animals between 15 months and 2 years

of age. This change has had no unfavourable effect on the size of the individual animals, or the weight of the quarters: indeed, the chief statistics dealing with these points (published in 1872 and 1908), demonstrate that in the 50 years previous to 1908, the number of butcher's beasts, reckoned by the head of horned cattle, rose 750 000 which represents an annual increase of 200 000 tons of meat.

This shows that it is economical to kill cattle between the ages of 15 months and 2 years. According to some experiments made in the United States shortly before the War, 15 months appears the best age limit, for a greater increase of live-weight with smaller consumption of food can be obtained before 15 months than at any other period of the animal's life.

II. — The Annual Show of fat cattle held in London by the Smithfield Club is justly regarded as one of the most important exhibitions of the results of British Stock-breeding. The authors therefore were anxious to visit the Show in person and study it exhaustively, more especially as some innovations have been made such as making new classes for animals of less than 15 months old. These classes are open to most breeds and to exhibits in the Carcass Division.

The authors examine successively the constitution of the Smithfield Club, its financial resources, the programme of the Annual Show, the organisation of the latter and finally, the lessons to be learned from the Show.

THE SMITHFIELD CLUB was started in 1798, and its statutes have been but slightly altered. At the present time, it boasts of nearly 1400 members of which 350 are Life Members, while the rest pay an annual subscription of one guinea. Its sphere is limited to stimulating competition in the rearing and fattening of animals for the butcher.

*The financial resources of the Club* — These are confined to members' bequests made and profits realised on previous Shows. These revenues only amount to some £500. The Club receives no grant from the Government to defray administrative or exhibition expenses.

The Smithfield Club, on the occasion of its annual Show, is paid by the Society owning the Agricultural Hall a fixed sum in lieu of the gate-money which belongs to the said Society, and in addition a given proportion often amounting to a considerable sum, when the takings exceed a certain figure. They reached £1883 in 1920. To these receipts must be added the entrance fees for cattle and the fees paid for reserved stands by manufacturers of agricultural machines, seedsmen, and merchants taking part in an Agricultural Show, these amount to about £4 000; also the proceeds of the sales of catalogues, which reached £140 in 1920. If the members' subscriptions are taken into account the total sum available for the 1920 Show was £7240.

The Club paid out of this sum all the organisation expenses, the fees of the attendants and judges (£520) and the prizes awarded to exhibitors (£3820). This year about £5100 was given in prizes. In 1920, the budget closed with a profit of £1680.

This proves that official Shows, if well organised and held on premises free of rent, should be no charge upon the State finances.

**THE GENERAL ORGANISATION OF THE SHOW.** — The Smithfield Club Show has been held since 1862 in the same place where it is held to-day, viz., the Agricultural Hall at Islington, a building equidistant from the Abattoirs and from the Smithfield Meat Market.

The animals are not placed in stalls but are fastened to a rail about 3 feet high, so that they can be examined with equal ease both before and behind. The cattle lie on a wooden floor, about 6 in. from the ground and wide enough to allow for plenty of litter behind the cattle; this arrangement has the advantage of preventing the litter being carried away by the feet of the visitors. The Show building remains clean and there is an absence of dust such as rises when the floor is sanded. The feeding troughs, although movable, are fastened to the lowest iron bar.

The sheep-pens, which are also made of iron hurdles, are relatively low; this allows of both sets of animals being seen from the front when the pens are arranged in double rows.

Cards nailed on to small boards are suspended from a rod fixed above the rows of animals at a height of about 10 ft. On the cards are written the class, breed, number, age, in years, months and days, and the live weight of the animals, together with the names of the breeder and exhibitor; to these are attached cards showing prizes gained by the animals. In this way, the Show serves an educational purpose.

The exhibition of dressed carcasses takes place in an adjoining hall. Cards similar to those described above give the net weight of the meat, the weight of the fat, offal, tail, and hide, in the case of cattle, and the weight of the meat, fat, pluck and fleece in that of sheep. The weight of the meat and pluck alone are given for swine.

The dressed poultry are placed on their backs upon a slab with their heads hanging down, so that only the breast and feet are visible, unlike the practice in France. The method of exhibition shows off the breast development better than any other.

**Programme** — This contains two large divisions, the Live Stock Competition and the Carcass Competition respectively. The animals shown alive the first day are slaughtered the second day; the dressed carcasses being exhibited on the third day.

In the live stock division, there are 13 subdivisions for pure-bred animals (to each breed are allotted 3 to 5 places) and 3 subdivisions for cross-bred animals, the total number of classes being 58. The class for young bulls below 15 months old is an innovation. The limit of 15 months, which was the subject of much argument, is still considerably discussed, and a proposal has been made to reduce it to 12 months. All the animals must be castrated before they are 9 months old. In the case of ten breeds, the cattle must be entered on their respective Herdbooks, or have in their pedigree four successive pure-bred males.

**Sheep.** — These animals are allotted 89 classes for 17 breeds and 6 for cross-breeds. As a rule, there was for each breed one class for

sheep born in 1921 and 1920 respectively. The animals must belong to a registered breed and have been castrated before the age of 5 months. The sheep are shown in lots of 3.

*Pigs.* — There are 27 open classes, 16 for 9 pure breeds, 2 for crosses, 3 for piglings weighing less than 45 kg., on for young pigs weighing less than 64 kg. and 5 for pigs of less than 9 months. The latter are exhibited singly, whereas the animals in the preceding classes are shown in lots of 2. The conditions of registration in the Herdbook are the same as those for cattle. The boars must be castrated before they are 3 months old.

In the Carcass Competition, there are 4 classes for cattle, 6 for sheep and 4 for pigs. The classes are as follows :

- bulls, or heifers, of less than 15 months ;
- bulls over 15 months and of less than 2 years ;
- bulls of over 2 years and of less than 3 years ;
- heifers of not over 3 years.

This classification is not advantageous for heifers less than 2 years of age, though they are most valuable animals from the cattle-breeding standpoint.

In the 6 classes of sheep a distinction is made between those born in 1921 and 1920. The competitions are for long-woolled breeds and short-woolled breeds or their crosses respectively.

There are 4 classes for pigs, which are classified under the following heads ; pigs with a live weight of less than 45 kg. ; pigs with a live weight below 90 kg. ; pigs less than 9 months of age and below 135 kg. in weight ; pigs weighing between 72 kg. and 109 kg. and producing the best bacon.

The authors draw attention to the fact that the Carcass Competition is not as important as the Live Stock Competition as the number of classes in the former is smaller and the prices offered are of less value.

Although the conditions requiring registration in the Herdbook or a pedigree certificate are great guarantees against fraud, other additional measures are taken to ensure that the age of the animals shall not be incorrectly given. The regulations empower the Veterinary Inspector and stewards to disqualify any animal whose dentition proves its age to be more than has been stated.

One of the most interesting secondary features of the Show is the exhibition of dressed poultry. They are divided into 24 classes for pure-bred birds and their crosses, thus affording an excellent opportunity of comparing the conformation of the different breeds. The fowls must be plucked, except for the head and neck, they must not be singed, or have their breast-bones broken. The prizes awarded in the poultry division alone amount to £132.

. THE SHOW AS A WHOLE. — *Size of the classes.* — The size of the various classes in each division is almost the same, therefore there is little difference in the value of the prizes offered. When some breeds are more represented than others, this depends upon 5 classes being open to them instead of 3, which, is the usual number.

The large number of sheep in the Carcass Competition is chiefly due to 6 classes being open to them instead of 4 as in the case of the pigs.

After having examined the entry lists of the cattle, sheep, and swine, the authors come to the conclusion that in this Show, as in all other annual exhibitions, the number of animals competing is proportionate to the number and value of the prizes offered and that if the public are to be attracted and satisfied there must be a large number of classes.

*Judging.* — There is no jury. Two judges are appointed to decide the merits of the animals of one or several classes. The names of the judges are published when the programme is issued.

The judges carry out their mission according to their own pre-arranged plan. Should they fail to agree, they may appoint an arbitrator, who is called upon when occasion arises and decides the question and then retires. There are only 4 such referees for the whole Show, one for each class of live animals and one for the Carcass division.

There are thus only 44 judges. The Championship prizes are, however, always awarded in each division by 2 special judges appointed beforehand. They begin their work when their colleagues have finished judging the various classes, but according to the regulation hitherto in force they may not choose any animal as a champion of the classes, or breeds, which has been beaten at the present, or preceding Smithfield Show. This year, however, as in 1907, all the cattle competing for the highest honour of the Show had been beaten on some point, so that this regulation had to be suspended.

This method of awarding the prizes in competitions open to all breeds is much better than the plan formerly adopted in Paris, when a jury was formed composed of delegates from the jury judging the classes. But it entails the organising Committee finding two experts who have no special fancy for any particular breed.

Judging is carried out in the same way in the Carcass Division. Here, little attention is paid to early maturing and yield, the judges marking for quality of meat, proportion of fat, and the best cuts.

*Comparison of breeds and classes* — When examined successively, the various classes of cattle are seen to have very similar characters. They seem all to have had a common origin, or to be nearly related. No doubt there is a large amount of Shorthorn blood in all the animals, or they have been selected to conform to a single ideal: body parallel-piped, short neck, chest projecting, rump line perfectly straight, upper and under lines parallel.

The cattle are rather slightly built, as compared with those of the best French breeds. This depends partly on the fact that none of the animals are over 3 years of age, but also upon the great predominance of cattle of average bulk. The live-weight at a certain age is not the only factor to be taken into consideration even in butcher's beasts, far less in exhibits at a Show.

If the live weights of the animals are compared according to the method adopted in England viz., reckoning the weight at birth as zero, it generally

happens that the younger the animals, the higher is the daily increase in live weight. If the class of bulls of less than 15 months is considered, it is seen that the differences in development are very small between one class and another.

The conclusion reached by the authors is that the Smithfield Club Show brings into prominence the relative reduction in bulk of the English breeds, but gives no means of judging of their earlier, or later, maturity. The only advantage they can discover in the reduction of bulk is the better conformation of the smaller animals. But from the butcher's point of view, heavy beasts entail lower general expenses for the same yield and an equal proportion of fat, they are also more profitable to the Cold Storage Industry, always assuming equal yields and the same amount of fat, than smaller animals. It has also been scientifically proved that the latter require more nutritive elements for their maintenance alone. The large improved French breeds can thus well stand comparison with the English breeds.

The authors say that these observations also hold good for the breeds of sheep and pigs, and their conclusions regarding these animals are the same as in the case of the cattle

The English appear to share the authors' opinion where sheep are concerned and award higher prizes to large, less well-formed breeds, such as Suffolks and Cheviots (provided they mature sufficiently early and are very hardy), than to Southdowns. As the pigs are classified according to age, the development of each breed is best shown by the differences in the weight of the animals

*Carcass competition* — After examining the different classes the authors found that the prizes were awarded to the finest finished animals, whether cattle, sheep, or swine. Very fat animals are not sought after as much as formerly, hence there is no object in producing more than half-fat animals for the butcher. In judging the exhibits at the Show, more marks were given for the number of first-class cuts and the net meat return, than for fatness.

As regards the sheep, since the age of none of the animals in the classes was stated, the observations were limited to their conformation and the quality of the mutton. Southdown and Southdown crosses produce the best shaped legs of mutton with little bone and well-distributed fat.

*Conclusions.* — Although open to criticism on many points, the Show taken as a whole is of the greatest practical utility. It serves the interests of the breeders of pure-blood stock by demonstrating the meat-producing qualities of these animals. The over-fat condition of some of the exhibits may even be justified from this point of view. What appears to be merely a hobby often proves to have more practical bearing than is at first apparent.

In the Carcass Competition, the Show possesses within itself a useful check to any tendency to run counter to the pre-established object, for the value of the dressed carcasses can be as exactly determined as that of the live animals.

The two divisions of the Show are complementary.

## CROPS AND CULTIVATION

- 687 - **Correlation between the Temperature and the Dates of Flowering in New England, U. S. A.** — LYON, C. J. in *Torrey*, Vol. 22, No. 2, pp. 19-20. Lancaster, Pa, April 1922.

AGRICULTURAL  
METEOROLOGY

Results of a series of observations made on the relation existing between the date of flowering of a large number of plants, and the temperature in New England (U. S. A.). The flowering period lasts from March for early-flowering species, till the end of June in the case of late-flowering species.

During the five years, 1917-1921, a positive correlation was evident between the date of flowering and the temperatures from March to June. Early flowering was very noticeable when the temperature was very high (1921), and the contrary effect was evident when the temperature was below the average (1917).

FRANCIS DARWIN arrived at quite different conclusions which contradicted any possible correlation between temperature and date of flowering.

- 688 - **Methods of Studying the Concentration and Composition of the Soil Solution.** — PARKER, F. W. (Agricultural Experiment Station, University of Wisconsin), in *Soil Science* Vol. XII, No. 3, pp. 209-232, bibliography of 27 works. Baltimore, M. D., Sept 1921 (1).

SOIL PHYSICS

A more exact knowledge of the soil solution is desirable for the study of many of the problems of soil fertility and plant nutrition. For this purpose several different methods have been used which may be classified into 3 groups: 1) water extraction method; 2) methods which aim at obtaining the true soil solution; 3) measurement of the solution directly from the soil. Several methods have been employed to obtain the true soil solution such as compression, centrifuging, suction and displacement. The last method consists of packing the moist soil in a cylinder provided with an outlet at the base, and coloured water, ethyl alcohol, or paraffin oil etc. may be used as displacing liquids. In certain cases a combination of the suction and pressure methods was employed with a view to accelerate displacement. Several suggestions have been made for direct determination of the soil solution, such as electrical conduction and freezing point methods.

All these methods have their disadvantages. The water extraction alters the equilibrium in the soil; it undoubtedly has a solvent effect; the results vary with the ratio of soil to water, the time of extraction, the effect of the carbon dioxide content of the water, as show by MIRSCHERLICH.

The pressure method (applying a maximum pressure of 53 000 lb. per sq. in.) is only applicable to finer-textured soils, with a high moisture content and is liable to alter the physico-chemical equilibrium in the

(1) See *R* Feb. 1919, No. 154; April 1920, No. 338. (Ed.)

soil (NORTHRUP). This method requires a complicated apparatus. Even the centrifuge and suction methods are only applicable to soils with high moisture content and only small amounts of the solution are obtained.

As regards electric conduction etc. the results are affected by texture of soil and physical characters.

The ISCHEREKOV displacement method appears to be the most satisfactory and the author has selected this method for comparison purposes.

Glass percolators 2.75 in in diameter and 15 in depth were used ; the bottom filled with a one-hole stopper. A small quantity of coarse quartz sand was placed in the percolator and soil then added. After packing, the displacing liquid was added and maintained at a depth of 2-3 in.

The extracts were made by adding distilled water and stirring in a large mortar for 3 minutes. After leaving 12 minutes, the mixture was filtered through Pasteur-Chamberland filters.

Freezing point determinations were made in the usual manner with a BECKMANN thermometer, and served as a means of determining the direct soil solution and also the concentration of the displaced solution and of the water extract.

Nitrates were determined colorimetrically, calcium, volumetrically, and organic matter by weight.

Ethyl alcohol, methyl alcohol, acetone and water were used by the author as displacement liquids. Ethyl alcohol gave the most satisfactory results and is very easy to test for its appearance in the displaced solution by means of iodoform reaction. The alcohol content in the filtrate possessed a very high concentration owing to the solvent action.

The composition of the soil solution obtained by displacement was not influenced by the displacing liquid used, the change therefore is not affected by the time of extraction.

The concentration of the displaced solution, all things being equal, was found to be inversely proportional to the moisture content of the soil. This agrees with the ISCHEREKOV observations. A comparison between the displacement method and water extraction shows almost identical results, the ratio between water employed and soil being 5 : 1.

As regards the freezing-point method, the results were very different from those obtained by calculation.

The depression of the freezing point has generally been greater than that of the displaced liquid. After numerous and varied experiments, the author concludes that the finely divided material causes this depression, probably due to capillary condition. A similar effect is produced with benzene and nitro-benzene.

Soils and well washed material freed from adherent moisture by centrifuging showed marked and nearly equivalent depressions of freezing point. This indicates that the moisture film adhering to solid particles in suspension opposes to a certain extent resistance to freezing. Depression of the freezing point is to a marked degree independent of

the dissolved material but the hypothesis of BOUYOUKOS and Mc COOR (1) which assumes that a portion of the water in the soils is inactive and does not take part in the dissolving of salts in the soil should not be upheld as the displacement method indicates that all the water in the soil acts as a solvent. Soils with a high moisture content but where the capillary condition is limited, gave results coinciding with those obtained by displacement such results being of practical importance. The author strongly recommends the displacement method which is the least involved and the most exact and which hitherto has been too much neglected. I, V

689 - **Use of Various Culture Media in characterising Actinomycetes.** - CONN H S in *New York Agricultural Experiment Station Geneva N Y Chemical Bulletin* No 83 pp 1-6 Tables (Geneva N Y April 1911)

The actinomycetes form one of the most numerous and interesting groups of soil micro-organisms their colonies may comprise from 40 to 50 % of all the colonies developed on the Petri plates (CONN)

A large number of types occur in the soil and a study of the morphology and chromogenesis permits direct classification

For some time they were grown on ordinary media sometimes on the glycerin agar media. KRAINSKY seems to have been the first to call attention to the fact that media containing no protein are much better adapted to bring out the characteristics of the different species. Chromogenesis is more frequent and more typical and may be of three shades depending on whether the colour is formed before aerial hyphae are produced or in the mycelium or in the media. The animal parasites do not appear to adapt themselves as readily as the saprophytic group to the simple media (without protein)

About 75 cultures were selected from 300 cultures obtained from various different soils. The formula which proved the most satisfactory for continued study was agar-agar 15 gm glycerin 10 cc dibasic potassium phosphate 1 gm sodium asparaginate 1 gm water 1000 cc. This very simple formula gives characteristic and vigorous growth. Cultures which are not distinguishable in this media may be separated in a malic acid or citrate media with glycerin, or in a medium adapted according to CZAPK's formula modified by WAKSMAN

The use of pure chemicals is advised and in exact measurement of the quantities of media employed as the slightest error may have a marked influence on the results. A further study of the media is recommended

690 - **Depth for Sowing Grass and Clover Seed.** WILLIAMS R D (Plant Breeding Station, Aberystwyth), in *The Journal of the Ministry of Agriculture* Vol XXIX No 1, pp 53-60 and No 2 table 1 pp 13-137 London, April May 1922.

Various opinions are held as to the most advantageous depth for sowing grass and clover seeds. To establish some definite basis on which to work

METHODS  
OF  
CULTIVATION

(1) See R 1921 No 597 (Fd)

experiments were made recently in England with the following species (1): CLOVERS: 1) Red (*Trifolium pratense*), 2) White (*T. repens*). — GRASSES: 1) Perennial Rye Grass (*Lolium perenne*); 2) Cockstoot (*Dactylis glomerata*); 3) Meadow Foxtail (*Alopecurus pratensis*); 4) Rough Stalked Meadow Grass (*Poa trivialis*)

Seeds were sown at varying depths in pots, boxes and beds in a light loam, and the selected seeds were tested for germination before sowing.

RED CLOVER. — A comparison of results given, at different depths proved very conclusively that the seeds should never be left uncovered, not only owing to the fact that uncovered radicles of seedlings take a hold on the soil with difficulty, but also because the marked effect on percentage of germination e.g. Pot cultures sown on the surface gave a 52 % germination (14 days after sowing) compared with 88 % at  $\frac{1}{8}$  inch. depth sowings

The best depth at which to sow red clover seeds in light loams appears to be  $\frac{1}{2}$  to  $\frac{3}{4}$  inch. Deeper sowings appear to have a deleterious effect on stem formation during the early stages of plant development. e.g. the average number of stems per plant at about 8 months after sowing, gave 2.2 for surface, 3.0 for  $\frac{1}{8}$  inch depth, 2.6 for 1 inch, and 2.4 for 2 inches. Apparently also, the seedlings are unable to reach the surface when sown too deeply this was proved by experiment, when the percentage of surface seedlings from seeds sown at a depth of more than 1 inch was nil

WHITE CLOVER. — Similar results were obtained when surface sown except that in wet weather, comparatively satisfactory results were forthcoming on saturated soil. The best results, however, under normal conditions were obtained by covering the seeds to a depth of  $\frac{1}{4}$  to  $\frac{1}{2}$  inch. If covered to depths of over 1 inch, only a very small percentage of seedlings appeared to reach the surface, and when they did appear, the seedlings were very slender, and remained etiolated for some time.

Although the seedlings possess smaller cotyledon leaves than red clover and can therefore push their way more easily to the surface, this advantage is counterbalanced by the smaller amount of reserve food material at their disposal which doubtless explains their retardation and marked weakness

PERENNIAL RYE GRASS. — It was proved that seeds should not be surface sown except during a long, unbroken spell of wet weather. The best results both as regards the number of surface seedlings and yields were obtained when the seeds were covered at depths varying from  $\frac{1}{8}$  inch. to 1 inch. In a normal year, it would probably be safer, however, to cover to a depth of  $\frac{1}{2}$  to 1 inch. At depths of 2 in. and 1 in. about  $\frac{1}{3}$  and  $\frac{6}{7}$  respectively of the seedlings failed to reach the surface and the subsequent yields of 21 oz. and 4 oz. of green fodder obtained compared very unfavourably with the 50 oz. given by the 1 inch beds. The deep sowings had also a weakening effect on the seedlings which did eventually reach the surface.

(1) The Latin names have been inserted by the Bureau. (Ed.)

**COCKSFOOT.** — Surface sowing were also disappointing. For field sowing the best depth appears to be about  $\frac{3}{4}$  to  $\frac{1}{2}$  in. A greater depth has proved inadvisable; the number of surface seedlings showed a steady decrease at deeper sowings, e. g. 50 % at 1 inch depth, 16 % at 2 inches compared with 60 % at  $\frac{1}{3}$  inch. This is worthy of special note as cocksfoot is often included with seeds subjected to deeper sowing, and should be started under the most favourable conditions when placed in competition with quicker growing grasses such as the rye grasses. A very deep covering evidently has a detrimental effect on the tillering capacity of the young plant.

**MEADOW FOXTAIL.** — The best time for sowing appears to be either June or July. An interesting comparison of the germinating capacities of meadow foxtail and perennial rye grass in spring and also in summer is made. Apparently the rye grass seeds will germinate equally well during both seasons, but the foxtail will not germinate satisfactorily except during warm weather. That the best results are obtained when the seeds are sown in June or July was confirmed by an experiment in which the seeds were sown weekly from early May to August.

Satisfactory results were obtained from surface sowings in wet weather, but as the seeds are exceptionally light in weight, it is advisable always to cover, so that they may not be blown away. Although the experiments on meadow foxtail are not conclusive, it is considered that the seeds covered to depths of  $\frac{1}{2}$  to  $\frac{3}{4}$  inch will give good results, but that deeper sowings to a depth of 2 to 3 in. will result in complete failure.

**ROUGH STALKED MEADOW GRASS.** — The results indicate that the seeds should either be left uncovered or buried very slightly, especially during wet weather; when the germination was interrupted by a spell of fine weather, the seeds gave better results when very lightly covered eg., about  $\frac{1}{8}$  in. to  $\frac{1}{4}$  in.. The June and July sowings gave superior yields to the May and August sowings. The germination of the surface sown seeds is often delayed for as much as 6 weeks or more, even under normal conditions as regards moisture, but apparently shade and excessive moisture are conducive to good germination results. For instance surface sown pot cultures gave a 61-63 % of surface seedlings under shaded and excessive watering conditions respectively compared with 49 % when exposed to light and 57 % with normal watering.

In order to test the evidence given by the experiments here discussed, field trials designed largely to ascertain the depth of sowing under various operations, and to test the degree of excellence of the stands, were also conducted in 1920-21 and results are shortly to be published

M. L. Y.

691 - **Studies on the Decomposition of some Common Green-Manuring Plants at different Stages of Growth in the Black Cotton Soil of the Central Provinces, India.** — BAL, D. V., in *Agricultural Journal of India*, Vol. XVII, Pt. II, pp. 133-154, tables 8. Calcutta, March 1922.

Owing to the fact that black cotton soil, found throughout a large part of the Deccan (India), is so deficient in nitrogen and organic matter that

MANURES  
AND  
MANURING

green manures are essential, a detailed study has been made of the following factors connected with their application, viz 1) the rate of growth of plants used as green manures, 2) the composition of the plants at various stages of growth, 3) the rate of decomposition of the nitrogenous and carbonaceous constituents of plants at various stages and of different parts of plants i.e. leaves and stems 4) the effect of varying proportions of stems on the decomposition of leaves

Experiments were made with seeds of sann-hemp (*rotolaria juncea*) and dhaincha (*Sesania aculeata*) sown at the beginning of the monsoon. The soil used for both laboratory and pot culture experiments was from the Nagpur farm (1) a typical black cotton soil

From the results obtained it is evident that as the green plants advance in age, the proportion of leaf to stem decreases also the percentages of moisture but the percentages of carbon carbohydrates and fibre increase. There was no appreciable change in the nitrogen percentage.

The following Table shows the results of a detailed analysis of the various samples

*Composition of Green Manure Plants at various Stages of Growth*

Green Manure	Moisture	Ether extract	Protein	Fibre	Ash and sand	Carbohydrate	Nitrogen	Carbon	Organic matter
Sann hemp (1 week growth)	88.5	0.16	2.74	1.81	1.60	5.10	0.44	5.11	9.90
" " (4 weeks " )	82.5	0.27	2.79	5.69	1.80	6.95	0.45	7.84	15.70
" " (8 weeks " )	74.6	0.68	1.99	10.55	2.62	9.66	0.32	11.15	22.88
" " (12 weeks " )	65.0	0.47	2.01	16.56	1.90	14.06	0.32	15.86	33.10
" { " " { " { stem alone }	64.0	0.38	1.44	19.30	1.33	13.55	0.23	16.13	34.67
" { 2 weeks { " { leaves alone }	69.0	0.90	4.42	6.41	2.90	16.37	0.71	13.46	28.10
Dhaincha (1 weeks growth)	89.4	0.19	3.15	0.92	1.57	4.77	0.50	4.48	9.03
" (4 weeks " )	82.6	0.47	3.18	4.68	1.62	7.16	0.51	7.95	15.78
" (8 weeks " )	79.0	0.72	3.13	4.69	2.24	10.22	0.50	9.35	18.76

The earlier the sann hemp is used as green manure the more rapid is the decomposition of its carbonaceous and nitrogenous constituents. This is evident from the data given as regards the total percentage of nitrogen nitrified at various stages of maturity in leaves and stems. The diminution of nitrifiable nitrogen in sann-hemp of advanced age does not appear to be due to any deleterious influence of the stems upon the nitrifi-

(1) Physical analysis, clay 45.62 %, fine silt 21.82 %, silt 10.79 %, fine sand 4.23 %, coarse sand 6.04 %, moisture 6.37 %, calcium carbonate 0.10 % (See B. DALY in The Biological Determination of the Relative Availability of Different Nitrogenous Organic Manures in Black Cotton Soil, *Agricultural Journal of India, Special India Science Congress No 1919, Vol XIV, Pt III*)

cation of leaf nitrogen. As a result of the chemical determinations made in connection with the fibre resistance to the action of micro-organisms it is possible to attribute the reduction in nitrification with advanced age to the increasing amounts of fibre and the consequent comparatively non-available form of the nitrogen content. The increasing amount of carbohydrates, however, very probably exerts some deleterious influence on nitrification, but no definite opinion is given as regards this point. The regular decrease in moisture content with advancing age of the green manure is, however, considered to be partly responsible for the decrease in nitrification.

The nitrogen in the leaves of the sann-hemp is apparently more easily nitrified than that in the stems. During the experiments made, the decomposition of the leaves of mature sann hemp, covering a period of nearly 3 weeks, produced twice as much carbon dioxide as that of the stems. This indicates that when the plant is 12 weeks old, the leaf carbon is more readily oxidised than the carbon in the stems. The slowness of decomposition in fully matured green plants should not be attributed to any effect of the increasing proportion of stems in relation to leaves, but rather to the change in the physical condition of the plant tissues etc. The fact that the presence of stems does not affect oxidation of leaf carbon is indicated as follows —

- 5 gm leaves alone per 100 gm soil gave off 153.1 mg of carbon as carbon dioxide,
- 5 gm stems alone per 100 gm soil gave off 128 mg of carbon as carbon dioxide

With *Sesbania aculeata*, there was no marked decrease in the rate of nitrification of the comparatively older plants, though there was a certain amount of decrease in the decomposition of carbonaceous constituents.

While these results throw some light on the quantitative rate of decomposition of the nitrogenous and carbonaceous constituents of green manuring plants, they also confirm the results obtained in experiments showing that sann hemp of about 6 weeks growth is in a condition to undergo rapid decomposition and so becomes of value to the succeeding crop; the moisture factor should, however, not be overlooked. M. L. Y

692 — **The Effect of Straw on the Biological Soil Processes.** — MURRAY, T. G. in *Soil Science*, Vol. XII, No. 3, pp. 233-259, fig. 1, bibliography of 14 works. New Brunswick, N. J., Sept. 1921.

In the wheat-growing areas to the east of Washington the return of straw to the land constitutes the only practical method of restoring organic matter to the soil, but it is known that this reduces the yield of the succeeding crop.

It was considered advisable to ascertain the reason for this reduction in crop yield, and if possible to devise a method by means of which the straw could be utilised without this drawback.

The matter had already received attention, STÖRMER showed that the addition of carbon bisulphide to a soil treated with straw doubled the yield. VAN SSELHORST and FRECKMANN found that when nitrates

were applied, denitrification was proportional to the amount of straw present, and that lime and sulphuric acid lessened, but did not overcome the effect of the straw on the crop yield. CHIRIKOV and SCHMUK state that on sandy soils calcium carbonate acts in the same manner, and that the injurious effect of the straw is not due actually to denitrification, but to the conversion of nitrates into insoluble nitrogen compounds. BISCHOFF grew mustard and buckwheat and found that on sandy soil the injurious effect of straw was more marked than in the case of clay soils and that nitrate of soda reduced the loss. VON MAY studied the effect of straw on potatoes and suggests that the loss is caused by the fact that microorganisms appropriate the available nitrogen as a source of energy. DORYLAND in the case of oats, found that the addition of straw in large quantities to the soil caused a decrease in the ammonifying power and an increase in the consumption of ammonia and nitrates. These results were due to an increase of microorganisms, favoured by the addition of straw, the same effect being produced by the addition of dextrose to soil.

The author placed soil in glass tumblers containing about 130 gms. and added finely chopped straw in amounts of from 0.1 gm. to 5 % and 0.2 gm. of ammonium sulphate.

The tumblers were kept at a temperature of 20° C. And the work was carried out in duplicate, with controls. Determinations of nitrate content and total nitrogen were made every six weeks.

After 18 weeks, there was a loss in every case in nitrate formation, and a reduction of the original nitrate content, proportional to the addition of straw. When more than 0.9 % straw is present a harmful effect is exerted upon the process of ammonification. At the same time, the total nitrogen remained constant, the nitrates being transformed into organic substances not available to plants. The bacteria increased in numbers, and evidently utilised the nitrates and changed them into more complex forms. The straw also served the bacteria as a source of carbon and the nitrates as a source of nitrogen. The organisms found to multiply in this manner are those usually present in the soil, such as *B. subtilis* and *B. mezatherium*.

Many others were found when straw was present, e. g. *B. siccus*, *B. lactis*, *M. radiatus*, but those normally found in soil predominated. The colonies had a softening effect on agar-agar, probably due to the setting free of nitric acid.

The author isolated a species of nitrifying bacterium capable of liquifying agar-agar in a few weeks.

693 - **The Influence of Wheat Straw on the Accumulation of Nitrates in the Soil.** — SCOTT, H., in *Journal of the American Society of Agronomy*, Vol 13, Nos 6-7, pp 233-258, figs 7, bibliography of 28 works. Lancaster, Pa and Washington, D. C., Oct 15, 1921

The application of straw to cropped land and its apparently injurious effects, indicates lack of nitrogen and led the author to undertake a study of the effect of straw on the accumulation of nitrates in the soil.

The general problem of organic matter and nitrification has occupied the attention of a large number of investigators. The author reviews the literature this subject. WINOGRADSKY and OMELIANSKY showed that glucose and the peptones retarded the activity of the nitrifying organisms at concentrations exceeding 0.025 %; their work being completely arrested by the presence of 0.2 % of these substances.

Small quantities of organic matter did not seem, however, to hinder nitrification. As regards the straw, results are contradictory and depend on the amount applied, the type of soil, the quality of the straw, etc. This accounts for the fact that HILL noted a favourable effect, WRIGHT found that the process of nitrification was inhibited until decomposition was well advanced, and NIKLEWSKY demonstrated that straw has an appreciable effect on the action of sulphate of ammonia and nitrate of soda.

The author carried out an experiment under glass and in the field. Nitrate determinations were obtained by the phenoldisulphuric acid colorimetric method of analysis and parallel determinations were made from time to time using the aluminium reduction method.

In the experiments under glass, straw was applied at the rate of 0.5 and 1 %. In both cases the nitrates disappeared almost entirely at the end of 15 days. At the end of 36 weeks, the soil with 0.5 % straw slightly exceeded the control. If sulphate of ammonia is applied to the straw (0.1 and 0.5 %) for 2 weeks, there is a marked decrease in nitrates, but this is followed by a rapid increase up to a maximum of 2.1 ‰ of nitrates compared with 0.35 for the control, and 0.31 in the soil to which straw alone had been applied.

In the field several plots of equal size were treated in various ways. The soil is a silt loam and straw applied at the rate of 2 and 4 tons per acre had a distinctly injurious effect on the growth of wheat, hindered ripening and reduced the yield except on plots possessing a high nitrate content at the time when the straw was applied.

In one case, the yield was higher than that of the control. Otherwise, when 4 tons of straw per acre were applied and worked into the surface 6 inches, the nitrate content was low in the spring, but during the summer the equilibrium was re-established. At the rate of 2 tons per acre, no effect was observed. Four tons of straw applied as a top dressing reduced the nitrate content the following spring and summer; 2 tons had no effect in the spring but a fairly marked increase of nitrates in the summer. Straw application showed the lowest temperature and the highest moisture content, especially as a top dressing. L. V.

694 - **Experiments on the Season for the Application of Sodium Nitrate and on the behaviour of Leguminous Crops after the Application of Nitrogenous Manure.** — AVANZI, E. (Istituto Agrario della R. Università di Pisa) in *L'Agricoltura Italiana*, Year XLV, Pts. 2-3, pp 1-10. Pisa, 1922

Report of field experiments made on small plots or in frames in the autumn, 1918 to 1921. The crops concerned were: winter wheat, wheat, sugar beet, maize, fodder beet, spring wheat, maize, hemp, spring flax,

[693-694]

millet, sarrasin, haricots, clover, sainfoin, lucerne, beans, lupin, green peas and vetch. In some cases a single application of sodium nitrate was made and in others several applications control plots being kept for comparison, and finally, with others nitrogenous fertilisers were employed. Attention was paid to unusual weather conditions, and in certain cases, an analysis was made of the soil, especially with reference to the nitrogen content. After determinations were made as to the nitrogen percentage of certain crops (leguminous), the ratio was estimated, and when raised to 100 used as the basic index for the control.

From the results taken as a whole, certain conclusions may be drawn, taking into account the conditions under which the experiments were made. With the winter wheat on clay soils, which are poor in nitrogen, it appears that the application of sodium nitrate may be held back with advantage until the time arrives for tillering, which in the area concerned, starts towards the end of the winter. With the spring wheat, no definite conclusions are possible, as no opportunity was allowed for recording the grain weight. It appears, however, from a survey of the yields in general, that the results obtained in the foregoing experiments are justified, as the best results were given when the sodium nitrate was applied at the sowing period and later at the tillering stage.

With maize, the following result was obtained: the yield increased as the application of the sodium nitrate was retarded. It should be noted that the soil concerned was fresh, somewhat light and quite fertile. With forage maize, cultivated in light clay soil and sown early, contrary results were obtained and early applications of the nitrate gave the best results; the highest yield was returned when the nitrate was applied at sowing time.

With forage beet grown on clay soil, the yield was highest, when two applications were made, once at sowing and once as a surface dressing. The yield obtained in this way, although much greater than that obtained when one application only was made at sowing, is far inferior to that obtained when the whole quantity was applied as a surface dressing.

With hemp, results do not agree; but it seems to be advantageous to apply the nitrate twice, as surface dressings. With flax, on the contrary, an opposite effect is shewn.

With leguminous forage crops, it has been proved that the most practical method is to apply in moderate quantities after sowing. Used in larger amounts, the yield tends to decrease, with the exception of clover and sainfoin, but as a general rule, an increase in nitrogen content in the roots and stocks was found. Medium quantities of nitrate have proved useful for all other leguminous crops.

Results indicate that the beneficial effect of sodium nitrate does not apply only to the first crop, but also to the following crop.

There is no tendency to modify the popular opinion with reference to sodium nitrate as a manure, but results taken as a whole indicate, however, that for clay soils, where nitrification is slow and inactive, and

where the loss of nitrogen is less to be feared, the application of sodium nitrate may be hastened opportunely. Even in districts, where spring rains are scarce, the application of this fertiliser may be hastened to advantage, on condition, however, that only relatively small quantities of fertiliser are used, in order to prevent any possible deleterious action caused by drought. It should be noted in such cases that, if an early application of nitrate is likely to result in partial loss, delay may impede its complete utilisation.

The question which concerns the existing relation between green manures (leguminous) and the nitric nitrogen and fixation of atmospheric nitrogen by these plants, is not dealt with to any considerable extent.

These experiments are still in progress both in the field and in the laboratory.

695 - **The Influence of varying Amounts of Sulphur in the Soil.** — LIPMAN, J. G., PRINCE, A. I., and BLAIR, A. W., New Jersey Agricultural Experiment Station, *Soil Science*, Vol. XII, No. 3, pp. 197-207, figs. 2, bibliography of 15 works, New Brunswick, N. J., Sept. 1921 (1)

The senior author has already called attention to the rapid oxidation of sulphur when intimately mixed with the soil, and with McLEAN and LINT has shown that the phosphoric acid of rock phosphate is made available by the sulphuric acid thus formed. Sulphur was also suggested as a means of combating potato scab. It was recognised that the sulphur might have a detrimental effect on soil reactions, nitrate formation and crop yields. In order to obtain more definite information as to the action of sulphur, experiments were carried out in which sulphur was added at the following rates per acre: 200 lb., 500 lb., 1000 lb., 2000 lb., 4000 lb. Each plot had a control to which no sulphur was added. All plots received fertilisers containing 4 % nitrogen, 10 % phosphoric acid and 3 % potash, at the rate of 600 lb. per acre. This was made from dried blood, acid phosphate and chloride of potash. Barley and soya-beans were grown in succession. The sulphur and fertiliser were broadcasted a few days before sowing the barley. Immediately after the harvest, at the end of July, the ground was disked and sown with soya-beans, harvested the 3rd October. Germination was fairly uniform, but as the season advanced there were signs that injury was being caused by the heavier applications of sulphur. The greatest yield was given by the plot to which was added sulphur at the rate of 200 lb. per acre: if this quantity was exceeded there was a decline in yield, until with 4000 lb. of sulphur almost all the plants were killed.

The beans were harvested on October 8: the yield was greater on the plots given 500 lb. than those with 200 lb. of sulphur; this may have been due to uneven distribution of seed. The larger applications of sulphur reduced the yield to such an extent that where the greatest amounts were applied the plots yielded nothing but grass and weeds. The control plots

(1) See. R 1919, No. 193; 1920, No. 397; 1921, No. 25 and 804. (Ed.)

always gave a higher yield than those with sulphur. The detrimental influence caused by the larger additions of sulphur is due to the formation of sulphuric acid. The increase of acidity was shown by determination of the hydrogen-ion concentration, carried out every two weeks by the colorimetric method of GILLESPIE. In the case of plots receiving the heaviest applications of sulphur the pH values varied from 5.6 at the outset to 3.9 — 3.6 at the end of the tenth week.

The plots to which the lowest additions of sulphur were made gave acidity readings quite close to those of the check plots. The results obtained are set out in two very convincing tables. The lime-requirement determinations were carried out by the modified VEITCH method, and showed that a knowledge of the pH values will, in many cases, enable a forecast to be made as to the lime-requirements of a soil.

In the nitrate-determinations the colorimetric method described by SCHREINER and FAHMYER was employed. Attention may be drawn to the low nitrate concentration of the sulphur-treated plots immediately after harvesting the barley. Nitrates were found in considerable quantities in samples from plots that showed the highest hydrogen-ion concentration.

This seems to indicate that nitrification is not necessarily inhibited by a highly acid condition of the soil; a view which, although confirmed by other workers, is contrary to that hitherto held by most investigators.

L. V

696 — **Nitro-Cultures and their Distribution in Canada.** — INGLIS, R. A., (Junior Botanist Central Experimental Farm, Ottawa), in *The Agricultural Gazette of Canada*, Vol IX, No 1, pp. 14-17, fig 1 Ottawa, Jan Feb 1922

In 1915, the Central Experimental Farm in Ottawa undertook the free distribution of nitro-cultures throughout the Dominion of Canada. This Service is too little known and appreciated. The author considers it advisable, therefore, to give a short account of its objects, work and methods.

Amongst the large number of bacteria which exist in the soil, only two or three species are concerned with the problem under discussion. The Leguminosae is an extremely large family, but amongst the crops grown in Canada, which include rather more than a dozen species, all the plants live symbiotically with the organism known as *Bacillus radicicola*, with the exception of soy bean.

This bacillus has, however, developed specific strains, adapted to the inoculation of certain leguminous crops and as a general rule cross-inoculations between these groups do not occur or, if they do, it is only with difficulty. Generally the best results are obtained with organisms belonging to a specific plant on other plants of the same species. The bacteriologist's work does not therefore end with the isolation of the bacillus, but demands classification of the various strains. It is recognised that four groups of bacteria appropriate to 4 groups of leguminous plants are sufficient for the farmer.

I. CLOVER GROUP: including *Trifolium pratense*, *T. incarnatum*, *T. repens*, *T. medium*, *T. hybridum*;

II. ALFALFA GROUP: including *Medicago sativa*, *M. lupulina*, *Melilotus alba*, *M. officinalis*;

III. PEA GROUP: including *Pisum sativum* and var. *arvense*, *Vicia sativa*, *Lathyrus ocastratus*;

IV. BEAN GROUP: includes *Phaseolus vulgaris*, and *P. multiflorus*.

The soy bean *Glycine hispida* is inoculated by a different organism, probably a *Pseudomonas* (LÖRNIS and HANSEN, Jan. 1921), still under observation.

The finished product as it comes into the farmer's hands consists of a corked phial containing a jelly substance, viz. the artificial soil medium with the nutritive substances in solution requisite to maintain the bacteria alive in transit, and a thin layer of viscid transparent slime, which consists of millions of bacteria. Each bottle contains on an average, sufficient bacteria to inoculate about 1 bus. of seed of the particular variety specified by the farmer. These bottles should not be exposed to direct sunlight, which would kill the bacteria, and should not be opened till required for use.

The transference of the bacteria to the seed is effected by washing the slime of the jelly by means of some liquid; sweet skim milk with a little sugar added has proved satisfactory. The seeds are treated with this slightly sticky liquid and are sown when dry. A cloudy day is best for sowing, to avoid exposing the bacteria to sunlight.

The Dominion and provincial agricultural institutions are supplied at their request, with reasonable quantities of culture, within the resources of the central station. Individual farmers are not allowed gratuitously more than 3 bottles each, sufficient for treating some 180 to 200 lb. of seed. Each applicant should state the kind of seed he wishes to inoculate and an approximate idea of the date of sowing, to enable the Station to supply the cultures as fresh as possible. Applicants are requested to co-operate with the Station by sending information as to the results of inoculation. Two reports are quoted which testify to the striking results obtained.

697 — **The Food Plants of the Philippines.** — WESTER, P. I., in *The Philippine Agricultural Review*, Vol. XIV, No. 3, pp. 200-384, plates 35 × 1 map Manila, 1921

The number of food plants in the Philippines, and particularly fruits have been increased very considerably in recent years, partly by discovery of hitherto un-recorded, useful indigenous species, and partly through the introduction of exotics. A revised list has therefore been prepared for reference purposes.

A large collection of economic plants, including also annual agricultural crops, is being made at the College of Agriculture (University of the Philippines), Los Baños, Laguna, and it is expected that within a few years sufficient material will be available for wholesale distribution throughout the Archipelago. The information relative to temperate zone vegetables is

AGRICULTURAL  
BOTANY  
CHEMISTRY  
AND  
PHYSIOLOGY  
OF PLANTS

based largely upon data accumulated at the Trinidad Experiment Station, Bagnio, Benguet, the Singalong Experiment Station, Manila and the Lamao Experiment Station, Bataan. According to recent reports, not including the 20 species of algae and fungi, 121 native species of nutritive plants exist in the Philippines and these in addition to the imported species, make a sum total of 444 species and sub-species, an increase of 76 over the list published in 1916.

Although rice, sugar cane, coconut, abaca, maize and tobacco occupy the first place, there are several less-known crops which are likely become important, e. g. the marang (*Artocarpus odoratissima*) and the bauno (*Mangifera coesia*).

Of the introduced and well-established species of tropical fruits, the coconut, banana, mango, mandarin, chico (*Achras zapota*), lanzon (*Lansium domesticum*) and papaya, are the most important, and the kamote (*Ipomeea batatas*), ubi (*Dioscorea alata*), gabi (*Colocasia esculenta*), mungo (*Phaseolus aureus*) and Cucurbitaceous plants, among the vegetables.

In the list given, which includes a description of each species, from the morphological standpoint, and notes as to respective economic qualities, certain points are of outstanding interest. The large number of species of the genus *Rubus* with edible fruits is worthy of attention, — viz. *R. copelandii*, *R. betulacifolius*, *R. ellipticus*, *R. elmeri*, *R. fraxinifolius*, *R. moluccanus*, *R. nigrobaccus*, *R. niveus*, *R. pectinellus*, *R. rolfei*, *R. rosaeifolius* etc. These are of especial value in plant breeding work, for hybridisation with temperate species with a view to obtaining a superior hybrid fruit adapted to the highlands and medium elevations. The existence of 4 distinct, edible fruited rattans is of interest, as well as the occurrence of 10 *Eugenia*s, 4 *Dillenia*s, and 12 *Garcinia* spp., natives of the Philippines. The maté (*Ilex paraquariensis*), native of Paraguay and Brazil which has adapted itself so readily to prevailing climatic conditions, and which is utilised as a beverage, resembling tea, appears to be an industrial crop of great promise.

It is worthy of note that *Hedyocarpus hutchinsonii*, one of the sources of chaulmugra oil (1), recently discovered to be a specific for the cure of leprosy, is a native plant which occurs fairly abundantly in certain regions. Apart from this species, there are many medicinal and dye plants, trees producing gums and resins and tanning extracts, and also fibre plants which are beyond the scope of this article.

It appears that the Philippines, in addition to being self-supporting from the agricultural point of view, lend themselves readily to an extension of the export of numerous nutritive crops, as well as fresh and preserved fruits of various kinds. Up to the present, the cultivation of certain valuable fruits has been too much localised, and consequently almost unknown in other parts of the country.

699 - Analysis of Fijian Wild Cane (*Saccharum officinarum*) var. (?), Roots of *Cordyline Terminalis*, Exudation from *Myoporum platycarpum*, and some Australian Fruits. - STEEL, T, in *Proceedings of the Linnean Society of New South Wales*, Vol 46 Pt 4, pp 487-491 Sydney 1921 Summarised in *The International Sugar Journal* Vol XXIV, No 280, p 213-14 London, April 1922

I FIJIAN WILD CANE (*Saccharum officinarum* [?]) — No use has up till now been made of the long slender cane known locally in Fiji as «Vico», which grows in abundance on the banks of the fresh water rivers. The author made an analysis of four different samples of the red and yellow varieties and at the same time also of the native cane called 'Anani' and the introduced variety Honolulu

	Sucrose		Reducing Sugars		Other organic Matter		Ash		Fibre		Water		Average weight per stalk in kg	
	%	%	%	%	%	%	%	%	%	%	%	%	kg	kg
Wild Cane														
• Red	3.33	1.68	1.00	1.68	1.37	1.56	1.59	1.30	22.48	18.46	70.89	75.80	0.38	0.61
• Yellow	3.16	3.27	0.97	0.74	1.71	1.58	1.75	1.55	26.15	27.08	66.80	66.38	0.45	0.51
Anani	10.88		0.52		1.73		0.62		15.54		71.52		—	
Honolulu	15.08		0.61		0.80		0.49		11.98		70.52		1.51	

2 ROOTS OF DRAGON TREE (*Cordyline terminalis*) — The roots contain a large proportion of inulin which during roasting becomes transformed into levulose, the roots then become soft and have the appearance of having been soaked in molasses. Apart from their recognised food value in Fiji, in some parts the roasted roots are fermented and a liquor distilled from them. The percentage composition of the roots gave for the raw material and roasted, respectively

	Levulose	Inulin etc.	Caramel etc.	Ash	Fibre	Water	Weight of roots in kg
	%	%	%	%	%	%	
Raw	3.32	30.19	—	0.86	11.59	52.98	1.64
Roasted	38.53	—	10.85	1.00	12.58	38.00	2.08
	40.49	—	6.93	1.26	14.06	38.64	1.30

3 MYOPORUM PLATYCARPUM — A dark brown sugary mass exuding from punctures in the tree made by insects was analysed and contained % mannitol 44.0, reducing sugars 5.4, insoluble, 40.8, ash 1.9 and water 7.9

4 AUSTRALIAN FRUITS — *Eupomatia laurina*, *Ficus macrophylla*, *F. Cunninghamii*, *Ficus rubiginosa*, *Polocarpus elata* and edible fig. On analysis the total sugar content (dextrose and levulose) was found to vary from 0.30 to 13 %, the seeds, fibre, pectose etc 3.40 %, the ash from 0.4 to 2 %

M. L. V.

700 - **Hydrocyanic Acid in Sudan Grass.** — SWANSON, C. O. (Professor of Agricultural Chemistry, Kansas State Agricultural College), in *Journal of Agricultural Research*, Vol. XXII, No. 3, pp. 125-129, tables 18 Washington, Oct. 15, 1921 (1).

In a previous paper the author has shown that hydrocyanic acid is obtained from green Sudan grass (*Sorghum exiguum*) by maceration and digestion in water, but the acid does not exist in the free state in the plant. Freezing which is generally considered to promote the development of this poison, merely bursts the green cells and thus facilitates the liberation of the acid. It was also shown that although in some cases poisoning had occurred, under normal conditions no poisoning took place.

In view of the importance of the question, the author undertook further investigations and adopted the Prussian-blue method of analysis. One objection to colorimetric measurements is the difficulty of obtaining a uniform colour and the precipitate was very often quite green. However, apart from this objection this method is the simplest in practice. Calculations are based upon approximately 200 gm. of green material, not taking into account dry matter. When the plant was wilted or dry, the weight of the sample used was proportionately lessened. The sample was cut in pieces and a part macerated with or without sand. Distillation was made in a dilute solution of potassium hydrate or caustic soda. The proportion of hydrocyanic acid obtained was in every case very small and seldom more than 0.015 %.

Practically all the hydrocyanic acid was found in the leaves up to as much as 67 mgm. per sample, but none was found in well-developed stems. The younger plants contained more than the mature plants (60 mgm) and this may be attributed to stem development. If only the leaves are used the difference is much less, except when the plants approach maturity, and more is found in the summer than in the autumn. It may be assumed therefore that the hydrocyanic content is higher when the plant is in a vigorous growing condition, which confirms the theory of RAVENNA and ZAMORANI who state that hydrocyanic acid is an intermediary product between the nitrates and amino stage, which is followed by the protein stage. The maximum amount of hydrocyanic acid was obtained by maceration and digestion in water in room temperature for about 6 hours. After 2 or 3 days there was a decrease and finally the acid disappeared.

Even after the plant has been cut and during the hay-making, the acid may easily be obtained by the addition of hot water, but liberation of the acid is soon stopped. This change agrees with the above mentioned theory: when the plant has been cut, the absorption of nitrates is prevented and this stops the production of hydrocyanic acid. Certain experiments indicate the part oxygen plays in the phenomenon. Drying eliminates all the acid from the plant and renders it innocuous.

The green plant does not contain the free acid. If hot water or an acid is added no acid is forthcoming. On the contrary, the enzyme action is inhibited which induces the production of acid. Hydrochloric acid (even

(1) See R. Oct-Dec 1919, No 1104. See also No 728 of this Review (Ed)

from gastric juice) paralyses the enzyme action and hence there is no danger with green plants. A similar action results with the alkalis. It should be noted that Sudan grass contains less hydrocyanic acid than sorgho or kafir.

L. V.

701 - **Vitamine Content of Vegetable Oils.** — DRUMMOND, J. C. and ZILVA, S. S. (Biochemical Laboratory, Institute of Physiology, University College, London and Biochemical Department, Lister Institute, London) in *Journal of the Society of Chemical Industry*, Vol. 41, No. 8, pp. 125-127. London, April 29, 1922.

It is a recognised fact that vegetable oils and fats contain a very limited proportion of soluble vitamins or vitamins A, and in some cases the larger number of these oils are completely deficient, which renders them of much less nutritive value than animal fats, especially butter.

The object of the present investigations is to discover whether it is possible to obtain vegetable oils of a comparatively high vitamin value. Although much still remains to be done as regards this question, the results obtained are of interest. The examination has been made on behalf of the Medical Research Council with the assistance of two commercial firms and also the Imperial Institute, South Kensington. The subject of these tests presents certain difficulties, which cannot be dealt with *in vitro*, but only *in vivo*, as the chemical reaction of vitamins is unknown. It has been necessary to employ a large number of animals, such as rats etc.

In a preliminary series of experiments the author tested the vitamin content of various fruits and seeds utilised for oil extraction, in order to discover if they were of low value and if extraction impoverished them. Previous experiments (MCCALLUM, DRUMMOND, and COWARD) gave negative results; further tests were therefore necessitated and twenty varieties of seeds were examined. Animals were fed on rations deficient in vitamin (basal diet) and consequently a hindrance to development, and fixed quantities of seeds were added to see if this would to a certain extent supply the deficit. The interpretation of results was not always easy; for example, certain seeds, such as cotton, have apparently a toxic effect, and this has been attributed wrongly to lack of vitamin.

Taken as a whole, oil seeds evidently lack vitamin A; the vitamin content in the leaves is not transported to the seeds.

Cotton seed and kapok proved toxic; white maize, soya beans, etc., entirely deficient; arachis, sesame, yellow maize etc.; low content; palm kernels, rape; very low; only linseed possessed any appreciable value, as already noted by MCCALLUM; a daily supplement of 2 gm. produced practically no growth; but 4 gm. gave slow but steady growth of the animals tested.

The low vitamin content in oil seeds encourages the idea that crude oils are equally impoverished and it was decided to investigate this question. To avoid oxidation, which might have an inhibitive effect on the vitamin, oil extraction was made by petroleum spirit (b. p. 40-60° C) at low temperature and pressure, the last traces being removed by a current of CO<sub>2</sub>. It appears that the vitamin is carried over into the extracted oils, which

confirms previous observations made by the authors concerning the vitamine content of certain crude commercial oils, although concentrations were invariably low. As a rule 1.3 gm. of crude oil supplied daily to the animals gave a very slow rate of growth. Average butter, on the contrary, at the rate of 0.2 gm. and cod liver oil (high vitamine A content) gave excellent results.

A low vitamine content of refined linseed oil has however been reported. It is not feasible that the vitamine was destroyed by oxidation. Probably a portion still remained with the seed in a form difficult to extract by solvents. The vitamine remains in the seed even after mechanical extraction; in fact the commercial refined linseed oil is deficient in vitamine. The problem requires further study.

The high vitamine value of crude palm oil from the African fruit was shown by DRUMMOND and COWARD and is deeply coloured with carotene and xanthophyll. Certain examples somewhat resemble butter, which recalls the suggestion advanced by STEENBOCK that the vitamine A is associated with pigments of the lipochrome class. This theory is therefore inexact, but it is nevertheless true, especially with many vegetable products, that vitamine A is frequently associated with these colouring matters.

An attempt was made to prepare from crude palm oil a fraction unsaponifiable and it was found that this product possesses a high vitamine content: care was necessary to avoid oxidation during saponification. The authors have not been able to use to any extent this fraction for raising the vitamine value of vegetable oil margarines, since the product was unpalatable. Further investigations are necessary if the unsaponifiable constituents are to be treated successfully in order to obtain a utilisable economic product.

L. V.

702 - **Changes in the Composition of Pepper (*Capsicum annuum*) during the growing Period.** — SIEVERS, A. T. and MCINTYRE, J. D. (Bureau of Plant Chemistry, U. S. Dept. of Agriculture), in *The Journal of the American Chemical Society*, Vol. 43, No. 9, pp. 2101-2104, Easton, Pa., Sept. 1921.

The change in chemical composition of the plant (fruit, root etc.), during growth has very often been studied, and in addition to being an inviting field of research from the scientific standpoint, it possesses also a practical interest, as it serves to show at what stage of growth a product should be harvested in order to assure maximum quality and yield. This is the case with the development of sugar in the sugar beet, sweet potato, sweet maize, orange, citric acid in lemon; volatile oils in aromatic herbs and alkaloids or other active principles in medicinal plants.

Much work has been done on the chemical composition of the paprikas but more especially with the variation between the several parts of the fruit or the effect of the addition of foreign matter on its composition. No systematic study of the chemical changes up to maturity has been made. The author has selected a variety of *Capsicum annuum* L. a large fruited

red and pungent variety (1) and traces the development of the pungent principle at various stages of growth. Six different sizes of fruit were picked: the smallest measured 2.5 cm. length and less, the largest more than 10 cm. The colour varied from green in the first 3 sizes, to dark red in the largest size. The fruits were carefully cleaned and dried, calyxes removed and the dry pods then ground and analysed.

Taken as a whole the total sugar percentage varied only slightly (11.9 to 14.39 %, 5.81 to 8.59 being reducing sugars), which does not show any definite change during ripening. The same may be said of the alcohol extract (from 18.72 to 72.15 %) and the ash (8.13 to 6.78 %, practically all soluble). Ether extract is a fairly accurate measure of maturity (2.14 to 9.18 %), also the volatile ether extract (0.19 to 0.85 %) and the non-volatile extract (1.95 to 8.33 %). In the first case the increase was especially marked at the end of the growing period, rising from 0.24 to 0.85 % between stages 5 and 6, an excellent indication of the stage of maturity. In some cases it will be necessary to use the normal ether extract for comparison purposes.

As a means of determining roughly the relative pungency of the pepper, it has been proposed that the quantity of sugar required to neutralise the characteristic pungency be determined. In the experiments in question, the quantity increased with the development of the fruit; for 0.2 gm of pepper from the first to last stage, from 0.39 to 32.2 gm. of sugar was required. From stage 5 to 6 an increase from 12.48 to 32.2 gm was necessitated.

It should be noted that the maximum value is obtained with fully matured fruit, that is when the colour is dark red, although the colour of the pepper is in reality of no great importance. L. V

#### 703 - Action of Selenium on Plant Growth and Modifications due to Radio-Activity. -

STOKLASA, J., in *Comptes rendus des Seances de l'Academie des Sciences*, Vol 174, No 10, pp 1256-1258 Paris, May 8, 1922

Six different species of plants were under observation viz. *Hordeum distichum*, *Zea Mays*, *Polygonum Fagopyrum*, *Vicia Faba*, *Soja hispida*, *Lupinus angustifolius*. Sodium selenite proved harmful to development at concentrations of  $5 \cdot 10^{-2}$  to  $5 \cdot 10^{-6}$  of molecular weight expressed in grammes, per litre of nutritive solution. This injurious effect increased with concentration. Sodium selenite, used in equal proportions proved far less toxic, and it appears that if further diluted ( $0 \cdot 6^6$  to  $5 \cdot 10^{-5}$  P M), it encouraged plant development, especially with the maize. The injurious effect of selenite was either widely distributed or almost entirely neutralised by radio-activity, supplied in the form of radio-active water at the rate of 0.0000056 mg. of radium per plant per day, in pots containing 3500 cub. m. of nutritive liquid, with  $5 \cdot 10^{-4}$  P. M. of selenite per litre. The experiments

(1) As a rule the *C. annuum* varieties are not pungent and this belongs rather to *C. nutescens*, *C. baccatum*, *C. indicum*, *C. longum*, with small fruits. In Italy they are known as "peperoncini diavoletti" from which the red or Cayenne pepper is obtained. The fruit and powder are also sometimes called by the Hungarian term paprika. (Ed)

lasted for 12 to 15 weeks. As an example, after 99 days, from *Hordeum distichum* was obtained 22.09 gm. organic matter without emanation and 50.03 gm. with emanation.

A similar effect has also been noticed with germination. This may be attributed to the oxidising influence of the emanation which changes the selenite into seleniate, which is less toxic, but the author considers it more probable that other reactions take place which may modify intracellular changes, with or without the intervention of chlorophyll.

To ascertain the dynamic force of radio-activity, it is to be noted that a similar action is exercised by light. Thus, selenous anhydride is much more toxic to plants than sulphurous anhydride, in the present experiments, a dose at the rate of 0.001 : 100 volume, killed all the plants in 1 to 2 hours, whilst the sulphurous anhydride had hardly any effect. If, however, the selenious anhydride is used in the presence of light, it proved less active. At 0.00005 it no longer destroyed the chlorophyll with the same facility and arrested photosynthesis less than the sulphurous anhydride.

The explanation of this fact is simple, light exercises a reducing action on soluble selenium compounds and transforms them into inert colloids (the selenium alone is not injurious to plant growth, as it is insoluble). Radio-activity both favours and induces this protective reaction.

The living cell possesses therefore the faculty, under the action of light and especially under the influence of radio-activity, of reducing and rendering inactive the soluble selenium compounds. The author has carried out experiments to demonstrate these reactions I. V.

704 - **Growth and Correlation in Sea Island Cotton.** — MASON, T. G. (Economic Botanist and Acting Assistant for Cotton Research, Imperial Department of Agriculture for West Indies), in *West Indian Bulletin*, Vol. XIX, No. 2, pp. 214-230, figs. 9, bibliography of 6 works. Bridgetown, Barbados. March 31, 1927.

Investigations undertaken to ascertain the relation existing between growth processes in one part of the cotton plant and other neighbouring parts as a guide to agronomists and plant breeders in future work. The experiments were conducted at the Experiment Station, St. Vincent with a variety isolated by HARLAND, well adapted to the prevailing conditions in St. Vincent. Every possible facility was given for free development and for light to reach the lower fruiting branches. The development of the central axis system of branches was studied in two groups of plants from one of which the vegetative branch systems were removed.

After a brief survey of the arrangement of the branch system of the Sea Island Cotton plant, the author gives detailed notes as to the fate of axis elongation, of node production and of flower bud production for both pruned and unpruned plants, illustrated by curves representing the computed values.

It was found that in all three cases the rate had a distinct tendency to approximate closely to the course of an auto-catalytic reaction. It was clearly shown, however, that the mere correspondence between the observed and computed values could not warrant the conclusion that growth was

After the first choice in the plantation it is essential to select well developed specimens with an abundance of leaves, with blades measuring at least 170 cm. in length. Special attention should also be paid to the flowering period, the final biological phase in the life history of the plant, and late flowering specimens should be noted.

As regards longevity, the following periods have been notified: —

	years
On the plain (red soil) . . . . .	4
On coral reefs . . . . .	10
At a height of 1400 metres . . . . .	6
In the Hawaii Isles . . . . .	7-9
In Cuba . . . . .	15
In the Bahamas . . . . .	6-12

The fibre content varies from 1.8 to 4.8 % and appears to be independent of the stage of maturity of the leaf, age of the plant, etc. With reference to strength of the fibre, determined by traction, out of 5272 trials, it is estimated that a bundle of fibres 20 cm. in length, will resist a weight of 2399 gm. In certain cases a maximum of 4500 gm. has been reached. The strength of the fibre is independent of manurial treatment.

From each selected specimen, 12 to 20 leaves are gathered, weighed and preserved in water until their weight remains constant, that is to say, until imbibition is complete. The fibre is then extracted, dried and weighed, and the weight calculated in relation to the weight of the leaf impregnated with water, assuming the latter to equal 100. The best plants are propagated by means of small bulbs and the ensuing generation should be compared with the mother plant.

707 - **Yellow Stripes on the Leaf a Hereditary Character of Maize.** — DEMEREC, M., in *The Journal of Heredity*, Vol. XII, No. 9, pp. 400-407, figs. 1. Washington, D. C., Nov. 1921.

The zebra striping is not evident at the early stages of growth. It forms part of a group of characters due to a gradual decrease in the quantity of chlorophyll, a decrease accentuated with the age of the plant.

The first symptom is the appearance of yellowish spots; these spread gradually finally uniting to form characteristic transverse stripes.

Specimens of this kind were observed for the first time in the  $F_3$  of "California Rice"  $\times$  "Tom Thumb p. p.". Crossings made with the normal type indicated that the character in question is Mendelian and recessive as regards the green coloration.

G. A.

708 - **Manitoba Wheat in Algeria.** — DUCELLIER, L. (Professeur à l'Institut Agricole d'Algerie) in *Revue agricole de l'Afrique du Nord*, Vol. 20, No. 137, pp. 170-171, figs. 1. Algiers, March 17, 1922.

The various Manitoba wheat varieties have been isolated by the author and kept under observation at Maison-Carrée. They number 15 and belong to 4 species; bearded and beardless; soft bearded and beardless

soft with dense ears, and hard, beardless. The beardless soft wheats with white or red ears predominate.

The chief defects associated with the Manitoba yield in Algeria are the lack of uniformity and the excess of poor and brittle grains which renders the sale difficult in contrast with what happened in France, where its good milling qualities were appreciated.

The Manitoba wheat is suitable for late sowings ; it grows rather more rapidly than the tender Algerian wheats, sown out of season, and from the point of view of quality, the Marquis variety, also isolated by the author, is preferable.

709 — **Experiments with Fodder Plants in South Africa, and their Chemical Composition.** — SKIBBE, A. and SELLSCHOP, P. F. (School of Agriculture and Experiment Station, Potchefstroom), in *Journal of the Department of Agriculture*, Vol IV, No. 4, pp. 338-340, plate 1, bibliography of 5 works. Pretoria, April 1922.

FORAGE CROPS,  
MEADOWS  
AND PASTURES

The various chemical changes which take place as a result of over-drying have a natural tendency to make fodder plants less digestible, and the method of storing and mechanical condition of the grasses affects to a certain extent the availability of the nutrients. This is demonstrated by the analytical data derived from analyses made in South Africa with Kikuyu grass (*Pennisetum clandestinum*) indicating a decided variation in composition.

The authors give a summary of the origin, morphological characteristics, habit, propagation, type of soil required, uses and average yields of the best known forage crops, viz. dhal bean (*Cajanus indicus*), chick pea (*Cicer arietinum*), *Sesbania aculeata*, tick bean (*Vicia faba*), peanut (*Arachis hypogea*), Sudan grass (*Sorghum Sudanese* Stapf) and napier fodder (*Pennisetum purpureum*). The appended Table gives a summary of the cultural methods associated with these crops in a compact and complete form very useful for reference. An equally interesting table shows the chemical composition of these plants, both of the green, and air-dried samples, water-free basis analysis, and of the concentrates obtained through chemical analysis of the seeds.

M. L. Y.

710 — **Lucerne in Tucumán, Argentina.** — SCHVELTZ, T. F., in *Revista Industrial y Agrícola de Tucumán*, Vol XII Nos. 1 and 2, pp. 17-32, figs. 4. Buenos Ayres, 1921.

For several years the "Estación Experimental agrícola" at Tucumán has carried out experiments with different varieties of native lucerne from Mendoza, Prov. of Salta, Catamarca, San Juan, Prov. of Buenos Ayres, Médanos, Santiago, etc. and has introduced varieties from Grimm, Peru, Dakota, Utah, Kansas, Arizona, California, Colorado, Germany, Italy and Turkestan.

In the early comparison trials, the Peru lucerne proved superior to all others and the Experiment Station ordered from Peru in 1919, 15 tons of seed for distribution to farmers, who reported later satisfactory results. In 1920, the introduction of new seeds from Peru became impossible owing to trade restrictions. The Tucumán Station had however succeeded in obtaining a new type of lucerne, quite different from the Peru variety but

of good quality, — well developed, high yield and a frequent cropper during winter, hence the name "alfalfa invernal". A sowing made at the end of July 1919, on irrigated plots gave 2 crops in 1919, from January to December 1920, 99 060 kg of green fodder was obtained from 9 croppings. Under the same conditions Peru lucerne gave 106 160 kg for 9 croppings; Dakota lucerne 90 371 kg for 8 croppings. In 1921 the figures were respectively 8 croppings 100 880 kg, 9 croppings, 85 080 kg, 7 croppings, 90 221 kg, 7 croppings 84 279 kg.

Sown in unirrigated plots early in June 1920, 2 crops were obtained in 1920, and 7 in 1921 growing 69 750 kg of green fodder per hectare. The common lucerne gave 54 800 kg in 5 1/2 croppings.

The Tucumán Station has undertaken the distribution by sale of this new variety of lucerne F D

711 - Grasses of Agricultural Value in Southern Rhodesia. — MUNDY H G, BLACKSHAW, G N and BLACK F V in *The Rhodesia Agricultural Journal* Vol XIX No 2 pp 134 149 tables 1 Salisbury April 1922

PART I — DESCRIPTION AND FIFTH CHARACTERISTICS — For about 12 years the Department of Agriculture in Rhodesia has been making investigations with the object of introducing grasses, which by their hardiness and drought and frost resisting qualities would furnish improved pasture during the winter months. It has been suggested however, that with very few exceptions the better known and more valuable grasses from other parts of the world have not proved satisfactory in Rhodesia. Similar experiments made with African and especially with the more promising Rhodesian species gave on the contrary very encouraging results, 55 native species or sub-species 10 African species (not known to be native to Rhodesia), 10 species survivors of exhaustive trials of recent introductions whose value has not yet been determined, are under observation at the Salisbury Experiment Station.

The authors describe the grasses in such a way as to enable the farmer etc to identify the species which up to the present have proved the most successful and will repay the cost of introduction. The identity of all the species referred to has been established by the Director of Royal Botanic Gardens Kew —

INDIGENOUS Rhodesian Tussock Grass " (*Setaria Lindenberghiana*) valuable for dry lands ' Peuhlonga grass ' not identified botanically, it has never yet flowered on the experimental plots and flowering specimens have not yet been procured, cattle and sheep appear to be very fond of this grass, False Paspalum' (*Bracharia brigantha*) of two types, one broad-leaved and the other fine-leaved ' Swamp couch Grass " (*Hoemarthria fasciculata*), valuable on water logged pastures, " Fine Guinea Grass " (*Panicum maximum*), much liked by stock either cured or fresh (as much as 15 tons per acre has been obtained) Buffalo grass " (*Setaria sulcata*), grows wild in damp and sheltered places and has been found equally successful on dry soils, relished by stock and of high feeding value, " Golden Timothy Grass " (*Setaria aurea*) (= ' Rhodesian Timothy '), abun-

dant on heavy wet soils in Rhodesia; "Red Rhodes Grass" (*Eustachys petrea*), "Antelope grass" (*Echinochloa pyramidalis*), "Tall Couch Grass" (*Cynodon Dactylon*), "Native Paspalum" (*Paspalum scrobiculatum*), "Common Red Top Grass" (*Tricholaena rosea*), "Bristle Leaved Red Top" (*T. setifolia*).

EXOTICS. "kikuyu" (*Pennisetum clandestinum*), introduced 5 years ago from Kenya Colony, and tested on a considerable scale; it is not recommended to leave kikuyu pasture for more than 3 to 5 years. It is especially suitable for sheep and there is no difficulty in getting rid of this grass; Natal Grass (*Pennisetum unisetum*), makes good growth; can be used as hay; during the rainy season, it reaches a height of 4 to 4 ½ ft.; "African Star Grass" (*Cynodon plectostachyum*); moderate resistance to drought and frost, "Perennial Canary Grass," recommended, high feeding value, little affected by frost, requiring however good land and irrigation, "Upright Paspalum" (*Paspalum virgatum*), grows to a height of 3 to 4 ft., somewhat coarse and like other similar species, subject to ergot; "Rhodes Grass" (*Eustachys gayana*), good results if irrigated and in India it has given excellent results as irrigated forage.

PART II. -- CHEMICAL COMPOSITION OF GRASSES. — Analyses of 24 grasses grown on a red loam at the Agricultural Experiment Station, Salisbury, have been made at the Chemical Laboratory of the Department of Agriculture. Some of the more important results are shown in the following Table. The samples were taken before and after flowering.

Name	Moisture %	Fats (ether extract) %	Crude protein %	Carbohy- drates %	Crude fibre %	Ash %
AIRDRIED SAMPLES.						
<i>Panicum maximum</i>	10.04	1.61	10.94	36.04	32.60	8.77
<i>Setaria sulcata</i> . . .	9.81	1.91	13.31	37.80	27.38	9.79
<i>Setaria aurea</i> . . .	8.30	2.62	14.12	36.74	26.73	11.49
<i>Brachiaria brizantha</i> .	9.48	1.95	10.25	35.79	33.07	9.46
<i>Eustachys petrea</i> . .	11.25	2.98	10.25	39.46	28.25	7.81

[121]

712 - *Pennisetum purpureum* as a Forage Crop. — BRÜNNICH, J. C., in *Queensland Agricultural Journal*, Vol XVI, No 1 fig 1, pp. 6-8. Brisbane, 1921.

The Australian farmers have recently proved the value of Elephant grass or Napier grass (*Pennisetum purpureum*) as a forage crop. This plant is a native of Africa which crops heavily, and is very resistant to drought and has apparently an excellent nutritive value at all stages of development.

In order to confirm this reputation the author examined a number of samples collected in various districts and at different seasons. The results of the analyses indicate clearly that only the young plants should be considered as fairly good quality forage, and that the feeding value becomes less with age and is very low when finally mature.

With *Pennisetum* as with the larger proportion of Australian forage plants, the protein content is low, and as the proteins constitute the essential element in meat production, it is advisable to supplement this feed with a certain quantity of concentrated foods, such as bran, cottonseed cake, etc.

All the samples examined were tested for hydrocyanic acid, but the results were invariably negative. As regards this question, attention is called to the fact that other forage plants (*Sorghum* spp.) possess a hydrocyanic content at certain stages of growth (1) and that generally the toxicity decreases to a considerable extent with age.

E. F.

#### FIBRE CROPS

713 - Experiments in the United States with Meade Cotton, the Upland Long Staple Variety to Replace the Sea Island Variety. - MELOY, G. S. (Bureau of Markets) and DOYLE, C. B. (Bureau of Plant Industry), in *United States Department of Agriculture, Bulletin* No. 1030, pp. 1-24, tables 5, pl. 10, bibliography of 14 works. Washington, D. C., March 10, 1922.

Owing to the spread of the boll-weevil (*Anthonomus grandis*) in the south-eastern United States, the production of the valuable fibre obtained from the Sea Island cotton has been on the decline. The late maturity etc. render this variety peculiarly susceptible to attack, and although experiments have been made to develop earlier strains, no practical results have been obtained.

The value, however, of a new variety of the Upland type has in recent years been clearly demonstrated. The early-maturing long stapled variety "Meade" has given promising results and where definite comparisons have been possible it has produced at least twice as much as the Sea Island cotton, and appears to be comparatively immune to boll weevil attacks. For example — in one badly infested area, the Meade yielded at the rate of 1499 lb. of seed cotton per acre and the Sea Island at the rate of 501 lb. Similar results have been since obtained elsewhere in the States.

The production and maintenance of an adequate supply of pure seed has been found to present difficulties. Communities of farmers are being encouraged to co-operate with ginners to provide the necessary facilities for dealing with these difficulties, and the question is receiving careful attention.

(1) See No 700 of this Review (Ed.)

During 1920, a publicity campaign was conducted in Georgia (1), which has gone far to increase the popularity of the Meade cotton.

Spinning tests of the Meade fibre in comparison with both the Sea Island and Egyptian cottons have shown that the difference between these fibres, especially in the finer yarns is so slight as to be practically negligible. Although the percentage of waste for Meade fibre is somewhat higher, this may be overlooked, as the waste may be reduced by slight adjustments made in the spinning machinery.

M L. Y.

714 - **The Behaviour of Pima Cotton when Grown under different Conditions of Soil Moisture and Available Plant Food in the United States.** KING, C J (Office of Biophysical Investigations) in *United States Department of Agriculture, Bulletin No 1018*, pp 1-21, tables 8, bibliography of 21 works Washington, D C, March 15, 1922

Although the experiments conducted in Arizona U S. A. do not suggest a satisfactory method that can be recommended for general practice, the author considers that some of the resulting data are of sufficient importance as to be worth recording for the use of other investigators and the public in general.

These experiments were made in Phoenix (Ariz) on a heavy clay loam with a subsoil of coarse sandy loam, inter-spersed at a depth of 5 to 6 ft with calcareous material. Plot I was irrigated at intervals with a view to maintaining during plant development a constant supply of available moisture at the rate of an approximate increase of 7% in the upper 2 ft of soil. Plot 2 was irrigated shortly before the exhaustion of all available moisture in the upper 4 ft soil, at the rate of 5½% increase and Plots 3 and 4, were irrigated when this applied to the upper 5 ft of soil at the rate approximately of 4% moisture increase.

To determine whether the supply of plant food was in any way correlated with the water requirement, cottonseed meal and 16% acid phosphate was applied to plot 4 at the rate of 500 lb per acre.

Judging by the results obtained it was ascertained that there is apparently no relation between soil-moisture conditions and the period of boll development. In addition the data indicate that the heavy application of fertiliser containing 10% available phosphoric acid had a negligible effect on the rate of maturity.

There appears to be an important relation between the increase of shedding rate (based on the number of bolls available for shedding) during the first two months of the flowering season, and the gradual reduction of the moisture content in the sub-soil. The mean interval between the opening of the flower and the completion of shedding was approximately 10 days, but this varied with weather conditions.

Plants watered soon after the first flowerbuds began to form, and then at frequent intervals, produced a greater stem growth and number of flowers during the first 45 days of flowering than plants which received water 16 days later. Plants on soil watered sparingly throughout the seas-

(1) See, 'Meade Cotton', published by the Georgia Breeder's Association (1920) (Ed)

on produced a larger number of bolls late in the season than when water was applied in larger quantities. By October the highest "potential seed-cotton production" per plant was on Plot 3, while the highest actual yield was obtained on Plot 1.

The data indicate that attention should be directed to the fullest possible stimulation of comparatively early fruit setting, especially where there is a tendency to early frosts, as the number of bolls set during this period largely determines the extent of the crop. There are indications that an internal physiological reaction results from prolonged lack of water in the plant tissues, which tends to inhibit their response and recovery under favourable conditions during later development. M. L. Y.

RUBBER GUM  
AND  
RESIN PLANTS

- 715 - Rubber Content of North American Plants. Special Investigations with the *Asclepia* spp. and *Apocynum* spp. - HALL, H. M., and LONG, F. L. In *Carnege Institute of Washington, Publication No. 313*, pp 1-65, tables 14, plates 3, bibliography of 19 works. Washington, D. C., 1921

The purpose of the investigation was to make a preliminary study of the rubber content of various North American plants from the point of view of scientific interest and to find if possible, some latex plant sufficiently promising to justify cultivation as a rubber producing crop. The present studies here reported are concentrated chiefly on the value of *Asclepias* (Milkweeds) and *Apocynum* spp. (Indian hemp), and similar plants in which the rubber occurs in the form of emulsion in the latex. The work described in this paper is a continuation of the survey begun as a war emergency project under the State Council of Defense in California (1), which centred especially round the rubber value of *Chrysothamnus* and *Haplopappus* spp. (the rubber in this case, however, occurs in the form of solid particles in the plant cell, and not in the latex).

Altogether some 225 North American species have now been examined and a record made as to the presence or absence of rubber in their tissues. About 6 species of shrubs and 16 species of latex-bearing herbs are considered worthy of further study and experiment.

The authors gives a resumé of earlier investigations made, but considers that with the exception of *Castilla* and guayule (*Parthenium argentatum*), former researches have not obtained sufficiently definite results to establish an estimation of the respective rubber value of the various species examined. The present investigations here reported, have, however, extended the work to diverse species and to other ecologic and genetic forms of the species examined hitherto, and a much more definite basis for further work and possible cultivation of certain species, has been established.

The acetone-benzene method of analysis was employed; the rubber percentages determined represent therefore, material practically free from resin or other admixtures. The data are based upon the dry weight of the material analysed.

(1) HALL, H. M. and GOODSPEED, T. H., Rubber Plant Survey of Western North America. *University of California Botanical Publications*, No. 7, pp. 159-178, 1919. (Ed.)

*Asclepias* spp. — The perennials described die down near the base each year, new shoots appearing at the beginning of the following growing-season. These are distinct from the milkweeds with woody stems.

The plants grow rapidly from seed and from portions of the root, and it should be noted that the plants are found to have made good growth on land considered so poor and dry that it is not at present utilised for cultivation purposes.

The plants examined appear to contain a much higher percentage of rubber in the leaves than in the stems or roots. The one exception was a nearly leafless desert milkweed (*Asclepias subulata*) the stems of which contain from 2-6.4 %. This is a species of outstanding promise. Others considered of special interest owing to the rubber content of their mature leaves are :

*Asclepias brachystephana* 2.1 to 2.9 %; *A. californica* (= *Gomphocarpus tomentosus*), 2.6 to 4.3 %; *A. galioides*, 0.6 to 5.2 %; *A. latifolia* (= *A. jamesi*), 2.0 to 3.8 %; *A. mexicana*, 1.4 to 4.8 %; *A. speciosa*, 1.0 to 3.0 %; *A. sullivanti*, 1.2 to 8.1 %; *A. syriaca* (= *A. cornuti*), 1.1 to 4.4 %.

*Apocynum* spp. *A. cannabinum* (Indian hemp) and *A. androsaemifolium* (Spreading dogbane) showed on an average from 0.7 to 5.1 % rubber content.

In addition to the above-mentioned species, 6 others are reported as worthy of consideration, although perhaps not of equally high value, viz. *Acerates auriculata*, *Asclepias criocarpa*, *Asclepiodora decumbens*, *Cryptostegia grandiflora*, *Jatropha cardiophylla*, *Hymenocys floribunda utilis*.

In every case the authors give full details concerning the morphological characteristics, distribution, and ecology of each species.

An additional list is given of species of latex plants with comparatively negligible quantities of rubber; but certain individual plants, amongst them contain a sufficiently high percentage to encourage further investigations.

Special attention has been given during the 3 years devoted to the studies here described, to the extent and cause of the variation in rubber content of the *Asclepias* spp. It has been ascertained that taking into consideration the evident numerous existing strains, it should be possible to develop those with the high rubber content, by breeding and reproduction. Detailed studies were carried out with several species to determine the presence or absence of a correlation between the age of the plant and its rubber content.

Results indicated that the total amount increases as the plant matures and decreases later, or, in the case of stems, as lignification sets in.

*Properties of the Rubbers.* — The product obtained from *Asclepias* and *Apocynum* is considered as true rubber with only a small admixture of resins, fats, etc. Rubber prepared from the latter is probably superior to that from *Asclepias*. No thorough test has, however, yet been made of the rubber from either genus. The collection of material for the purpose of rubber extraction to permit of extensive tests, is now being undertaken.

*By-products.* — These in the form of fibre and paper pulp have been obtained from the residue after the extraction of rubber.

No opinion is expressed regarding the financial results that might follow from an attempt to grow the plants on a commercial scale. The author considers, however, that considerable scientific experiment should precede any such attempt. Sufficient data have now been accumulated to justify the recommendation that these experiments be now undertaken. In this connection should be considered those native shrubs in which the rubber occurs as solid particles and also various exotic shrubs and herbs, as well as indigenous species of *Asclepias* and *Apocynum*.

Up to the present the desert milkweed, *A. subulata* offers the best possibilities. This perennial grows rapidly on neglected areas, gives large yields which can be handled almost entirely by machinery, reproduces after cutting, and yields a paper pulp of better quality (43 % dry fibre and 28.5 %, bleached paper) than that from other species.

Much more extended and detailed investigation will be necessary before anything definite can be ascertained as regards the possibilities of these plants as agricultural crops, but the desirability of instituting further studies has most certainly been established.

M. L. Y.

716 — **Cover Crops on Young Rubber Plantations in Malaya, and the Advantage of Growing *Centrosema Plumieri* (Butterfly Pea) and *Mimosa invisa* (Giant Mimosa).** — SPRING F. G., in *The Agricultural Bulletin of the Federated Malay States* Vol. IX, No. 3, pp. 169-171 + 1 fig. Kuala Lumpur, July, Aug. and Sept. 1921

The growing of cover crops in young rubber plantations is at present receiving more attention in Malaya than it has ever done in the past, owing to the difficulties attached to clean weeding, etc. Certain objections are raised to the cover crop system, but the author considers that to avoid the difficulty of detecting harmful weeds growing amongst the cover crop, careful selection should be made of a suitable crop which should provide plenty of shade on the surface, but should not be tall-growing or woody in habit. In this way the extra cost of weed eradication etc. could be avoided. The objection raised as regards the spread of *Fomes* sp., root disease of rubber etc. and difficulties of inspection work, has been dealt with in conjunction with the Government Mycologist who states that unless diseased timber is to be found in a particular area the spread of fungous diseases will not be influenced by intercropping. Bad attacks of *Fomes* are merely local and need not be taken into account in dealing with the question as a whole.

In bringing out the obvious advantages of growing suitable cover crops, the author emphasises the fact that surface wash of soil is prevented. Hitherto the damage done by soil wash can hardly be over-estimated. The combination of this property of the cover crop with its utility as a subsequent green manure is of undoubted importance.

As regards the selection of cover plants, the two dwarf growing plants Giant Mimosa (*Mimosa invisa*) and the Butterfly pea (*Centrosema Plumieri*) are considered to be the most suitable for Malayan conditions.

*M. invisa*, is a remarkably strong growing plant and provides excellent shade over the ground. This will thrive where *C. plumieri* would prove a total failure. It has a beneficial effect on the physical nature of both light and heavy soils, and has been successfully used as a check for weed growth and in the eradication of the most injurious weed the "lalang" (1). Sowing is at the rate of about 2 lb. per acre and afterwards attention is limited to weeding at the early stages of growth, and thinning out round the base of the rubber trees. In Sumatra the crop is kept low by beating periodically with sticks.

*C. plumieri*. — This plant develops a large number of nodules on the roots and therefore serves also as a suitable green manure as well as a cover plant. About 4 lb. of seed are required per acre. Later the plant requires no further attention than the *Mimosa*. Although by nature a climbing plant, no difficulty is found in keeping it away from the rubber trees; when it is established, it will continue to thrive when the rubber is in bearing and there is no need to eradicate it when the tapping stage is reached.

It has been reported that *C. plumieri* does not thrive in wet or low lying situations. This plant is a prolific seed producer, and, if a relatively small area is planted, very shortly sufficient seed is obtained for planting comparatively large areas. The seed can be stored for several months without injury to germination. Although effective as a preventive of soil wash, the plant can only be cultivated with difficulty on eroded surfaces, and demands whenever possible a good top soil.

In addition to these two crops, it is noted that the Sarawak bean (*Dolichos Hosei*) and the horse gram (*D. biflorus*), have proved useful. The former does extremely well on light clays and soils with a good proportion of humus. This low growing leguminous creeper has done well amongst coconuts. It is always propagated from cuttings planted 3 ft. apart. *D. biflorus* has been used with advantage as a green manure but is not recommended as a cover crop as it occupies the land for a limited period only.

Several other leguminous creepers have been introduced into Malaya, but apart from their utility as green manure, their suitability as permanent cover crops is very questionable.

717 - Germination and Preservation of Sugar Cane Pollen. — VENKATRAMAN, T S, (Government Sugar Cane Expert), in *Agricultural Journal of India*, Vol. XVII, Pt. II, pp. 127-132 + 1 plate Calcutta, March 1922

SUGAR CROPS

After numerous unsuccessful attempts to germinate cane pollen in artificial culture media, attention has been directed to growing the grains on live stigmas in the field, and the experiment was extended to stigmas other than sugar cane. After a series of trials, the stigmas of the following plants gave satisfactory results:—

*Datura fastuosa* var. *alba*, *Carica Papaya*, *Hibiscus vitifolius*, *Gynandropsis pentaphylla*. Ultimately *Datura* was selected as the standard and gave the most satisfactory germination; the flowers are also easy to

(1) *Imperata arundinacea*. (Ed.)

emasculate, the stigmás are ready long before the anthers open, and the stigmás remain in condition for a sufficiently long time when the bases of the flower-stalks are kept in water.

Details of the method adopted for testing viability are described.

As regards the preservation of sugar cane pollen, experiments showed that, if the pollen is kept in a moist atmosphere but with free access to the open air, it keeps viable for only a short time 1-3 hours, after which it loses vitality. Pollination should, therefore, be carried out as quickly as possible after the pollen has been collected.

A method is described by which sugar cane pollen could be preserved in a viable condition for as long as 11 days. M. L. Y.

718 - **Sugar Cane Varieties in Porto Rico** (1). - EARLE, F. S., in *Journal of the Department of Agr culture of Porto Rico*, Vol. V No. 3, pp. 1-141, bibliography of 23 works. San Juan, 1921.

The cultivation of sugar cane varieties especially adapted to certain soils and conditions, resistant to disease etc. is of ever-increasing importance. The excessive attention paid by sugar cane investigators to the discovery of new seedling varieties has led to the setting aside of old and hitherto important kinds, which cannot be regarded as advantageous. The author emphasises the desirability of continuing to test the older varieties until the adaptability of new seedling varieties to local conditions has been fully established.

In a previous paper (1) the author gave a description of different varieties of cane from the standpoint of their cultural value and characteristics. In the present article additional data are given for varieties already described, and others are also discussed and a brief outline is given of the history of cane varieties in Porto Rico. A paper entitled "An Annotated List of Sugar Cane Varieties" (*Journal of the Department of Agriculture of Porto Rico*, Vol. IV No. 3) which contains an alphabetical list of all the names applied to varieties in different parts of the world, was prepared as a part of this series of studies. This synonymous study has served to clear up a number of uncertainties as regards nomenclature.

The prevailing idea that old existing varieties are subject to deterioration in quality as been upset. The Caña Blanca or Otaheite cane has been quoted as an example but it has been proved that this variety described as "degenerated" grows on virgin land with its old vigour and that the failures recorded were attributable entirely to soil deterioration etc. Deterioration should not therefore be considered an inherent characteristic of cane varieties. This inherence does not, however, imply immutability and it is unfortunate that less attention has been given to the improvement of *existing* varieties through the selection of bad variations etc.

The Insular Station has recently carried out a considerable amount of chemical investigation to determine the effect on the sugar content of

(1) See *R* Jan 1920 No. 52 (*Ed*)

the juice, produced by the flowering and subsequent growth of the axillary buds. The results of the analysis of samples taken at different stages from a number of varieties show that on an average the flowering cane gives about 1 % more sucrose and 2 % higher purity than the non-flowering, and the percentage of reducing sugars is also appreciable less. These differences appear to be more marked early in the season. The conclusion is therefore drawn that flowering is not desirable in late varieties, nor in fields reserved for late cutting, but it is clearly of advantage for early canes.

The question of ripening in connection with prevailing conditions is considered and the effect of certain cultural methods. After cutting, it has been proved that cane deteriorates much more rapidly than when still standing in the field and the lack of attention to this fact has resulted in serious and unnecessary losses. The importance also of a comparative study of the keeping qualities of different varieties of cane is emphasised, and in this connection, the question of 'long ratooning', i. e. letting the ratoons from late spring harvesting remain until the beginning of the second succeeding harvest, thus allowing 20-22 months growth. The enormous yields so often reported from Hawaiian with yellow Caledonia var. have all come from these old canes, representing two seasons' growth. This question as regards several well established varieties requires careful consideration and study.

Details (and a key) are given for the different listed varieties both from the botanical and agricultural standpoint, and also for their economic value. The kinds mentioned in this list are adapted to any type of good cane land and may be planted either in the autumn or spring except when otherwise notified.

719 - **Tea Seed Production of Java and Sumatra.** — *The Dutch East Indian Archipel*, Vol. IV, No. 21, p. 222. Buitenzorg, Jan. 10, 1922.

In Java and Sumatra there are about 180 tea-seed nurseries belonging to some 134 owners. Together they cover an area of about 500 hectares and contain more than 630 000 seed plants. The majority are situated at a height of 1000 to 4000 feet, many seed-nurseries were laid out during the years 1901 to 1913. The 630 000 seed plants produced 8 600 maunds of seed in 1917, and when the nurseries have arrived at their full capacity for production this figure will have risen from 12 000 to 21 000 maunds, a figure which will probably be reached in 1923.

The import of seed from British India which amounted to 8 200 maunds in 1912-13, fell to 339 maunds in 1919-20, and now that there is no question of extending tea estates, the demand for seed is naturally very small. Demand is sure, however, to increase with the return of more prosperous times, but the large imports of former days can no longer be expected, and Java and Sumatra will probably have a considerable over-production of tea-seed.

The Tea Experimental Station is helping planters to lay out seed nurseries on a scientific basis. Generally the plants are too close and it is advisable to plant seedlings about 6 feet apart and to thin them out later.

STIMULANT,  
AROMATIC,  
NARCOTIC AND  
MEDICINAL  
PLANTS

Pruning should be judiciously done and moss and weeds removed, while digging, and manuring are generally unnecessary and often unprofitable because they promote the development of leaf-growth and delay the flower production. Seeds should not be gathered and only the fallen fruit should be collected, collection being made twice a week.

The laying-out of a seed nursery is specially to be recommended where an extension of an estate has been planned. If the object is to put the seeds on the market, the fact that overproduction is imminent must not be overlooked. If a seed-nursery becomes no longer profitable, the plants may be pruned off and used for gathering purposes. But if the nursery is situated at too great a distance, then there is no other remedy than to simply let the plants grow into a wood. The collecting of seeds for pressing oil is also worthy of consideration G. A. B.

720 - **General Survey of the Cultivation of the Vanilla Bean, and its Preparation for Commercial Use.** — STANISLAUS, I. V. S. (Consulting Chemical Engineer, New York), in *The Tea and Coffee Trade Journal*, Vol. 1., No. 4, pp. 528-532 and No. 5, pp. 671-678 New York, April and May 1922.

Although the common vanilla is recognised as *Vanilla planifolia*, it is noted that it is doubtful whether commercial vanilla is entirely derived from this species. The Mexican varieties of bean for example are obtained also from *V. sultensis*, *V. pomboia*, and *V. aromatica*, the Brazilian and Bahia beans from *V. gardneri*.

The author gives a summary of the geographical distribution of this plant the cultivation of which has extended from South America throughout the Tropics especially in Mexico, Seychelles, Réunion, Tahiti, Mauritius, Java, Fiji and the West Indies. The different values of the beans obtained from the various countries is discussed, with special details concerning the Mexican (1) and Guadeloupe beans. The actual production of vanilla beans for the season 1920-21, not including the Mexican has been estimated as follows — Madagascar and Dependencies 1 150 746 lb.; Mauritius, 1102 lb; Réunion 176 368 lb; Seychelles 6 614 lb.

The author gives a description of the botanical and also of the general characteristics of the plant and states that vanilla is suited to a hot, moist climate, if without excessive rains. Artificial fertilisation is as a rule necessitated owing to the fact that natural cross pollination by bees and humming birds is only possible in Mexico, and elsewhere bees rarely visit the flowers.

It is estimated that an average worker can fertilise 2 000 flowers per day if the plants are fairly close together.

*Methods of preparation and curing.* — A comparison is made between store curing; the last named is the most generally employed to secure uniform curing and each size is cured separately.

The best method of preserving vanilla beans for commercial purposes has been found to be storage in a temperature slightly higher than room

(1) See *R* Oct 1921, No 1008. (*Id*)

temperature : the idea of storage in ice-boxes or in cold cellars is no longer in favour DE GROOTE of the Mellon Institute of Industrial Research has recently stated that any system of storage permitting the air to circulate round the beans in the inner part of the bundle is to be recommended.

Attention is drawn to the sophistication treatment of collected beans occasionally practised, the most serious being the production of so-called vanillin crystals. On soaking the beans in a concentrated solution of benzoic acid in alcohol, after evaporation the crystals of the acid have a general appearance of vanillin crystals. Detection is possible, however, as the benzoic crystals are flattened and rhomboidal and generally lie flat upon the bean, while the others are generally needle-shaped and stand out at right-angles. It may be noted that the lack of crystalline coating is no proof of inferior quality of the bean. It has been stated on good authority that crystals are not infrequently entirely absent on the best Mexican beans. Other less notable forms of sophistication are also described.

As regards the chemical composition of the bean, the author describes the two ferments to be found in the plant, one as an oxydase in leaves, shoots etc. and readily extractable by water; the other as a hydrolysing ferment in the sap. Quite apart from the two kinds of resin also found in the bean, both are apparently necessary for vanillin formation, which is a coniferin derivative. The vanillin manufactured by oxidation of isoeugenol obtained from oil of cloves and from anisidin is of inferior quality to the extracts from vanilla beans. It is interesting to note that although Mexican beans show the lowest vanillin content, the quality of the extracts obtained is superior to that prepared elsewhere in flavour etc. The actual percentage content is shown in the following chemical analysis (HAARMANN): Mexican 1.69 %, Réunion 2.48 %, Java 2.75 %. M. L. Y.

721 - **Chaulmoogra Oil from *Taraktogenus Kurzii*, and its Medicinal Value as a Leprosy Cure** (1). - I. ROCK, J. F. (Agricultural Explorer of the Office of Foreign Seed and Plant Introduction, Bureau of Plant Industry, U. S. Department of Agriculture), Hunting the Chaulmoogra Tree, in *The National Geographic Magazine*, Vol. XL, 1, No. 3, pp. 243-270 + plates + 1 map Washington, D. C., March 1922 - II Chaulmoogra oil and Leprosy, in *The Agricultural News*, Vol. XXI, No. 518, p. 68-69 Barbados, March 1, 1922.

The value of chaulmoogra oil in the treatment of leprosy has for some years been recognised and it has given very good results. Two constituents of this oil, viz. chaulmoogric and hydnocarpic acids and especially their *ethyl esters* have proved effective.

As a result of the probably scarcity in the United States of this oil which is derived from *Taraktogenos Kurzii* King, the author was requested by the U. S. Department of Agriculture to obtain seeds of this species for introduction into Hawaii and other tropical possessions, where leprosy occurs, with a view to establishing chaulmoogra plantations. The report of the forthcoming expedition is here given (Pt. I).

(1) See R. Dec. 1917, No. 1166 (Ed.)

II. — A scientific discussion as to the chemical composition of this oil and its use in the treatment of leprosy patients. The oil seems to act as an internal disinfectant, killing the bacterial germs. Reference is made to the interest in this subject roused in the West Indies and it is also stated that efforts are being made to establish a *Taraktogenos Kurzii* tree in the Botanic Gardens, Dominica (*Annual Report 1920-21*). M. L. Y.

722 — **Alkaloidal Content of Leaves and Stems of Ipecacuanha from the Federated Malay States.** — *The Agricultural Bulletin of the Federated Malay States*, Vol. IX, No. 3, pp. 178. Kuala Lumpur, July Sept 1921

A sample of leaves of the ipecacuanha plant was forwarded to the Wellcome Research Laboratories, London, for analyses, and Dr. T. A. HENRY, the Director reports the following results.

*Leaves and stems* 1.5 % alkaloids, soluble in ether of which 0.45 % were emetine.

*Roots* of good quality contain 2 to 2 ½ % of alkaloids, soluble in ether, of which 0.5 to 0.75 % is emetine.

Dr. HENRY states that the discovery that the leaves contain emetine is interesting since there is no previous record on this point

As is well known the roots are a commercial drug. It is considered, however, that the collection of leaves might be injurious to the plants, and further investigation seems desirable. M. L. Y.

#### FRUIT GROWING

723 — **Cultivation of Lemons in Argentina.** RIVEROS, D., in *El Campo*, Vol. 6, No. 66, p. 165. Buenos Ayres, April 15, 1922

In the Argentine the provinces of Catamarca, La Rioja, Corrientes and the Northern areas are the districts particularly suitable for lemon growing. In the province of Corrientes, certain plantations of some importance are already established, but these have not been developed as much as was expected. Attempts have also been made elsewhere, but without success. For example, the fruit produced in El Tigre will not keep owing to the prevailing moisture in this area and to the high nitrogenous soil content.

As regards, insect pests, the scale insects which attack other citrus fruits are abundant in the northern part of the Republic owing to the lack of natural enemies. F. D.

724 — **Superior Italian Cherry Varieties.** — BRIGANTI, G., in *Italia Agricola*, Vol. 58, No. 11, pp. 301 + 1 table (col.) *Plaisance*, Oct. 15, 1921. Vol. 59, No. 5, p. 157 + 1 table (col.), May 15, 1922

Two excellent varieties of cherry are notified (1) and described viz.: "Cicalone" and "Zuccherina".

The first is characterised by vigorous growth, size, deep violet-red colour, acid flavour and small stone; the second by the well developed tree, the size, very sweet flavour, light ruby red colour, small stone, fine skin, and especially the early ripening of the fruit and consequently its appearance on the Naples market, as early as the beginning of May.

The fruits of these two varieties are not suitable for export, as the flavour and scent is only acquired when completely ripe. F. D.

(1) See R., Nov. 1921, No. 1124 (*Ed.*)

**725 - Plum Growing in California and Methods Employed for Drying the Fruits. —**

HENDRICKSON, A. H., in *College of Agriculture, Agricultural Experiment Station, Berkeley California, Bulletin* No 328, pp 1-38, figs 12 Berkeley, Ca., June 1921

Full details are given as regards the choice of stock, planting, irrigation, cultural operations, control of plant diseases and insect pests connected with plum orchards in California. The myrobalan stock is preferred to the almond and peach stocks, especially on deep moist soils. The two last named stocks are considered best on drier, gravelly soils.

As regards the curing process, most of the plums are sun-dried; although in recent years, an increasing proportion have been dried in evaporators (1). For sun-drying, trays holding about 60 to 70 lb. of green fruit are used. Approximately 1000 to 1500 trays and 250 to 350 lug boxes are necessary for 100 tons of fruit. From 10-14 days are allowed for this form of drying. In an evaporator the length of time varies from 12-72 hours, according to the size of the fruit, the temperature maintained and the type of evaporator etc. Although sun-drying has advantages from the point of view of cost and labour, the evaporation process ensures the curing of the entire crop, regardless of unfavourable weather.

A survey of the cost of production is made apart from the necessary additional equipment cost etc., which has shown an increase in recent years, owing to the price of labour. (The cost of cultivation, including ploughing, was probably at least 20\$ per acre). The prospective returns cannot be estimated with any degree of certainty.

It is calculated, however, that for the first 3 or 4 years, the orchard may be intercropped to provide a maintenance revenue; during the 5th and 6th years, the trees usually produce enough fruit to pay expenses and possibly to give a small profit. A fair crop for central coastal regions is estimated at 4-5 tons per acre, in the foothills, not more than 2 tons per acre, on deep fertile soils, inland, as much as 20 tons per acre have been obtained.

M. L. Y.

**726 - Price paid to Producer and Price charged to Consumer for Wood in France. —**

FORESTRY

ROULFAU DE LA ROUSSEIERE, in *Bulletin de la Société des Agriculteurs de France, Supplément au Bulletin d'avril 1922, Comptes rendus de l'Assemblée générale de 1922* fasc 2, pp 50-66 Paris, 1922

The author first shows the difficulty of ascertaining the price paid to the producer due to the lack of regular standards for the different conditions of the wood at which the price is quoted: standing, felled, either by the proprietor or the timber-merchant, but remaining where felled, felled and delivered at the timber-yard of the saw-mill or placed on the truck ready for transport; sawn only and delivered at the timber-yard of the saw-mill; delivered in the form of floor-boards, squared beams, scantlings, plants, laths, etc.

(1) For a technical description of evaporators see R. Aug. 1921, No. 858, R. Sept 1921, No. 953, R. Dec. 1921, No 1274. (Ed.)

The following, however, are some data as to the price paid to the producer and price charged to the consumer of *wood for working*:

Description	Gross value of the m <sup>3</sup> in fr.			Coefficient of increase		
	1914	1920	1922 (Febr.)	1914	1920	1922 (Febr.)
<i>Oak 0.45 m. in diameter</i>						
standing . . . . .	45	90	60	1	2	1.3
logs (unbarked) . . . . .	55	130	95	1	2.4	1.8
sawn . . . . .	79	241	185	1	3	2.3
<i>Beech, 0.38 m. in diameter</i>						
standing . . . . .	25	60	35	1	2.4	1.4
logs (unbarked) . . . . .	35	100	65	1	2.6	1.9
squared and cross beams . . . . .	50	170	124	1	3.4	2.5
<i>Fir</i>						
standing . . . . .	22	75	35	1	3.4	1.6
logs (unbarked) . . . . .	30	110	65	1	3.7	2.2
sawn . . . . .	55	195	125	1	3.6	2.3
<i>Poplar, 0.48-0.50 m. in diameter</i>						
standing . . . . .	22	50	30	1	2.3	1.4
logs (unbarked) . . . . .	30	85	60	1	2.8	2
sawn . . . . .	42	123	95	1	3	2.3

Regarding cost of working, labour and transport, the author observes that their increase seems to account for the differences between the coefficients of the prices charged by the producer and the wholesale merchant, whether trader or sawyer, but not by the retailers. He gives the costs in connection with oaks of medium size, but only for sawn wood at the sawyer's timber-yard, in the country, free of town-dues, taking profits and general expenses on the supposition that the felling-ground is 5 km. from the station and including unloading, also that the buyer's saw mills are near a station not more than 60 km. from where the logs are put on rail, these logs to have a circumference of 1.20 m. to 2 m. at the root and the figures to include costs of working, transport and sawing into lengths.

The following are the prices paid to producer and charged to consumer for *firewood*:

	Coefficient of Increase
In 1914 for the "stere" (1 cub. m.) with all kinds mixed, the average price paid to the grower (prices vary considerably according to locality) was 5 fr.	1
In 1919-20, before the economic crisis it was under the same conditions, 12 frs.	2.4
In 1922, either there were no buyers or it averaged with very considerable variations 5 fr.	1
In the country delivered, to consumer, including town-dues 1 fr. in a small town situated 30 km. from the forest ground the "cord" cut and shaped was quoted by the timber merchant to the customer in 1914 at 14 fr.	1
In 1919-20 it fetched, under the same conditions, 40 fr.	2.8
In 1922 it fetched 30 fr.	2.1

	1914	1920 and 1921	Increase	Coeffi- cient	1922 Feb- ruary	Coeffi- cient of increase
	fr	fr	fr		fr	
Felling of 1,400 cub. m. rough to obtain 1 cub. m. dressed . . . . .	1.40	5.25	3.85		5.25	
Cartage (by road) of 1,400 cub. m. to the rail- way station (5 km.) . . . . .	8.40	35.00	26.60		35.00	
Loading cub. m. 1,400 at the station (on rail- way trucks) . . . . .	0.90	3.00	2.10		3.00	
Transport by rail of 1,400 cub. m. to the saw mill supposed near a station 60 km. from the first. . . . .	6.75	19.50	12.75		19.50	
Storage in the timber-yard . . . . .	1.00	3.00	2.00		3.00	
Sawing into lengths, per cub. m. of trim- med length (1,400 cub. m. rough) . . . .	20.00	50.00	30.00		50.00	
Total No. 1 . . . . .	38.45	115.75	77.30	3	115.75	3
Merchant's profit and general expenses together estimated as 20 % of the gross selling price of 1,400 cub. m. rough sold retail trimmed (130 fr. in 1914—400 fr. in 1920 — 300 fr. in 1922) . . . . .	26.00	80.00	54.00		60.00	
Total No. 2 . . . . .	64.45	195.75	131.30	3	175.75	2.7
For the Paris market, at a supposed distance of 150 km. from the former, the following must be added :						
Transport to station and loading on truck . .	2.50	9.00	6.50		9.00	
Transport from departure station to Paris, 150 km . . . . .	9.50	29.70	20.20		29.70	
Cartage on arrival . . . . .	10.00	30.00	20.00		30.00	
Excess of merchant's profit and general expenses in proportion to change in selling price :						
20 % on { in 1914 : 160 — 130 = 30 fr. {						
{ in 1920 : 600 — 400 = 200 fr. {	6.00	40.00	34.00		30.00	
{ in 1922 : 400 — 300 = 100 fr. {						
Paris town dues, unchanged (11 fr. 28 c.) . .	—	—	—		—	
Total No. 3 . . . . .	92.45	304.45	212.00	3.3	274.45	3

In Paris, the price paid to the wholesale merchant for 1000 kg. (the "stere" = 450 kg.), double sawn, delivered to the house in lots of 500 kg. and upwards, and including town dues but not "pour-boire" was :

	per 1000 kg	per . . .	Coefficients
In 1914 . . . . .	60 fr.	27 fr.	1
In 1919-20 (from 180 to 200) . . . . .	190 "	86 "	3.2
In 1922 . . . . .	150 "	68 "	2.5

The comparative cost of working, transport and delivery to domicile of 1 "stere" of dressed firewood in 1914, 1920 and 1922, in a forest with a railway station situated 30 km from a small country-town, where the dues are 1 fr per «stere» is as follows

Items of Cost	1914	1920	1922
	fr	fr	February
Felling, shaping and stacking	1.50	6.00	5.50
Cartage to station 5 to 6 km	1.50	6.00	5.50
Loading on truck	0.25	1.00	1.00
Transport by rail, 30 km	1.05	2.80	2.80
Carting from Station to timber yard	0.50	1.50	1.25
Stacking in timber yard	0.30	1.00	0.80
Delivery to customer	1.00	4.00	3.50
Town dues	1.00	1.00	1.00
Total	7.10	23.30	21.35
Price paid to grower for standing timber	5.00	12.00	5.00
Total cost price	12.10	35.30	26.35
The timber merchant sells at	14.00	40.00	30.00
Profit per 'stere' after deducting all general expenses and taxes, including that on turnover	1.90	4.26	3.32
If it be reckoned that this profit should have been at least 20 %, these last figures should be increased by	2.80	8.00	6.00

The following are the items of cost to be taken into consideration in fixing the retail price of charcoal per sack of 30 to 40 kg in a small town situated 30 km from the forest ground (table p 845)

The table gives the comparative cost of working, charring, transport and delivery (as charcoal, to domicile of 1 "stere" of fresh hard wood mixed with  $\frac{1}{3}$  or  $\frac{1}{4}$  of white wood, in a small town situated at 30 km from the forest ground, in 1914, 1920 and 1921-22, as compared with the prices of charcoal sold retail per sack of 30 to 40 kg

The bark constitutes another important product. The various items of the costs of the returns are given (table p 847)

The author sums up the present state of the timber market in France as follows

*Wood for working* whereas in 1920 when prices had reached the highest point the grower sold wood of all kinds for working at an average coefficient of 2.6, the wholesale timber-merchant sold at 3.1 and the retailer at 4.5, labour (felling, sawing and transport) cost 3, and in the forest, the woodman alone 3.7. At present the grower sells at an average coefficient of 1.6 (and for oak, which forms 70 % at least of the total, only 1.3), the

wholesale merchant at 2.4, the retailer at 3.5, labour and transport together cost 3 and the woodman alone 3 8

*Firewood* : in 1919-20 when prices were highest, the grower sold at an average coefficient of 2 4, the wholesale timber-merchant at 2 8, the retailer at 5, the woodman alone cost 3 6. At present the grower sells at 1, that is, at the 1914 price, and does not even find buyers for  $\frac{2}{5}$  of the timber felled, the wholesale timber-merchant at 2 1, the retailer at 3 and the woodman still at 3 6

	1914	1922	Coefficient of increase
	fr	fr	
The "stere" of standing white wood (350 kg) for converting into charcoal was worth net, to the grower	1	1	
100 kg of charcoal delivered to the customer in the small town fetched	14	35	2 5
As 1 "stere" of wood for charring yields 65 kg of charcoal on an average, the "stere" of fresh wood converted into charcoal costs the customer	9 15	22 75	2 5
The total cost of converting 1 "stere" of fresh wood into 65 kg of charcoal including town-dues of 1 fr per 100 kg of charcoal and tax on turnover (see details annexed) is	5 80	18.22(1)	3 1(1)
By deducting this cost from the preceding totals the timber merchant's profit on 1 "stere" of fresh standing wood by selling the charcoal is	3 35	4 53	
And as the merchant has paid the producer for 1 "stere" of standing fresh wood	1 00	1 00	
It follows that for every "stere" of fresh wood, the merchant to cover his general expenses and profit has	2 35	3 53	
and this profit and general expenses work out, on 25 %, at a percentage of	25 %	15 4 %	

(1) Including a tax of 1 1 % on 22 fr 75 = 0 fr 25 c

The grower to-day sells all standing wood for working, especially resinous wood, firewood and charcoal, at extremely low prices. The prices of manufactured wood products are still too high for the customers who use the wood at home, but the position in this department shows

Details of cost	1914	1920	1922 (Feb- ruary)
	fr.	fr.	fr.
<b>Preliminary data.</b>			
One "stere" of fresh hard wood mixed with $\frac{1}{3}$ or $\frac{1}{4}$ of white wood produces an average of 65 kg. of charcoal, which sell, per 100 kg. (= 4 hl.) at . . . . .	14.00	60.00	35.00
Hence the "stere" producing these 65 kg. is valued at . . . . .	9.15	39.00	22.75
<b>Items of cost of working per "stere" to be deducted :</b>			
Felling and shaping . . . . .	1.50	6.00	5.50
Charring . . . . .	1.25	5.00	4.50
Sacks and string per 65 kg. of charcoal . . . . .	0.50	2.00	2.00
Transport to station of 65 kg. of charcoal and loading on truck . .	0.60	1.75	1.50
Railway transport of 65 kg for 30 km . . . . .	0.20	0.52	0.52
Cartage on arrival . . . . .	0.20	0.80	0.70
Expenses of delivery retail per sack of 1 hl. 75 . . . . .	0.80	3.00	2.50
Town dues . . . . .	0.75	0.75	0.75
Total cost . . . . .	5.80	19.82	17.97
The 65 kg. or 1 "stere" net standing therefore realise . . . . .	3.85	19.80	4.78
Less tax on turnover . . . . .	—	0.45	0.25
Net proceeds . . . . .	3.35	18.73	4.53
The timber merchant having paid the producer for the "stere" . .	1.00	7.00	1.00
His profit and general expenses amount per "stere" to . . . . .	3.35	11.73	3.53
= a percentage of . . . . .	25.6	30	15.4

signs of improvement. Labour has not suffered since it averages a coefficient of 3, which corresponds to the increased cost of living. The prices at present realised by the grower are extremely low, for though the rise in price of firewood is nil, and between 40 and 50 % for wood for working as compared with 1914, this rise is of real effect when compared with a diminution of 300 % in the buying power of money and 300 % increase in the cost of living. And when the consumer at last sees this percentage of 300 % diminish, that of the producers, at present nil or almost so, far from disappearing, will, as regards hard wood for working, rise.

	1914	1922	Coefficients
	fcs	fcs	fcs
The average price of bark per 1,040 kg loaded on railway truck is	75	200 (1)	2.7
The cost of barking, properly so called, in the forests, is	35	90	2.6
To which should be added			
Carriage to station or tannery, supposed distance of 5 to 6 km	5	18	3.6
Loading on truck	0.60	2	3.3
Withies	3	8	2.7
Discount of 3 % off the selling price agreed on unless other wise stipulated	2.25	6	
Tax on business turnover		2.20	
Which brings the total expenses up to	45.85	126.20	2.8
The net proceeds after deducting these expenses from the selling price are	29.15	73.80	
The average price paid to the grower for the bark on the tree was	2.1	6.1	
Leaving the timber merchant (as profit and to cover general expenses)	6.15	13.80	
Or per cent on the total price	12	6%	

(1) According to the market price in Feb 1922.

## LIVE STOCK AND BREEDING.

- 727 - **Supposed Poisoning of Sheep by Button Grass (*Eleusine aegyptiaca*).** — BERNY I. L. and WHITE C. F. in *Queensland Agricultural Journal* Vol XVI Pt V, ng. 1 p 17 Brisbane, 1921

HYGIENE  
OF CATTLE

Sheep belonging to BERNY, put to pasture in a meadow, 90% of which was covered with "button grass" (*Eleusine aegyptiaca*) on the following day showed serious symptoms of poisoning, which proved fatal to 2 or 3 animals. As regards the rest the symptoms disappeared during the next night.

WHITE, who made a study of specimens of the plant, has not been able to produce reactions with a withered plant, sufficient to prove definitely a glucoside with a hydrocyanic acid content, but he calls attention to the fact that "button grass" contains this glucoside in fairly large proportions during the whole year except in mid-winter and towards the spring. The case quoted is the first in which button grass has been definitely associated with stock poisoning.

E. F.

- 728 - **Poisoning of Cattle by the Prussic Acid in Sorghums.** — VINALL, H. N. (Office of Forage Crop Investigations, Bureau of Plant Industry, U. S. Dept. of Agriculture, Washington D. C.), in *Journal of the American Society of Agronomy*, Vol 13, Nos 6-7, pp 267-280 bibliography of 22 works Lancaster, Pa. and Washington D. C., Oct 15, 1921.

A study of the literature dealing with this question. Certain facts are worthy of special attention. Poisoning of cattle with green sorghum

has been known for some years: PEASE (1877) states that in India large numbers of deaths were due to this cause: the crop was "semi-parched for want of rain". Sorghum poisoning was frequent also in 1887 and 1895, both dry years, and the natives accounted for it by the attack of a small insect, known as "bhaunri" which is prevalent in dry seasons and poisons the sorghum. Other theories include the belief that the sorghum leaves collected in the paunch and gave off gases, causing death by asphyxiation. PEASE decided on investigation that death was due to nitrate of potash which occurs in abundance in stems of withered sorghum plants, especially at the nodes. The symptoms of poisoning from nitrate of potash are somewhat similar to the symptoms of prussic acid poisoning. This theory was disproved later or at any rate, it was found that nitrate of potash was not invariably the cause of sorghum poisoning.

At the Nebraska Station (U. S. A.) in 1900, HILTNER found no substance in the plant which had caused death. In 1901 SLADE, assistant chemist at the same Station, suggested that the damage was due to prussic acid. The year following, the two English investigators, DUNSTAN and HENRY reported for the first time this discovery in a paper received by the Royal Society of London on April 24, read May 15 and published in the "Chemical News of London," June 27, 1902. Independently, SLADE also isolated prussic acid from a sample of fresh sorghum, about August 1, 1902. His report was sent to the Journal of the American Chemical Society for publication October 3, 1902. AVERY continued the work of SLADE and, in collaboration with him and PETERS, a careful summary of results was published in 1903, which leaves little room for doubt that prussic acid was the direct cause of sorghum poisoning. CRAWFORD found for the first time in 1906 that prussic acid exists also in Johnson grass (*Holcus halepensis* L.) and FRANCIS traced the acid in Sudan grass (*Sorghum exiguum*) in 1915.

According to DUNSTAN and HENRY the prussic acid does not exist in this form in sorghum, but under certain conditions is liberated from cyanogenetic glucoside, known as "dhurrin". Decomposition is effected by hydrolysis, by an enzyme emulsin, which may result under certain conditions in the liberation of the poisonous acid; dilute hydrochloric acid may have a similar effect. An empirical formula is given for the glucoside and the resulting decomposition is explained. SLADE and AVERY arrived at practically the same conclusions. WILLIAMSON (1917) claims that prussic acid is found in sorghum in both a glucoside and non-glucoside form. The work of RAVENNA and BOBINI (1912) agrees with this; they claim to have found free prussic acid in sorghum leaves as well as in the leaves of peach, cherry, laurel and flax. It is satisfactory to note, however, that these Italian investigators themselves modify their results somewhat by acknowledging the facility of producing free prussic acid by autolysis during the experiment.

According to data carefully selected and compared, it appears that Sudan grass is less poisonous than common sorghum. An average of 18.9 lb. is necessary to poison cattle and with common sorghum, only 7.6 lb. is required.

The leaves contain the larger proportion of poison, and the fact that animals prefer the leaves, explains why small quantities are sometimes sufficient to prove fatal; in one case there was poisoning with only 8 lb. of Sudan grass leaves.

Sorghum and Sudan grass cured as forage are usually harmless. Two theories are put forward: according to AVERY the enzyme remains inactive, but DOWELL claims that when the plant is dried, the acid is volatilised. Verification of this theory is still necessary and will have a practical application in determining the most desirable methods of curing the plant.

Adverse climatic conditions, such as drought and frost favour the formation of prussic acid. This has been proved by several experiments and the average analysis shows that there is more than twice the amount of prussic acid in injured plants than in normal. In one case only the normal plant was richer in acid than the plant which had suffered from frost. In accepting this conclusion, it is necessary to distinguish between plants stunted by drought, frost, arid soil, etc. These all showed a low prussic acid content, especially if the poor soil lacked nitrates.

The percentage of acid decreases with the age of the plant. Cold climates are more favourable to acid production and this point is discussed at length. Varietal differences also have a marked influence on the acid percentage.

The poisoning (of which the symptoms are described) is so quickly fatal that treatment is difficult. Glucose, dextrose and other forms of sugar are known as antidotes. As these are formed from amides during digestion, a possible explanation is given of the fact that animals fed on maize can afterwards feed on large quantities of sorghum with impunity. Other remedies are discussed: salt purgatives, peroxide of hydrogen, etc. Their immediate application is necessary.

729 - **Control of Tuberculosis in California.** — See No. 679 of this Review

730 - **Warts on Horses and Cattle.** — WILLIAMSON H., in *The Pastoral Review*, Vol XXXI, No. 8, p. 620, Sydney and Melbourne, Aug. 1922

Little is known as to the nature and origin of these warts and consequently the treatment can only be based on observation. The author divides them roughly according to form and the best method of treatment:

a) pedunculated, or narrow-necked, a ligature may be used with or without caustic agent to hinder the blood circulation in the wart; the action may be hastened by a previous dressing of chloride of zinc or of corrosive sublimate;

b) encysted warts; open the cyst with a knife and permit the escape of the pus.

c) broad based warts; treat with washing soda or soap powder to soften the surface and then with a caustic agent to penetrate into the wart. A very efficient but not the safest paste is one composed of arsenic and soft soap. Warts which develop on delicate parts of the body (eyelids etc.) should be treated with a solution of collodion 7 parts to salicylic acid 1 part.

731 - Investigations on Infectious Abortion in Cattle and Swine in the United States, —

I STAFSETH, H J and HUDDLESON, J F Studies in Infectious Abortion, *Michigan Agricultural College Experiment Station, Technical Bulletin* No 49, 30 pp, Lansing, Mich Nov 1920 — II HALLMAN, E T, Infectious Abortion in Cattle, *Michigan Agricultural College Experiment Station, The Quarterly Bulletin*, Vol III, No 3, pp 81, East Lansing, Mich, Feb 1921 — III CONNAWAY, J W DURANT, A J, and NEWMAN H G, Infectious Abortion of Cattle *University of Missouri, College of Agriculture, Agricultural Experiment Station, Bulletin* 189 pp 57-58, Columbia, Miss, 1921 — IV SCHROEDER, F C, Bureau of Animal Industry, Investigations on Bovine Infectious Abortion, *Journal of the American Veterinary Medical Association*, Vol LX, No 5, pp 542-561, Washington, Feb 1922 — V CONNAWAY J W, and DURANT, A J, and NEWMAN H G, Infectious Abortion in Swine, *University of Missouri, College of Agriculture Agricultural Experiment Station, Bulletin* No 157, 28 pp, figs 12 bibliography of 16 publications Columbia Miss, 1921 — VI HUDDLESON, J The Susceptibility of Swine to Contagious Abortion (*Bacterium abortus* Bang) *Michigan Agricultural College Experiment Station The Quarterly Bulletin*, Vol 4, No 2 pp 43-45 East Lansing Mich Nov 1921

I This work is divided into 4 parts (of which the first 3 are written by Dr H J STAFSETH)

1st Part — ON THE PRESENCE OF THE *Bact abortus* IN THE INNER LAYERS OF THE MEMBRANE OF THE UTERUS OF A FEMALE NOT IN GESTATION (pp 3-6)

The present state of our knowledge on the etiology of infectious abortion leads us to conclude that *B abortus* attacks the uterus only during gestation and disappears rapidly after abortion or normal delivery. It must be admitted then that *B abortus* does not remain permanently in the uterine cavity. On the other hand it is known that certain pathogenic agents may exist in the under layers of the skin and the intestinal mucus without causing trouble although the tissues attacked are generally subject to the characteristic infection of these micro-organisms. The author therefore wished to ascertain whether *B abortus* could penetrate to the deep layers of the uterine mucus and remain there in a state of latent infection.

With this object, he made a bacteriological examination of the uterus of 6 cows which had aborted and were seriously infected. He found a slight bacterial flora (*Staphylococcus pyogenes aureus et albus*, *Streptococcus* sp, *Micrococcus* sp, *B subtilis*, *B coli communis* and *Trichobacterium* sp) in the mucus of the uterus but in no case was there any *B abortus*. This investigation does not definitely solve the problem on account of the small number of animals examined.

2nd Part — NOTES ON THE ISOLATION AND CULTURE OF *B abortus* BY USING LIVER AND SPLEEN SECRETION AS A CULTURE MEDIUM (pp 7 to 11)

*B abortus* is generally associated with other micro-organisms which multiply much more rapidly in artificial mediums than the first named, and impede its development. It is therefore difficult to obtain a pure culture. The author was able to isolate certain species of *B abortus* fairly easily by using culture mediums to which he added hepatic or splenic secretion.

Development was accelerated by the addition of small quantities of starch and dextrose.

3rd Part. — ON THE POSSIBILITY OF DISTINGUISHING INFECTED ANIMALS FROM HEALTHY ONES (4 tables) (pp. 12-24).

It is known that cattle may be infected with *B. abortus* without immediately showing signs of the disease and that so far no characteristic and specific biological reaction is known by means of which infected animals may be detected. The author, using the works of other writers (1) tried two "abortines": alcoholic ether extract of *B. abortus* and a bacillary solution; the latter gave good results. The subcutaneous reaction is obtained by injecting this solution in the abdomen of a guinea pig and shows itself locally under the form of a hardening and reddening of the part, which mortifies after 2 or 3 days. This reaction is specific. The author also observed that:

a) the guinea-pigs in which dead *B. abortus* cultures have been injected do not react against them; b) the dead culture treatment, before or after infection, has no influence on subcutaneous reaction; c) the dead culture treatment does not render the guinea-pigs immune against the *B. abortus* infection,

4th Part. — ISOLATION OF *B. abortus* IN MILK (pp. 25-30).

To prevent or cure infectious abortion, it is often necessary to ascertain whether *B. abortus* exists in the milk of the apparently healthy cow. The isolation methods are attended with more or less serious difficulties, for which reason the author describes another with which he obtained good results. He employed agar-agar with a hepatic or splenic infusion as a medium. He was able to prove that: a) the development of the *B. abortus* culture depends essentially on the concentration of the hydrogenions in the medium; b) the medium containing the culture should be placed in a closed vessel in which 10 % of the air has been replaced by CO<sub>2</sub> gas; c) other micro-organisms which may exist in the milk should be prevented from interfering with the development of *B. abortus*; to effect this, a saturated aqueous solution of gentian violet should be added to the medium in sufficient quantity to ensure a 1/10000 dilution of the final solution; this substance has a selective action on the bacteria.

The method described gives the same results as those obtained by the known methods and has the advantage of being simpler, more economical and rapid.

II. THE BULL AS A FACTOR IN THE TRANSMISSION OF THE DISEASE. —

Recent researches tend to show that the importance of the bull as a vehicle for the germs of infectious abortion is not so great as was believed and that abortion may be checked to a great extent by separating the females which are not in gestation from the places and animals infected. In the present state of our knowledge, it seems evident that the infection of females takes place more often after conception and that any measures taken after impregnation to check infection reduce cases of abortion in a herd.

In practice the following advice may be given: a) the isolation of infected cows and their frequent disinfection;

(1) FLEISCHNER E. C. and MAYER, K. F. The bearing of cutaneous hypersensitiveness on the pathogenicity of *B. abortus bovinus*. *Amer. Journal Hyg.* vol. 16 No. 4. (Authors note).

b) the greatest care should be observed by the owner of uncontaminated herds in burying cows, as infection is most frequently introduced by an infected female.

III. INFECTIOUS ABORTION OF CATTLE. — Experiments to determine the effect of a more or less prolonged suspension of reproduction on the persistence of *B. abortus* Bang in infected cows. These experiments have proved that the cows cannot destroy and eliminate the disease germs. Further, infected calves no longer react against them unless they are reinfected. Cows not used for breeding do not become reinfected by continuous exposure to infection through contact with cows which react and are not in calf.

The bacteriological examination of the glands of a castrated ox, a cow and a bull artificially infected has shown apparently that the castrated ox was less capable of eliminating and destroying the disease germs than the bull, but that neither are so favourable to its reception as the cow. In the latter, the genital organs are more subject to functional trouble after infection, while the udders and teats present conditions which are favourable to the existence of the *B. abortus*.

For the suppression and prevention of infectious abortion in the herd, the authors advise the application of the serological test to all the animals in order to find out which of them show a positive reaction, to fatten and sell for killing those among the latter which are not of special value as breeders; to isolate promptly all the cows which show a tendency to premature calving; to separate from the herd those animals which react at the moment of calving; to destroy all still-born calves and cauls by burning or burying deep in the ground, to disinfect stables and litters; and to spray with antiseptics all cows which have just calved.

IV. INVESTIGATIONS ON BOVINE INFECTIOUS ABORTION MADE BY THE BUREAU OF ANIMAL INDUSTRY OF THE UNITED STATES DEPARTMENT OF AGRICULTURE. — Report submitted at the XXV<sup>th</sup> meeting of the U. S. Livestock Sanitary Association held at Chicago at the end of November, 1921. The author describes briefly the principal facts connected with the symptomatology, etiology and therapeutics of infectious abortion which have been confirmed and studied by the members of the Bureau which is under his direction. Many of these works have been published, but we will confine ourselves to calling attention to the present one.

V. INFECTIOUS ABORTION IN SWINE. — The investigations which have been carried on for some years in the Experimental Stations of the Missouri, have brought to light the following facts. The specific cause in the majority of cases of abortion in sows is a micro-organism very similar to, if not identical with *B. abortus* Bang; the identity of these two micro-organisms has been proved by a series of fixing tests for the complement and for agglutination, for the isolation and identification of the specific micro-organism, for the production of the specific reaction against abortion in sow's blood after an inoculation of *B. abortus* from a cow; and by observing the quasi-abortion of cows and sows feeding together on the same pasture.

The transmission of the disease is especially caused, it seems, by the

ingestion of contaminated substance (foetus, cauls, milk etc. The contamination of one sow by another through the agency of the boar is probable but not certain. Young pigs are also liable to infection, as also boars, and females not in pig. In the case of the young animals the reaction of the blood generally becomes negative after a few weeks, whereas with adult sows infection continues a certain time, and may even become permanent, though sows which have aborted and continue to react positively may give birth to live young. Nevertheless some become temporarily or permanently barren. Some give birth in one litter to an equal number of dead foetus and of live and healthy young. Healthy offspring may be obtained from a sow and boar both infected, by isolating the young as soon as they are born to prevent reinfection.

As preventive and curative measures, those used against infectious abortion in cows are advised; subject parents and recently born young to a serological test, isolate sows which have aborted immediately, carefully disinfect the young and destroy dead foetus and cauls.

Animals which react positively should be fattened and sold for killing if not specially valuable as breeders. In the case of a good sow, it is better to keep her for breeding, isolating the young at birth.

Vaccination is of doubtful efficacy and may perhaps infect the animals treated with permanent traces of disease germs.

Rules are given as to the method and interpretation of serological tests for the discovery of infected animals, for the treatment of the diseased sow and for boars and animals belonging to an infected herd which shows a negative reaction.

VI. IS THE PIG SUSCEPTIBLE TO INFECTIOUS ABORTION? — Some cases of abortion reported at Michigan have induced the author to undertake a bacteriological study of the disease: he concludes that pigs show great immunity against *B. abortus* Bang. Young sows eight weeks old reared on cow's milk naturally infected and afterwards contaminated by a culture of cow's and sow's *B. abortus* gave birth to young, all living except one and afterwards showed a negative reaction.

Young sows brought up on the milk of an infected cow and living in a meadow with cows, became pregnant normally when adult and gave birth to young all living and healthy. Two of these sows had been vaccinated several times. After the test, all the sows and their young showed a negative reaction.

F. F.

732 — **Investigations on the Use of Vaccines prepared with *Bacillus ovisepticus*.** — NEWSOM, I. E., and FLOYD CROSS in *Journal of the American Veterinary Medical Association*, Vol. LX, No. 5, pp. 562-579, tables 10, Washington, Feb. 1922

Recent investigations have rendered doubtful the efficacy of vaccines at present employed in the control of haemorrhagic septicemia, and even the possibility of the preparation by means of methods so far known, of really effective vaccines. The authors present verified data, with reference to this question and as a result of experiments made with *Bac. ovisepticus* which should facilitate the solution of this much discussed problem.

Successful results have been obtained with (doses varied according to circumstances): a) vaccines, for general commercial use; b) a vaccine prepared specially; bacillus grown culture prepared in boiling media for 48 hours and at 60° C for ½ hour, followed by the addition of phenol at ½ %; c) similar vaccines, but prepared according to a modified method (simple addition of phenol and no heating); d) cultures of the living organism.

Experiments have been made with rabbits, and also more particularly with sheep. The vaccines in which the bacillus have been destroyed by heating gave little or no immunity. Sterilisation with phenol renders the vaccine even less effective. Cultures of living bacilli have been tested only with sheep. The minimum fatal dose has varied with breed, but usually it is fairly high if inoculation is sub-cutaneous. The authors consider therefore that the use of living *Bac. o. septicus* as vaccine is not dangerous if the doses are limited to those generally employed in laboratories (1).

In view of our present knowledge, the use of the living organism as a vaccine is advised in preference to that of bacilli destroyed by heat or antiseptics.

E. F.

733 - Diseases in Domestic Birds transmissible to Man. — MURELIO, M., in *Bassa Corte*, V III, fasc. 52-53, pp 1010-1020 Molassana (Genoa), April-May 1922

Among the various diseases, common to man and to birds which the author calls "anthropornithologic", he mentions "psittacosis", Maltese fever and the sleeping sickness.

The first, of bacillary origin, is incurable and contagious both to parrots and to man by direct contact. The author recalls an epidemic which broke out in Genoa in 1891, and which was fortunately localised in a block of houses, though not before several human beings had fallen victims.

He proposes therefore to place parrots coming from America under observation for a period of at least 20 days.

Maltese fever (caused by the *Micrococcus melitensis*) attacks chickens in two forms: the acute form lasting 8 to 10 hours and the form which causes death after a longer period. The author recalls an epidemic which broke out in 1911 among chickens in the neighbourhood of Nîmes, which proved mortal in 70 % of the cases. It was studied by M. DUBOIS.

From observations made by the author in Liguria, there is some connection between the "sleeping sickness" of chickens, which succumb immediately or almost so, and lethargic encephalitis in man. The infection is of short duration, and is caused by the *Streptococcus capsulatus gallinarum*.

F. D.

(1) It is interesting to note that MEISNER and SCHERN (*Arch. f. Tierheilk*, Vol. 36, p. 208) have succeeded in isolating a bacillus so virulent that it is fatal even when given in small quantities (*Author's note*)

734 - **Spirochetosis in Rabbits.** — RUPPERT, F. (Mitglied des Staatsinstituts für experim. Therapie), in *Berliner tierärztliche Wochenschrift*, XXXVII year, No. 42, pp. 493-496, 4 fig., bibliography of 18 works Berlin, 20th Oct. 1921.

Rabbit spirochetosis is the name given by the author to a contagious sexual disease caused by the *Spirochaeta cuniculi* (1) and already described under various names by different authors. Spontaneous outbreaks have been reported in England, Holland, Germany and France. It is transmitted from one individual to another during sexual intercourse. This has been proved from experiments made by the author, as also the fact that infection shows itself after a 2 to 4 months' period of incubation, during which the spirochetes live on the genital parts and are a constant source of infection to all animals having sexual relations with the animal infected. By placing the spirochetes in contact with the skin of the genital parts, the disease is easily transmitted from one individual to another; in this case, incubation lasts 20 to 72 days. No one has yet succeeded in transmitting it to white rats and guinea-pigs. The symptoms may be classed in two series corresponding to the two successive stages of the disease: in the first period (about 3 weeks after the artificial infection) the genital parts become inflamed and a watery fluid collects between the prepuce and the penis, spirochetes are sometimes, but not always, found in this fluid. After 2 to 3 weeks the secretion becomes purulent and small abscesses of the size of a millet seed form on the prepuce (or on the edges of the vagina). The vagina and prepuce become red and increase to 3 or 4 times their normal size. Subsequently the abscesses dry up and form small scabs, which are easily detachable. Spirochetes are always found on the injured parts and their number increases considerably during the course of the disease. In the second period the diffusion of the virus takes place: abscesses of the size of a lentil form, mostly around the anus, rarely on the muzzle. Sometimes small abscesses are seen which may unite, and form one only. By pressing the injured parts a watery fluid containing a large number of spirochetes is expelled.

The prognosis is as yet uncertain; animals infected may survive a year or even 18 months and have healthy offspring; on the other hand they may succumb to secondary bacterial infections which penetrate through the lesions to the organs of the body. An anatomopathological examination reveals all the characteristics of acute inflammation of the genital organs; the diagnosis is based on microscopic examination. The differential diagnosis between the experimental syphilis of rabbits and spontaneous spirochetosis is very difficult for these two micro-organisms show no morphological differences nor differing reactions under the staining media usually employed; while (2) the lesions produced in either case are so different that it may be considered that there are two distinct morphological species. For instance, in spontaneous rabbit spirochetosis, the hardening which is typical

(1) This disease is therefore distinct from rabbit syphilis produced by the experimental inoculation of *Sp. pallida* (Author's Note)

(2) According to research by KOLLE and MORBUS (1919-21, quoted by the author. (Ed.)

of human syphilis inoculated into rabbits is never met with, also *Sp. cuniculi* always settles just under the skin whereas *Sp. pallida* penetrates deeply into the tissues.

Arsenobenzoline products exert a specific therapeutical action : 0.04 gm. to 0.06 gm. of salvarsan of sodium and of silver per kg weight always cures. The infection may be contracted more than once, so that there is no immunity.

- 735 - Effectiveness of Tetrachloride of Carbon against *Uncinariae* (*Nematoda Strongylidae*) in Dogs. — ALLEN, I. A. (Animal Pathologist in Charge, Fox Research Station, Health of Animals branch, Canada), in *Journal of the American Veterinary Medical Association*, V LXI, No 1, pp 31-37 Washington, April 1922.

The author has used tetrachloride of carbon as a vermifuge (especially against *Uncinaria stenocephala*, but also against ascarides) in 399 cases, and has observed that it is more effective and less dangerous than chloroform and thymol.

It should be administered after a fast of 12 to 14 hours in the form of gelatine capsules, the dose should be 0.3 gm. per kilogram of weight. Afterwards it is well to administer a little castor oil to facilitate deglutition. With adults it is often necessary to overcome the resistance of the animal against swallowing the capsule — it sometimes happens in such cases that the capsule breaks and that artificial respiration must be resorted to.

#### FEEDS AND FEEDING

- 736 - Feeding and Contact Experiments with St. John's Wort (*Hypericum perforatum*) in New South Wales. — HENRY, M. (Government Veterinary Surgeon), in *Agricultural Gazette of New South Wales*, Vol XXXIII, Pt 3, pp 205-207 Sydney, March, 1922

Results of previous feeding experiments with St. John's Wort (*Hypericum perforatum*), indicated that the plant rendered the skin peculiarly susceptible to the action of the sun's rays, and that the animal suffered considerably in consequence. Further experiments have been made to test the effect of feeding the plant at a less-developed stage and also the effect of continued contact of the plant with the skin. Cattle and sheep were placed in a field almost entirely overgrown with *H. perforatum*.

In both cases the effects of internal irritation were evident, especially in the full heat of the day, and the abrasions were noticeable.

In the contact experiments, the animals were muzzled before being allowed to run in the paddock. No signs of ill-health or external skin irritation were observed, even when the plant was in full flower and there was much pollen.

The animals which had suffered as a result of feeding on this plant, recovered their equilibrium after removal from the field, and the abrasions were replaced by clean, healthy tissue.

M. L. Y.

737 - **The Mannitol-Producing Organisms in Silage.** — PLAISANCE, G. P., and HAMMER, B. W. (Bacteriological and Dairy Sections of the Iowa Agricultural Experiment Station), in *Journal of Bacteriology*, Vol. 6, No. 5, pp. 431-433, bibliography of 7 works. Baltimore, Sept. 1921.

The chemistry section of the Iowa Agricultural Experiment Station has shown (DOX and PLAISANCE, 1919), that mannitol is a normal constituent of silage and that it is formed by bacterial reduction of the fructose of the sucrose molecule. In silage fermentation the mannite is produced in considerable quantities, simultaneously with the acids, the alcohol, and the carbon dioxide, and its presence accounts in a large measure for the deficit noted when the sum of these products is supplemented by fermented sugar. Mannitol has also been found in various fermented materials such as wine, vinegar and sauerkraut, etc. as well as its production by organisms.

The aim of the present experiments was to isolate from silage, organisms capable of producing mannitol, either when grown in pure cultures in maize and maize juice, or by adding agar, peptone and sucrose, or by using chopped green maize adding about 5 % sucrose.

Mannitol determinations were made by extraction with boiling 95 % alcohol and after leaving to cool and crystallise, were then weighed.

If ether, chlorophorm, formaldehyde, or toluol were employed for sterilisation, no trace of mannitol was found ; the organisms are therefore indispensable

The organisms capable of producing mannitol were isolated from fresh silage ; small colonies were obtained on agar, and probably form part of a group of lactic bacteria ; the reducing element is evident in the pronounced change in colour in the fermenting juice. These organisms are well distributed and have been observed in the soil from a farmyard and also in milk. Undoubtedly many other organisms are associated with mannitol production but not so generally characteristic and invariably recognisable.

Mannitol has also been produced by organisms isolated in the sunflower, sugar cane, dandelion silage and in cabbage juice, but not in that of carrots, beets or apples.

The addition of fructose considerably increased the production (3.71 %) due to the direct transformation of fructose to mannitol. The addition of sucrose or inulin was less effective owing to indirect transformation. Results varied with the determinations made ; thus in one case, the sugar cane juice with 2 % sucrose gave 0.49 % mannitol, and in other cases 1.85 %. The carbohydrates, apart from those mentioned, gave entirely negative results.

When flooded with oil, which assists anaerobiosis, and consequently aids the reduction responsible for mannitol production, a much greater quantity is obtained, probably because the development of reducing agents encourages anaerobiosis, and this method is rendered superfluous.

The quantity of mannitol increases during ensilage, up to a certain limit ; reduction then follows, evidently due to repeated partial destruction, caused by the same organisms. This has been demonstrated in pure cultures obtained by experiment.

- 738 - **Malted-Grain Sickness of Cattle considered as one of the illnesses due to Malnutrition.** — POENARU, J. (Clinical Hospital of the Faculty of Veterinary Surgery, Bucarest) ("Clinique médicale de la faculté de Médecine Vétérinaire, B.") in *Comptes rendus des Seances de la Société de Biologie*, Vol LXXXVI, No. 11, pp 640-641. Paris, 18th Mar. 1922.

Six hundred oxen, fed exclusively on malted grain, soon showed symptoms of malt sickness: loss of appetite, diarrhea, difficulty in standing up, increasing weakness, and 12 oxen died in a state of extreme exhaustion. But as soon as this feed was mixed with others, such as: chopped straw, hay and a little bran, the morbid symptoms disappeared. The author subjected malt sickness to experimental investigation and observed that it may be included in the group of illnesses due to malnutrition, and that the indispensable elements lacking in malted grain, which is sterilised by the distillation temperature, contain the essential vitamins; if the latter are supplied by the addition of other food products, the sickness is averted.

**STOCK  
BREEDING**

- 739 - **The Application to Stock-Breeding of Some new Views concerning Heredity.** — DECHAMBRE, P., in *Comptes Rendus de l'Académie d'Agriculture de France*, Vol VIII, No. 11, pp. 359-365. Paris, March 1922

The progress of stock-breeding is intimately connected with the possibility of fixing by heredity the variations, or characters, that will improve the quality of animals. Hence the attempt to apply to stockbreeding the knowledge obtained from the researches on heredity that have been carried on for several years in the scientific world

From among the new facts concerning heredity that are of almost direct application to stock-breeding, the author singles out for special mention those bearing on the dominance of certain characters.

Generally speaking, albinism in all species is recessive. Thus, the products of a cross between breeds with pigmented mucous membranes and those with non-pigmented mucous membranes have coloured mucous membranes. Of this there are several instances in cattle; the hybrids of Charolais × Schwitz in the district of Aube and Côte-d'Or are white like the Charolais breed, but have a black muzzle, the hybrids of Charolais × Vendée breed are large animals with light coats, but black mucous membranes and legs; the hybrids of Limousin × the Brown Cevennes breed have the good conformation of the Limousin parent but black coat and legs.

Southdown rams, when crossed with white ewes, produce lambs with greyish faces and legs.

As dominant characters the author mentions the tuft of the Paduan fowl and the long hair of the guinea-pig. In horses, black and bay coats are dominant as regards chestnut, and grey and roan as regards bay.

In cattle, hornlessness is dominant as regards the possession of normal horns. When a polled bull is crossed with a normally horned cow, polled offspring are obtained. This was discovered in England a long time ago by crossing the Angus and Shorthorn breeds. The Sarlabot breed originated from a similar cross between the Normandy and the Angus and Red Polled

breeds. This cross was effected in 1852, and the polled character of the progeny was immediately fixed. For the last fifteen years, the author has used the Sarlabot breed in his crossing experiments at Grignon, where its essential character, absence of horns, proved itself to be dominant.

Early maturity, and high milk yield are some of the dominant physiological characters.

Dominance does not, however, always manifest itself even when the contrasting characters are well-marked. Piebald lambs with large black and white patches and "half-tail" resulted from the crossing at Grignon of a Berrichon ram with slender tail, and Somali ewes with thick tail, white body, and black head and upper portion of the neck.

Some colours are sex-linked, thus if a silver Hamburg hen is crossed with a golden Hamburg cock all the hen chicks are golden and all the cockerels silver.

Although the products of the first cross are generally very much alike owing to the presence in the parents of dominant and recessive characters, all homogeneity is lost when the hybrids are mated up together and the recessive characters again make their appearance.

This was discovered some time ago by the Marquis of Béhague in the case of Southdown  $\times$  Berrichon lambs, and it is therefore not advisable to mate hybrids together, but to obtain them direct by the crossing of pure-bred parents. This is very commonly done amongst sheep-breeders supplying the meat market, and is now gaining ground among cattle-breeders, pig-breeders and even poultry rearers in the case of produce destined for the table. The author maintains that equally good results could be obtained by extending the same practice to horses.

"As soon as experimental research work has been continued sufficiently long for it to be possible to determine the reciprocal relations of the dominance and recessiveness of many characters, the breeder will be able to know beforehand the characters that will reappear in the hybrids and thus be in a position to obtain, at least to some extent, animals suited to satisfy the needs of the moment, or the requirements of any particular market."

For this reason, the author is of opinion that "one of the great objects of the Stock-Breeding Research Laboratories should be the study of new methods of propagation based on scientifically conducted experiments, and applicable to practical stock-raising. These methods could either be applied directly, or after they have proved effective by testing them at special Institutes under the direction of the Agricultural authorities, and at Stock-Breeding centres."

740 - **Livestock in Eritrea.** — TARANTINO, G. B. (Osservatorio zootecnico, Asmara) in *Allienamenti*, Yr. II, No. 12, pp. 401-403, Palermo, Dec. 1921; Yr. III, Nos. 1-2, pp. 17-19, Jan.-Feb. 1922.

**STOCK RAISING**

In Eritrea, every native is in possession of a certain number of cattle and sheep. The census for 1905 and for 1920-1921 indicate respectively: horses 20 130 and 35 111, cattle 248 051 and 498 412; sheep and goats

679 457 and 1 531 149 ; camels 28 922 and 23 312. Except for the camels, which have slightly decreased in number, the total has shown an increase. It is observed that these data are certainly below the average, owing to the reserve of the native who objects to giving information concerning his stock, for fear of taxation, consequently a 10 % increase may be estimated

The actual condition of the stock has remained stationary ever since before the Italian occupation, the native is not interested in improvement, as the selling of stock is not his object he prefers rather to utilise the products himself. Near Asmara, where most of the Italian colonies are situated, a few half-breeds between the local cattle and Swiss breeds are seen, but these possess no special qualities

The trade in livestock and its products is very limited, slaughtering takes place on solemn occasions apart from this they are used in the fields, thrashing wheat etc as beasts of burden. As regards products these comprise butter, and skins for tanning purposes for local requirements

The chief cattle breeds are the Arado, found on the Upper plateau (Hamasiën, Seræ Accheli Guzai-Gasc-Settit) and Begait found on the western plateau (Barca and Gasc Setit) both breeds are seen in the Cheren province. The original Arab cattle are found on the coast, chiefly at Massowa

The Eritrean cattle like the Abyssinian breed are zebus. The Arado breed is characterised by its strength and adaptability to farm work and is easily managed. The Begait (dolichomorphous often without horns generally a white skin sometimes spotted) is on the contrary very timorous and difficult to approach

The Eritrean horses belong to the Galla, Dongola and Abyssinian breeds. On the Eastern plateau (Agordat Barenton) Dongolao stock raising is practised to a small extent (1) and native horses in Imbert (Asmaia). A Government stud station was established at Nacfa (Sahel) in 1918, at the present time a remount station has been installed at the Institute of serotherapy for a good Arab stallion. At one time horses were bred at Seimenzano and at Hamasiën this is no longer done because the land formerly used for grazing purposes is now utilised for cereal growing

On account of unfavourable conditions prevailing over the greater part of Eritrea such as excessive heat, pests etc, the superior imported stock have rapidly degenerated hence the reason why Syrian stallions, imported several years ago into Godofelassi (Seræ) and Agordat, have given unsatisfactory results. On the other hand, the donkey has proved resistant to these conditions. The mule breeding experiments made by the Government at Godofelassi the most fertile part on the Upper plateau have not been successful as the mares were debilitated by myriads of blood-sucking insects

(1) See R Feb 1922, No 188 (Ed)

A native breed of sheep covers the Upper plateau, medium size, tail large, wool short and chestnut colour, deficient in milk. The Maria-Mensa and the Habab tribes have raised the breed Arrit, which is hornless and abundant and deficient in milk. The breed Hamolé is raised on the Eastern plateau, a larger animal than the last named, with a long and scanty tail, without horns, white splashed wool, good milk.

True breeds are not to be found amongst the goats, they take their name from the colour of their skin which is red or black or from the tribes which raise them. As a rule, they are large, with long wool, comparatively good for milk, depending on the breed.

The author deals with steps the Government should take to encourage improvement of stock in the Colony and the export of meat  
F. D.

741 - **The Philippine Horse.** — LIZASO, J. in *The Philippine Agriculturist*, Vol. X, No. 4, pp. 135-144, bibliography of 8 works. Los Baños, Laguna, Nov. 1922.

HORSES

The latest census made in the Philippines shows 223 195 horses in 1915 and 203 430 in 1916, that is about 3 horses per 100 persons.

It appears that the Philippine horse is rather a composite animal containing characters from Chinese, Japanese, Mexican and Malaysia breeds etc. Consequently these characters are varied, according to which blood has dominated in a locality.

A study was made of 150 horses (142 males, 8 females), from Laguna.

The most common weight was from 450-500 lb, with an average of 470 lb. Very few weighed less than 400 lb or more than 500 lb.

The most common height was, from 12 to 12 ½ hands.

The ages varied chiefly from 4 to 6 years. The colour was bay of varying shades and next in order of frequency, black, roan, white, brown, grey.

In the head the most common defect was the projection of the upper jaw, the same defect with the lower jaw was less common.

As a rule the head was well cut, rather large, nose generally straight, nostrils fairly wide open, eyes large and bright, ears medium size and well carried. The neck was often large and heavy, but sometimes lacking muscle. Shoulders frequently lean but muscular, chest generally deep and broad; occasionally narrow-chested. Forelegs usually good, although scars have been observed, body fairly capacious and of good barrel, croup wide, but short and sloping, tail long and well carried, hind quarters generally deficient in muscle.

As a rule the build of the native horse is short and rather low-set, especially those of pronounced Chinese ancestry. These are of good quality and wonderful stamina and recuperative power.

The author considers that to encourage improvement young horses should not be worked too soon, at the age of 3 they may be given light work and only when 4 and not at 2 years as practised at present, should they be worked regularly. The horse should be improved by careful raising, use of harness and selection of breeding stock.  
F. D.

742 - **The Proportions of the Trotter.** — VAN MELDERT, L., in *Annales de Gembloux*, Year 25, Book 6, pp. 198-208. Brussels, June 1922.

The author uses the measurements (which he publishes in inches and in centimetres), of 4 trotting horses that have covered a mile in the United States in less than 2 minutes, as a basis for the study of these exceptional trotters and the comparison of their performance with that of 3 excellent Norman trotters. In order to reduce these measurements to the same scale, it was necessary to convert them into arbitrary figures, the height being fixed at 100. Table I gives these measurements; the 2 groups of the converted measurements are given in Table II.

TABLE I. — *Measurements in centimetres.*

	American trotters				French trotters		
	Peter Manning	Uhlan	Lee Arworthy	Arion Guy	Fuchsia	Conquerant	Normand
Height at withers	100.00	100.00	100.00	100.00	100.00	100.00	100.00
Height of croup	99.02	99.19	100.00	98.56	—	—	—
Total back length	98.20	101.19	99.16	98.36	—	—	—
Length of head	41.27	40.50	37.50	40.81	39.12	40.80	40.00
Length of neck	49.35	52.45	48.33	44.48	51.20	48.80	52.50
Girth of thorax at withers	100.31	111.90	112.82	106.12	—	—	—
Girth of thorax at middle of back	110.90	111.65	109.16	102.55	—	—	—
From shoulder-point to ground	58.61	54.61	56.66	57.15	—	—	—
Length of fore cannon-bone	19.00	—	18.33	17.95	—	—	—
Upper circumference of fore limb	34.06	32.93	28.33	27.77	—	—	—
Circumference of fore cannon-bone	12.50	12.85	12.50	12.16	—	—	—
From knee-joint to ground	30.10	35.33	30.83	30.20	29.50	29.50	29.50
Height of point of hock	38.02	35.34	38.75	36.16	39.82	40.00	40.00
Height of stifle-joint from ground	63.37	64.26	66.65	60.04	—	—	—
From point of haunch to point of hock	63.37	64.26	61.66	60.40	63	—	—
Circumference of hind cannon-bone	13.86	14.05	14.16	—	—	—	—
From stifle-joint to point of hock	34.53	—	33.33	34.26	34.10	—	—
Width of haunches	38.02	35.34	30.80	28.97	—	—	—
Width of chest	23.36	26.34	23.33	22.44	—	—	—
When neck is 100 head is	83.6	77.2	77.5	90.1	76.2	83.6	77.7
Totals of head and neck	90.62	92.95	85.83	85.29	90.32	89.60	92.50

The data thus obtained show that :

1) The body-length of the trotter should be less than its height at the withers. This difference should not, however, exceed  $1 \frac{1}{2} \%$  of its height.

2) The length of the head and neck have no influence upon speed, but they have much to do with the appearance of the animal. In the American trotter and the French trotter (Normand) the length of the head added to that of the neck may amount to 93 % of the height.

The length of the fore-cannon bone varies greatly in different indi-

viduals, and ranges from 16.5 to 19 %. The length of the cannon-bone thus has no effect upon speed, and as the height of the knee-joint plays no part in the mechanism of the trotter, the increased length of the fore-limb does not influence its speed in any way. It is therefore the hinder-part that impels the fore-part in trotters

TABLE II — *Table of percentages*

	Peter Manning	Uhlan	Lee Axworthy	Arion Guy
Height at withers	160 $\frac{1}{3}$	158 $\frac{1}{8}$	152	155 $\frac{1}{2}$
Height of croup	158 $\frac{3}{4}$	156 $\frac{7}{8}$	152	153 $\frac{1}{3}$
Total body length	157 $\frac{1}{2}$	160	151 $\frac{1}{8}$	153
Head length	66	63 $\frac{1}{8}$	57 $\frac{1}{8}$	63 $\frac{1}{2}$
Neck length	78 $\frac{3}{4}$	83 $\frac{1}{5}$	73 $\frac{1}{2}$	69 $\frac{1}{4}$
Girth of thorax at withers	175 $\frac{1}{4}$	177 $\frac{1}{5}$	172	164 $\frac{3}{4}$
Girth of thorax at middle of back	178	177 $\frac{1}{2}$	166	160
Height of shoulder point	94	86 $\frac{1}{3}$	86 $\frac{1}{3}$	89
Length of fore cannon bone	30 $\frac{1}{2}$	25 $\frac{1}{2}$	28	28
Upper circumference of fore limb	54 $\frac{1}{2}$	52	43 $\frac{1}{5}$	43 $\frac{1}{5}$
Circumference of fore cannon bone	20	20 $\frac{1}{3}$	19	19
From knee joint to ground	48 $\frac{1}{4}$	55 $\frac{7}{8}$	47	47
Height of stifle joint from ground	101	101	101	94
Height of point of hock	61	55 $\frac{7}{8}$	59	56 $\frac{1}{2}$
From point of haunch to point of hock	101	101	94	94
Circumference of posterior cannon bone	22 $\frac{1}{4}$	22 $\frac{1}{8}$	21 $\frac{1}{2}$	—
From stifle joint to point of hock	55 $\frac{1}{4}$	—	50 $\frac{3}{4}$	53 $\frac{1}{3}$
Width of haunches	61	55 $\frac{7}{8}$	47	45
Width of chest	37 $\frac{1}{2}$	42	35 $\frac{1}{2}$	35

Among the different measurements taken, one is of special importance, that of the upper circumference of the fore-limb. The more it is developed, the greater is the general development of the horse. Great speed is only attained by violent efforts. In the case of the 4 above-mentioned North American horses, placed in decreasing order of speed, the circumference of the upper part of the forelimb was respectively 34.06 — 32.93 — 28.33 — 27.77 % of their height at the withers.

Another important measurement depends on the size of the hind limb, this is the width of the croup from one haunch to the other. Of the 4 horses mentioned, the quickest had the widest haunches. The hock of the trotter is lower than that of the galloper. In the American trotter which was selected for speed alone, the hocks are lower than those of the French trotter, hence the superiority of the former animal.

This also teaches us that it is a great mistake on the part of breeders of trotters to use a thorough-bred English sire and that it is as absurd to have galloping races for trotters, as to make pure-bred horses take part in trotting races.

In the trotter, there should be considerable distance from the point

of the haunch to the point of the hock. The longer this distance, which should be 64 % of the height, the lower is the hock.

An examination of the pedigrees of the 4 American trotters studied shows them to be the products of close and continual inbreeding which proves that this method in the hands of a clever breeder can give good results. F D

## CATTLE

743 - **Cost of Maintaining Milch Cows in Michigan.** RIDDLE, I. T. and KURIZ W. J. in *Quarterly Bulletin Michigan Agricultural College Experiment Station* Feb 1921, and *The Creamery and Milk Plant Monthly* Vol. XI No. 2, pp. 3-33 Chicago Feb 1922.

The following figures on the cost of maintaining cows for the year ending April 30, 1921, have been collected from the Wayne and Monroe Counties (Michigan U. S. A.). Twenty-three dairy farms were studied and the average return per cow was 7104 lb of milk testing 3.33 % and yielding 236.8 lb butter fat. The average returns over the direct costs amounted to 91.91 %.

Out of the 23 herds in question 9 produced an average of 8178 lb of milk per cow making a net return of \$116.11. 11 herds produced 6218 lb of milk per cow with returns of \$87.11 over direct costs or \$29.00 less than the superior herds.

	dollars
548 lb ground oats	8.70
408 " muscical	6.64
14 " ground barley	2.53
14 " bran	3.50
486 " Commercial feeds	13.07
260 " hay (chiefly alfalfa)	24.04
1660 " other dry roughage	6.32
8722 " silage	21.50
424 " other succulent feeds	10.00
23 weeks pasture	14.47
42 lb litter	1.15
<b>Total feed costs</b>	<b>\$ 103.36</b>
Feed and litter costs for steer and bull per cow	17.57
Decreased inventory	5.17
Miscellaneous expenses (veterinary, etc.)	6.76
<b>Total direct costs</b>	<b>\$ 133.66</b>

These do not include labour costs, nor depreciation charges or buildings and equipment which are treated as general expenses, in order to render account keeping much easier and more readily comparable.

The average monthly labour requirements viz. hours of manual labour, per cow and per unit of young stock including bull, are shown as follows (from January onwards): 140 and 44, 128 and 40, 148 and 38, 147 and 43, 136 and 25, 121 and 21, 106 and 21, 104 and 20; 103 and 20, 111 and 21, 127 and 31, 140 and 45. Total for whole

year 151.1 and 36.9. Horse labour required 15 1 hours per cow per year, car or truck travelled a distance of 20 miles per cow. The average wage amounted to \$249 per hour (including board)

The investment per cow is: buildings, \$188 18, stock \$157 32, equipment \$11 55 Total \$357 05

Cost per animal unit (entire herd), respectively \$180 46, 126 60, 9 29, total \$316 36

The average returns per cow were

	dollars
Milk sold 6054 lb	170 82
Cream sold 29 lb	5 36
Dairy produce used at home 161 lb	4 45
Milk fed stock other than dairy (skim milk) 155 lb	0 55
Stock sales less purchases	21 55
Manure 5 63 tons	17 27
Miscellaneous	2 87
<b>Total returns</b>	<b>\$ 225.57</b>
<b>Net returns per cow</b>	<b>\$ 91.91</b>

The above figures refer to 425 dairy cows, 125 yearlings, 78 calves and 21 bulls, a total of 528 animal units (1 animal unit = 1 cow, 2 yearlings or 4 calves)

744 - **The Water Buffalo in the Northern Territory of Australia.** — *The Pastoral Review*, Vol XXXI No 5 pp 625 629 Sydney and Melbourne Aug 1921

The vast Northern Territory of Australia is essentially pastoral

Satisfactory results have not yet been obtained with European imported stock owing to the serious losses through diseases prevalent in this region. It is stated that a wiser plan would be to substitute the zebu and particularly the water buffalo as Eastern stock is far more resistant to disease

745 - **Advantages of Heavy Feeding of Milch Cows.** — ROSS H A in *Circular* No 250 Illinois Agricultural College and the Creamery and Milk Plant Monthly, Vol XI No 3, p 35 Chicago, March 1922

The author states that the present prices of butter fat make it possible to dispose of farm produce at prices much above their present market value, when heavy feeding of cows is practised

In Illinois, good cows are returning 85 cents per bushel for maize, \$24 per ton for hay and 89 50 per ton for silage on the 35 % butter fat basis. These results have been obtained from the Illinois Agricultural Experiment Station and refer to records for 528 cows

The average daily production amounted to 25 lb of 4 % milk per cow for the six months, November to April, and a total of 92 095 lb butter fat

The feeds consumed during the period were as follows for the 528 cows 893 688 lb concentrates + 831 954 lb. hay + 2 229 314 lb silage,

per cow respectively, 1 693 lb. + 1 576 lb. + 4 222 lb.; per lb. of butter fat produced, 9.7 lb. + 9.0 lb. + 24 2 lb.

These cows varied as to size, breed production and date of calving, but were typical of good milch cows found in Illinois.

If the concentrates in the ration consist of 2 parts maize and 1 part bran, and if the hay which is fed is a legume, the ration is well balanced and economical. With the bran costing \$18 per ton, cows like those studied, should give a return as follows: butter fat at 30 cents per lb. per bushel of maize, \$0.70; per ton of hay \$20 50; per ton of silage, \$8.00; butter fat at 35 cents per lb.; respectively (maize, hay and silage) \$0.85, 24.00 and 9.50; butter fat at 40 cents per lb. \$0 95, 28 00 and 11.00.

Only the feed costs are included in this estimation, the incidental expenses of the dairy and the value of the skim milk, are neglected.

Under existing conditions it is therefore evident that heavy feeding of milch cows is profitable, the increased grain ration is advisable as long as there is a corresponding increase in milk production, without a marked gain in body weight of the cow.

Where a legume hay is not available the ration maize + bran + silage + hay may be supplemented by linseed oil meal at the rate of 0.75 to 1 lb. per cow per day depending upon the amount of milk produced.

#### SHEEP

746 — **Shropshire Sheep; Distribution during Recent Years and their Value for Crossing.** — MANSELL, A., in *The Journal of the Ministry of Agriculture*, Vol XXIX, No. 1, pp 44-50, figs 2 London, April 1922.

Towards the end of 1882, breeders of Shropshire sheep established the first Sheep Breeders Association of the world, and the following year the first Flock Book was published. The formation of the association was hastened to some extent by the great demand for Shropshire sheep for export to the United States and Canada, and the buyers were asking for certificates of purity and origin.

It is estimated that no fewer than 20 000 Shropshire sheep were exported during the first 10 years of the Flock Book's existence and this activity has been maintained ever since, either for crossing with Merino or native breeds, or to raise pure bred flocks which would furnish rams useful either for wool value or meat and early maturity.

In the United States, the Shropshire breed, occupies the first rank amongst the pure breeds, in 1920 the total number was 124 453 out of 463 504 pure breeds, i. e. 26 5 %, Rambouillets next and then Merinos. A similar position exists in Canada.

Abundant testimony is at hand which demonstrates the value of the Shropshire breed for crossing purposes, in North America, New Zealand, and Tasmania.

The present prices for first-class animals is given as follows: rams 80 to 150 guineas, ewes 12 to 15 guineas, best quality rams 20 to 40 guineas; ewes 7 to 8 guineas.

Some 150 to 175 lambs per 100 ewes is the usual average; the ewes

are great milk yielders and the breed flourishes in all types of climate, humid or dry, at high altitudes or at sea level. The sheep may be kept between hurdles indefinitely, but better results are obtained if kept on pastures for the greater part of the year. F. D.

747 — **Data to Serve as a Basis for the Development of a Systematic Pastoral Industry in Cyrenaica.** — PROVENZALE, P., in *Allevamenti*, Vol. VII, Part 4, pp. 112-114. Palermo, April 1922.

The native of Cyrenaica breeds sheep only for meat production, though he makes butter from the ewes' milk. In the authors' opinion, excellent cheese could also be made from the milk, and the wool would find a ready market in Italy, where it is much needed to supply the textile industries for which before the War some 200 000 quintals of wool were imported from abroad.

Since the number of sheep kept in Europe and America is continually decreasing, it would be most advantageous to Italy to be able to draw much of her wool supplies from her own colony.

Latium is unable to satisfy the ever-growing demand for sheep-milk cheese of the Roman type; new markets for this product are daily opening, not only in all the Provinces of Italy, but also in America and Northern Europe. Roman "Caciari" were first started in Montenegro, and later in Sardinia (which became, towards 1900, the largest market), Lombardy and Albania.

The North African sheep is naturally, without any selection, remarkable for its hardiness, thrift, resistance to long journeys, and prolificness. The following figures show the returns on native flocks.

*Receipts:*

Butter . . . . .	1.250 kg.	at 10 lire	12.50 lire
Wool. . . . .	2.5 kg.	at 2.50 "	6.25 "
Lambs . . . . .	1 1/2 (3 in 2 years)	at 40.00 "	60.00 "
		lire	78.75

*Expenditure:*

Maintenance . . . . .	10	lire	
Risks and depreciation 15 % . . . . .	18	"	28 lire

*Net return . . . . .* 50.75

Value of sheep 120 lire.

thus the interest obtained is 42 % of the worth of the animal.

If the amount of milk used in cheese-making is equivalent to that producing 1 kg. of butter (13 to 15 litres) 1.5 kg. of cheese + 1.4 kg. "recuite" could be obtained and sold respectively for 10 and 5 lire per kg. A yearling sheep fetches 80 lire: choice wool, of which each sheep produces 2 kg., is sold at 2 lire a kg. The author reckons the cost of one sheep per annum at 30 lire to which must be added 10 % of its value, viz. 12 lire, to cover risks and losses.

He shows that it would pay better to substitute cheese manufacture for butter making.

During the very dry spring of 1921, the author obtained the following figures which may be regarded as the minima :

in full lactation (1 month after lambing) from 0.61 litre to 0.72 litre per head, per day : average 0.66 litre ;

at the end of lactation (4th month), 0.15 to 0.18 litre ;

average 0.166 litre ;

approximate daily average for the whole period (3 months) 0.45 litre ;

yield per head in the 90 days of lactation following the weaning of the lamb  $0.450 \text{ litre} \times 90 = 40.5 \text{ litres}$ . From this milk 18 % of fresh cheese can be obtained, or 6.2 kg. of ripe cheese (15 % being lost during the ripening process) and 12 % of "recuite" made from the remaining serum, this represents a little over 3 kg.

The yield of the Sardinian sheep should, however, be still higher. If these animals are to be imported, the Campidano type is the one to choose; the sheep of this region have some Berber blood owing to repeated crossing with Algerian and Tunisian animals which as compared with the Sardinian mountain variety are taller, produce wool of better quality and a higher meat and milk yield. This breed however needs the care which only Europeans are able to give it, if the flock is to be entrusted to native shepherds, it is best to choose the Sassari sheep as this is very hardy. There is always in any case a higher death rate in imported flocks, especially among the young lambs, and the meat and wool are of less value than those obtained from the indigenous animals.

The Sicilian sheep has already been introduced into Cyrenaica by colonists from Sicily.

No additional pasturage is required for sheep-breeding in Cyrenaica, for the Berber, as a rule, allows the flocks to graze freely on his land being well aware of the advantage it derives from the passage of the animals.

#### 748 - Sheep-Breeding in the Ancient Daunia (Italy) and the "Carapellesi" Sheep. —

ROSARIO, P., in *Allevamenti*, Year II, No 4 pp 112-113, Palermo, April 10, 1921, No 8, pp 253-257, August 1921; No 12, pp 125-126, 1 fig December 1921, Year III, Parts 1-2, pp 31-39, figs 4 January, February 1922

This is a study of the movements of flocks in Italy and the natural, ethnological and political conditions that have governed it from pre-historic times, through the ancient civilisations right up to the present day. The author draws his information from various sources and bases his article on copious archaeological historical, ethnological and geological data.

One of the most important meeting places of the routes followed by travelling flocks on their way from Apulia to the Abruzzi, or back again, was the ancient Daunia a small part of Apulia which is traversed by a net-work of tracks and lies between the streams of Celone and Ofanto and is crossed by the torrent known as the Carapelle (the Latin Daunus).

The name « carepellesi » is given to sheep having entirely and perman-

ently black fleeces, which were more prized in ancient times than white fleeces, owing to the backward condition of the art of dyeing at the time, sheep with more or less reddish, or brown, wool are known as "iezze".

The "carapelleso" belongs to the same Syrian race as the Karakul (*Ovis Aries asiatica*), and has like the latter a curl fleece but its black colour persists throughout its life, whereas the Karakul becomes grey when adult. The "carapelleso" is thus very suitable for crossing with the Karakul. The author suggests that these crosses might be effected at the National Sheep-Farm which the Ministry of Agriculture is about to start at Foggia. F D

749 - **Progress in Pig Breeding in England.** — *The Field*, Vol CXXXVII, Suppl to No 3574, p VI London, 1921

A review of the Shows held during 1921, indicates that pig breeding has made remarkable progress during and since the war. The increasing tendency to displace mongrel stock by pedigreed strains is evident, which indicates a growing membership of breed societies.

The utility value of the cross-bred pig is acknowledged. The stock raiser does not attach much interest to exhibitions but rather to the commercial market. However, it is evident that the above tendency will have an indirect bearing on the business possibilities, as it should result in improvement of breeds. The pig keeper who can observe the inherent characters of bought stock (often with young stock the characters are not easily discernible and some knowledge of lineage is essential) should be able to judge more readily the value of the pedigree animals on the market.

Amongst the systems of management, the simplest and most primitive is the most commonly employed, namely to allow the pigs to run wild on rough ground, with shelters for sleeping purposes. This has economic advantages, suitable also for pure breeds. The pig is one of the most sensitive of animals in regard to its food and comforts, and the vital factor is, therefore, the skill of the stockman in feeding and tending the stock.

Attention is drawn to the multiplication of breeds in recent years. 4 standard breeds are especially striking. Large White, Middle White, Berkshire, Tamworth. The Large Black has become popular and several others are also registered. E F

750 - **The Large Black Pig in England.** SPINCE, R S in *The Journal of the Ministry of Agriculture*, Vol XXIV No 1 pp 50-53, tables 1 London, April 1922.

The popularity of this breed has increased enormously since the formation of a society to register the pedigrees. For some time the Large Black appears to have had a dual origin, varying slightly in type, and raised in the Counties of Essex, Suffolk and part of Cambridge, and also in the South-West of England. An interchange of the two types has resulted in the present breed, prolific, early maturing, hardy, voracious, gives good quality pork, well suited for bacon, sausages etc.

It is admitted that no breed is superior to Large Black for crossing with Large White boars. The pork of the mixed breed is superior in quality and quantity. Large Black has now extended to all parts of England and Wales and has reached Scotland, where until recently breeding of pigs was not very general. In Ireland successful crosses have been made with Large Blacks and Large White, or Large White Ulster boars for use in bacon factories etc. It apparently is adaptable to the climate of South Africa, where all other introduced pure breeds have degenerated quickly.

The members of the breeders Society numbers about 1700. The percentage scale of points is adopted and is here described. The maximum is given to the back (15) which should be long and level, and to the hams (10 points) which should be large and well-filled to the hocks (1).

751 - **Effect of Rationing on the Development of Pigs.** — SWANSON, C. O., in *Journal of Agricultural Research*, Vol. XXI, No. 5, pp. 279-341, figs. 22, tables 25, bibliography of 11 works. Washington, D. C., June 1921.

A brief survey is made of previous investigations on the effect of ration on the development of pigs, followed by a description of the authors' own experiments forming part of a series of experiments begun at Kansas Agricultural Experiment Station in 1911. Young growing pigs were taken and one group was fed on maize alone, another on maize and bone ash or rather, "synthetic ash", a mixture of calcium phosphate, potassium phosphate, sodium chloride, calcium carbonate, sodium citrate, sodium tartrate and ferric citrate in the following proportions: 10 : 37 : 20 : 92 : 15 : 8 : 2. Another group received maize supplemented with feeds calculated to supply the protein or ash deficiency, or both such deficiencies. At the beginning of the experiment a few pigs were slaughtered, analysed and weighed. At the close of the trial one pig from each group was similarly treated. The results given in the Tables and figures are described in detail under four headings.

1. **CHEMICAL COMPOSITION OF PIGS AS INFLUENCED BY THE CHARACTER OF THE RATION.** — Pigs fed with a ration deficient in ash or protein had a very restricted growth. The composition of their bodies was characterised by wide variations among the different animals; generally a low fat and a high moisture content.

Pigs fed on a partially deficient ration, but sufficient to produce a restricted growth, had a high fat content.

---

(1) This breed, is gaining ground in Italy, where it has been recommended to replace the Large White, useful for transmission of characters such as early maturity and high production, but to the detriment of rusticity and especially the possibility of allowing to run free. The first breed should be kept to piggeries, where the products are disposed of in the homestead; the second should be suitable for rough ground and fattening on acorns. See R. Aug. 1921, No. 842. (Ed)

With pigs fed on a ration balanced in respect to protein and ash requirements, the moisture and fat content were nearly equal, with a tendency for the fat percentage to be somewhat lower than the moisture percentage. With pigs weighing less than 225 lb., whose ration was partially restricted, the fat content was higher than the moisture content.

A pig fed with a ration sufficient to produce a large and rapid growth and weighing over 225 lb. showed an increase in fat percentage with the increase in weight. The moisture percentage however decreased. The prolonged feeding of a deficient ration produces the same result, provided the pig attains a large size. The percentage of protein decreased with the increase in size, due to a large increase in the fat percentage. If the percentage of protein is calculated on the basis of body weight less fat, the percentage did not show any tendency to decrease with the increase in size. The same calculation applies to the ash percentage.

The general character of the ration affects the composition of the body as follows. A large amount of protein or ash will not produce a pig with a high protein or ash content. Such a ration will produce a rapid growth, and the pig will have the same composition as a pig of the same size, fed on a ration deficient in protein or ash, but taking longer time to develop. A large amount of ash in the ration will not materially influence the percentage of ash in the body. There is a closer relation between a pig's size and its composition than between the character of the ration and the pig's composition. If growth has not been too much restricted, the composition of a slaughtered pig of given weight may be used to calculate the weight of the chemical constituents in a living pig.

Attention should however be paid to the conditions under which the pig was raised.

II. CHARACTER OF RATION IN ITS EFFECT ON THE DEVELOPMENT OF LUNGS, HEART, LIVER AND KIDNEYS. — The specific character of the ration has, in general, the same effect on the development of the internal organs as on that of the body as a whole. Consequently a ration that will produce a rapid development of body weight will produce also a similar development of the internal organs. There is a distinct variation in the size of the internal organs quite apart from the composition of the ration. The relative smallness in some pigs of restricted growth, may be attributed to over-development of fat.

II. RELATION BETWEEN THE AMOUNT OF CHEMICAL CONSTITUENTS CONSUMED DURING THE FEEDING TRIALS AND THE AMOUNT STORED. — Pigs fed on maize alone store on an average 1 lb. of protein per 7.5 lb. protein consumed, provided that before the rationing is begun they have attained a certain size.

When maize was supplemented with proteins from milk (from  $\frac{1}{8}$  to  $\frac{1}{10}$  of the total protein in the ration), the pigs stored 1 lb. of protein per 5.11 lb. consumed. If supplemented with a medium amount of milk protein ( $\frac{1}{3}$  to  $\frac{2}{3}$  total), the pigs stored 1 lb. protein per 3.5 and 6 lb. consumed, respectively.

The most efficient ration is one which contains a small amount of

protein from milk combined with other feeds so as to give a wide nutritive ratio. When maize was fed alone, the total ash, fat and body protein stored was 1.1 lb per lb of protein consumed, supplemented by a small amount of milk protein it was 1.46 lb, and when supplemented by a medium amount of milk protein, 1.41 lb, when a large amount of milk protein etc was used, the body protein stored was less than 1.1 lb that is, a less efficient storage of nutrients than when maize was fed alone. These comparisons do not take into account the rate of growth.

The largest amount of storage of ash, fat and body protein in relation to the amount of protein in the feed was produced with a ration possessing a high nutritive ratio.

Nine out of the 24 pigs under observation stored more than 1 lb of fat per lb of protein consumed. Amongst these, the 4 which stored the largest amount of fat were fed with rations having a wide nutritive ratio. Most of the 24 pigs studied stored 0.8 lb to 1 lb of fat per lb of protein consumed. The source of protein did not seem to have any particular influence. The 2 pigs fed until nearly 3 years old which depended solely on the maize for protein stored as much fat as the younger pigs which received protein from other sources. The former stored less thermes (in proportion to the thermal value of the feeds consumed) than the pigs whose ration contained protein from animal sources. From the standpoint of energy storage the small amounts of milk protein were as efficient as but not more than the larger amounts. The feeding of maize alone is also not satisfactory. The addition of a small amount of protein from other sources ( $\frac{1}{3}$  to  $\frac{1}{10}$  of the total) is as efficient as when  $\frac{1}{2}$  or more of the protein comes from other sources.

IV EFFECT OF PROLONGED FEEDING OF MAIZE ALONE, MAIZE + ASH, AND PROTEIN-FREE SKIM MILK ON THE GROWTH AND DEVELOPMENT OF PIGS — The more important results obtained in this section of the experiments are shown in the adjoining Table.

Two pigs each 3  $\frac{1}{2}$  months old one fed on maize + ash, and the other on maize + protein free skim milk did not develop satisfactorily, for the first 500 days and then for 400 days showed satisfactory development. Another pig 4  $\frac{1}{2}$  months old fed on maize alone increased in weight very slowly for 300 days but afterwards there was a more rapid gain for the next 400 days which became still more rapid in the last 360 days of the experiment. When maize was the sole source of protein in the ration the proportion of protein stored to protein consumed was 1.7. This ratio was obtained when the maize was fed for a prolonged period "900 days". This agrees with the ratio obtained in several other cases, when maize was fed for a period of 180 days. This appears to be the limit of the possibilities of protein storage with maize.

The 2 pigs, one fed on maize + ash and the other on maize and protein free skim milk, stored 1 therm for 18.82 consumed, during the first 400 days of the experiment. During the last 500 days they stored 1 therm for 3.19 consumed. The pig fed on maize alone stored 1 therm for 8.23

consumed during the first 600 days During the last 400 days, 1 therm was stored for 2.93 consumed

*Proteins consumed and stored and thermic ratio  
in nutrients consumed and stored*

Period	Protein consumed lb	Protein stored lb	Ratio	Therms in nutrients consumed	Therms in nutrients stored	Ratio

## POULTRY

- 752 - **The Rate of Growth of the Domestic Fowl** (1). — BRODY S, (Missouri Agricultural Experiment Station, Columbia), in *The Journal of General Physiology*, Vol. III, No. 6, pp 765-777, figs 4. Baltimore, 1921.

This paper demonstrates the fact that the growing period of the domestic fowl is analogous to that of the mammal, being composed of 3 or possibly 4 cycles. Two of these are postembryonic with maxima at about 8 and 18 weeks respectively, varying somewhat with the breed; two or at least one, are embryonic with maxima at 11 to 12 and 15 to 16 days after birth. Hatching occurs during the first part of the 2nd or 3rd cycle. The velocity curves of each of these cycles are similar to and can be represented by the equation of an autocatalytic monomolecular reaction.

F D.

- 753 - **Nutrient Requirements of Growing Chicks.** — MUSSEHI, L F, HALBERSLEBEN, D A and SANDSTED, R U, Nebraska Experiment Station, in the *Journal of Agricultural Research*, Vol XVII, No 3, pp 139 150, 11 graphs Washington, Oct 15, 1922

Investigators in the field of nutrition have noted that chickens behave unlike rats or swine when limited to rations of one type, such as wheat or maize this led to an enquiry into the values and deficiencies of the common feeding stuffs used for poultry and egg production.

The author carried out a large number of experiments and proved that maize is not a satisfactory food on which to rear chicks.

The chicks chosen for the experiments were selected with great care, all were of the same age, viz, ten days, of equal vigour and development, and each group of nine was apparently uniform in all respects. The chicks were weighed individually every seven days and the figures obtained set out in graphs, the curves being typical of each group.

The ration was given in two parts, one as a coarse, the other as a fine feed; with the fine, or mash feeds, were mixed the supplementary ingredients, the effects of which the authors wished to study.

The results showed that maize is deficient in essential qualities, and is not suitable for the complete nutrition of growing chicks, which on this ration could not develop and ultimately died.

The addition of 5% of mineral substances, such as bone-ash, sulphur, salts of calcium, sodium and iron, were of assistance and made possible a slow, but continuous growth. The inclusion of maize gluten was ineffective.

The addition of 15% purified casein produced a marked improvement: it appeared that the casein supplied amino-acids, in which maize is deficient.

Supplementing the basal ration with other proteins, such as egg albumin and gelatin, lowered rather than raised the efficiency of the ration, and soya-bean meal was equally ineffective.

The addition of butter had no result. the fat contained substances which may have stimulated growth and so masked temporarily the lack of other essential accessories. There was a slight improvement in condition, followed by a loss of weight until the chicks died.

The addition of green foods brought about a decided improvement;

green wheat was given in abundance, and eaten by the chicks to the extent of about 5 %, dry weight, of the whole ration. The helpful influence of green food may have been due to an improvement in the physical condition of the ration, and to a stimulating effect on the appetite.

Further experiments are now being carried out to ascertain the specific action of green foods

With a ration formed of maize 65 parts, casein 15 parts, ash mixture 5 parts, starch 10 parts and unlimited green food, satisfactory growth to adult and egg-production stage was achieved, although the chickens were confined in a small pen under unfavourable conditions. L. V

**754 - Clover Flour and Grape-Pip Flour in Poultry Feeding.** — FRACANZANI G. A., in *Bassa Corte*, Vol. III, Parts 52-53, pp 1133-1136, figs 3 Molasana, Genoa, April-May 1922

The author draws attention to the fact that a habitual and liberal maize diet fattens poultry, but at the expense of egg production, and therefore suggests, in order to obtain a closer nutritive ratio viz., about 1 : 5, the admixture of cakes, clover, etc

Clover should be fed fresh when possible, but in winter, clover flour can be given, that is to say, the residuum after threshing, or the finely chopped hay after soaking in water for 10 hours

Clover and the meal made from it are rich in lime and thus aid in the formation of egg-shells

The author recommends rations containing clover flour, to some of them flour (cake) made of grape pips is also added, and makes an excellent paste which is too little appreciated at present

The following are daily rations for 10 tows: clover flour 230 gm. + wheat bran 180 gm + ground rice chaff 140 gm

Clover flour 170 gm + maize 110 gm + bran 120 gm

Morning: grape-pips flour 150 gm. + sesame flour 220 gm. + clover flour 180 gm, evening: oats (soaked in water for 24 hours) 150 gm + maize 200 gm

The author gives the results of some of his own experiments showing that egg production is increased by adding clover flour, or grape-pip meal to the paste fed to hens F. D.

**755 - Duck Hybrids.** - I LÉCAILLON, A., Sur les caractères d'un hybride issu de l'union d'un canard musqué mâle (*Carina moschata*) et d'une oie d'Égypte femelle (*Chenalopes aegypticus*), in *Comptes rendus de l'Académie des sciences*, Vol. 174, No 1, pp 68-69 Paris, January 3, 1922 — II IDEM, Sur les caractères d'un hybride mâle provenant de l'union d'un canard pilet mâle (*Dafila acuta*) et d'un canard sauvage femelle (*Anas boschas*), *Ibidem*, Vol. 174, No 13, pp 885-887, March 27, 1922 — III IDEM, Fécondité des hybrides obtenus par croisement du canard pilet mâle (*Dafila acuta*) et du canard sauvage femelle (*Anas boschas*), *Ibidem*, Vol. 174, No 22, pp. 1429-1433, May 29, 1922.

I. A brood hatched in the Toulouse Zoological Gardens contained, in addition to normal goslings, one male hybrid differing entirely in appearance from its parents. This bird which was the result of the cross *Carina moschata* ♂ × *Chenalopes aegypticus* ♀ might be regarded as com-

posed of a mosaic of characters some inherited from its father, e. g. size, absence of voice, colouration of plumage in the dorsal region etc., and the others from its mother, e. g. carriage, conjugal fidelity, plumage on ventral surface etc.

II. — In 1920, several hybrids were obtained in the Toulouse Zoological Gardens from mating a *Dafla acuta* drake with a common wild duck (*Anas boschas*). One of the ducklings was a male; the author describes its characters and compares them with those of the *Dafla acuta* and *Anas boschas* drakes

In some of its characters, this hybrid resembled more nearly the drakes of one or the other of the parental species, otherwise it was more or less intermediate between the two types of bird.

These two cases are instances of the class of hybrids in which the direct products of the mating of parents belonging to different species possess new characters, or else characters intermediate to a greater or less extent between those of the two parental species.

III. — The long-tailed duck (*Dafla acuta*) and the mallard, or wild-duck, mate readily both in the wild state and in captivity

Although animal hybrids are infertile (as are also the mules obtained by crossing the Barbary and domestic breeds of duck), the hybrids of the long-tailed duck and the mallard form an exception to the general rule which makes them especially valuable material to the student of the phenomena of heredity

The author has so far succeeded in breeding 3 classes of hybrids; 1) the direct offspring of two parents belonging to different species; 2) the progeny obtained by mating a male hybrid of class 1 with a mallard duck; 3) the products of the mating together of the hybrids of class 2.

F. D.

756 — **Problems of Incubation.** — LAMSON, G. A (Connecticut Agricultural College) in *The National Poultry Journal*, Vol II No 82, pp 396 397

The factors influencing incubation are numerous, they may be divided into factors having to do: 1) with the collection, selection and care of eggs before placing them in the incubator 2) with the handling and care of the eggs during incubation

At the World's Poultry Congress held at the Hague in 1901 the author presented the following rules, as a result of the study of the physiological development of the embryo and practical experience.

The eggs should not be kept more than 16 days previous to incubation and the freshest eggs are best. The temperature should not exceed 90° F. Eggs should be kept lying on their sides in a dry place, as moisture tends to increase the possibility of infection through the shell. Recent investigation has shown that there is little or no value in turning the eggs previous to incubation. Eggs laid early in the season and kept at low temperatures take longer to incubate.

It is not possible to determine sterility, fertility or sex from the size or shape of the egg

The use of large eggs for hatching is recommended on the ground that the size of the egg is a matter of heredity. Very large eggs however, as a rule do not hatch as well as medium sized eggs. Eggs with very porous or flaky shells with marked inequalities in thickness, do not hatch well. Very thin shelled eggs are likely to be broken during incubation. Excessively dirty eggs should not be used, and it may be advisable to wash eggs before incubation.

A thin muslin curtain tacked over the window will keep out direct sunlight and strong air currents.

Incubators should be set level in order to prevent warm places in the air chamber, incubators should be started 2 or 3 days before the eggs are placed in them.

To ensure the development of the embryo, without delay, the temperature should be regulated at 104 or 105° F before putting in the eggs and then maintained at 103° F. If the period of incubation is lengthened the tendency is to decrease the numbers of eggs hatched. The regulation of the temperature is of great importance, especially during the first 5 days of incubation. It is doubtful if varying the temperature during the three weeks of incubation has any advantages over a uniform temperature of 103° F.

Tests made with about 10 000 eggs using the calorimetric method in incubators with varying relative humidity gave the following results, which indicate that there may be a wide variation in humidity without much danger.

#### *Effect of humidity on incubation*

Relative humidity %	Average Loss of Weight per egg gm	% of fertile eggs hatched
70-80	3.0	55
60-70	4.10	57
50-60	5.61	55
40-50	5.52	10.2
30-40	6.57	11.5
20-30	5.22	14.5
15-20	7.74	14.7
		46.0

The method of incubation in rooms above a cellar has proved difficult owing to the fact that the conditions of humidity are very different from those in most rooms below ground level.

The practice of cooling eggs during incubation is not recommended. It is incorrect to say that cooling affects the vitality of chickens, out of 500 chickens, 34 had died at the end of 4 weeks, 20 of which had been cooled during incubation and 14 had not been cooled.

Ventilation may vary to a fairly large extent without any deleterious effect, only when the carbon dioxide reaches 15 % is the danger noticeable. If the ordinary incubator is well ventilated the question of carbon dioxide is negligible.

Eggs should be turned from the third day of incubation and at frequent intervals until at the point of hatching. It has been found that eggs turned at least 5 times during each 24 hours have given somewhat better results than those turned twice, and the latter showed an improvement on those turned only once. The common practice of turning each morning and evening is advisable from the economic standpoint. When turning it is advisable also to change the position of the eggs on the tray, thus equalising the effects of minor variations in temperature that may occur in the incubator.

The individuality of the hen has a marked influence on the vitality of the embryo; out of 1003 eggs laid by 18 hens, only 7 were sterile, whilst nearly 600 from the same number of eggs from other sources, were sterile. Hatching has varied from 90 % from some hens to 30 % with others. The choice of the mother hen is therefore probably the most important feature in incubation. There is less variation in vitality with the embryos of malebirds.

At the present time, the all important question is how to increase the vigour and strength transmitted from the hen to the embryo by means of wise selection of mother hens, proper feeding, good housing exercise, etc.

757 - **Poultry Rearing in Cyrenaica.** — PROVENZALE, P. in *Bassa Corte*, Vol. III, Part 50, pp. 1057-1058. Molassana (Genoa), February 1922

The native fowl of Cyrenaica belongs to the type common to the whole of North Africa. Although known as the Arab fowl, it is the product of crossing several breeds introduced from different Mediterranean countries. It is a small bird with a net weight never exceeding 1 kg. The colour of the plumage varies, but is generally uniform; the crest is small, or rudimentary, and the legs grey. The hens often lay daily, except during the autumn months, and produce a large number of eggs (total weight about 50 gm), but they are not good sitters.

In addition to the common type of fowl there are many representatives of the "pollo sultanino". This bird is of Turkish origin and has a small crescent-shaped tuft behind the comb. A few birds with feather less necks are also to be found; they are natives of Transylvania, but are called "Scandria", in Cyrenaica, on account of their supposed Alexandrian (Egyptian) origin.

The colonists have quite recently imported poultry from Italy, but the breeding results have been negative for the following reasons: want of protection from the changes of weather, especially from the ghibli; the want of resistance of European poultry and their first crosses to contagious diseases such as a form of diphtheria, coccidiosis, and a slow type of avian pest. The native fowl recovers from all forms of diphtheria and becomes immune, though it remains a carrier of the disease.

Egg-production is a very paying speculation. Before the War, Tripoli and Misurata used to export annually from 8 to 10 million eggs to Malta, Italy, France and Tunisia.

The meat is fairly good in quality, but little in quantity, owing to the small size of the birds. Caponising the cockerels has not proved successful for many reasons. As regards the acclimatisation of foreign breeds, the author advises the poultry rearer to turn his attention to the "Marsalese" breed, the product of selection by Prof. Tuccì.

Pigeons, turkeys and ducks have all been reared with great success in Cyrenaica, but rabbit-breeding is a matter of greater difficulty.

F. D.

755 - **Poultry Feeding Methods employed by Experiment Stations in the United States.** — Atwood H. (West Virginia), in *The National Poultry Journal*, Vol II, No 56, pp 41-42 London, 1921

*Cornell (Ithaca N. Y.) Ration for laying hens.* — The scratch grain consists of a mixture of 200 lb of cracked maize + 200 lb wheat + 100 lb. oats. The grain is scattered in deep litter, in small quantities in the morning and more at night. The mash is composed of 200 lb. maize meal + 200 lb wheat middlings (white) + 200 lb meat scrap + 100 lb wheat bran + 100 lb. ground heavy oats. + 25 lb. oil meal + 4 lb salt.

This mixture is fed dry in the open during the afternoon. The amount of feed is so regulated that about twice as much grain as mash is consumed. This ration is recommended for all breeds. For heavier breeds however, the morning feed is limited so as to encourage exercise and a bigger consumption of mash. Green food, grit and oyster shell are also provided.

*Ontario Agricultural College.* — A small amount of whole grain is fed in the litter morning and evening, the quality depends on the price. Crushed oats is always supplied and sour milk or buttermilk forms the protein ration. Considerable care is taken that the supply of green food is abundant, mainly in the form of sprouted oats, then cabbage, rape, etc. Where no milk is available, a mixture of 4 parts oats and 3 parts shorts, barley; maize or buckwheat meal is recommended, at the rate of 15 % for the heavy breeds, and 20 % for lighter breeds.

*Storrs Experiment Station (Connecticut)* — The scratch feed is composed of equal parts by weight of wheat and cracked maize, the mash consists of equal parts by weight of wheat bran, maize meal, ground oats, flour middlings, beef and fish scrap. The dry mash is always available for the hens; the principal feed of scratch grains is given about 4 p. m., but in winter a small amount is also given in the morning to induce exercise. Grit, oyster shell, charcoal and green stuff are also provided.

*New Jersey State.* — The mash is always available for the hens in hoppers, sufficiently large to permit one filling to last from one to two weeks at least. The following mixture is recommended.

Every morning about 9 o'clock, in a deep litter about 5 lb. of scratching ration is fed to each 100 hens, composed of equal parts of wheat and

*Dry mash ration.*

Feed	Quantity	Protein	Carbohydrates + fat $\times$ 2.25
	lb.		
Wheat bran . . . . .	200	24.2	90.6
Wheat middlings . . . . .	200	25.6	121.4
Ground oats . . . . .	200	18.4	113.6
Maize meal . . . . .	100	7.9	76.4
Gluten meal . . . . .	100	25.8	65.6
Meat scrap. . . . .	100 to 200	66.2	35.1
Short cut alfalfa . . . . .	100	11.0	42.3
Total . . . . .	1 000	179.1	545.0

Nutritive ratio 1:3.02

oats (protein 10.2 and 9.2 % respectively ; carbohydrates + fat  $\times$  2.25 ; 73.0 and 56.8 % ; nutritive ratio 1:6.6).

From 4 to 5 p. m., depending on the season, a ration is fed composed of 10 lb. to each 100 hens, fed in litter : 2 parts cracked maize + 1 part wheat + 1 part oats + 1 part buckwheat.

The proportions of protein are as follows, respectively, 15.8, 10.2, 9.2, 7.7 ; carbohydrates + fat  $\times$  2.25 ; 152.8, 73.0, 56.8, 53.3 ; nutritive ratio 1:7.8.

*Wisconsin Agricultural Experiment Station.* — The typical scratch feed consists of 2 parts cracked maize + 2 parts wheat + 1 part oats or barley. The mash consists of equal parts of ground maize, gluten feed, bran, middlings and meat scrap, fed at the rate of 1 lb. mash to 1 lb. scratch feed. A small amount is thrown in at night after the fowls have gone to roost, or in the morning before they go out. The fowls have easy access to the mash all the time, and a light mast moistened with skim milk or buttermilk when available is provided at noon. Cabbage, mangels and sprouted oats are given in winter and rape during the summer.

*Maine Agricultural Experiment Station.* — The following method has been found satisfactory. For each 100 hens, 4 qts. of whole maize are scattered in the litter in the morning, and at 10 a. m., they are given, 2 qts. of wheat and 2 qts. of oats. Dry mash is always available, but it is stated that it is not advisable to feed pullets recently transferred to the laying houses on too rich a mash. During the first month (September) the mash consists of 3 parts bran + 1 part middlings + 1 part gluten meal + 1 part meat scrap. The second month : 2 parts bran + 1 part maize meal + 1 part middlings + 1 part gluten meal + 1 part meat scrap.

For the third month, the same as for second month, with the addition of  $\frac{1}{2}$  part oil meal. During the following months the oil meal is alternately added and omitted. Sprouted oats are generally used as green stuff.

A fair degree of uniformity evidently exists among the various Stations both as regards scratch feed scattered in the litter and the use of

animal protein feeds (meat scrap, skim milk etc.), and green stuff, grit, and oyster shell. The following standardised ration may therefore be determined.

*Scratch feed.* — 5 parts cracked maize + 1 part wheat + 2 parts barley + 2 parts oats.

*Mash.* — Equal parts of bran, wheat, middlings, maize meal, gluten feed, ground oats, and meat scrap.

759 — **Bee-Keeping in Tasmania.** — OLDAKER, C E W, in *Department of Agriculture, Tasmania, Bulletin* No. 100, p 1-4, Feb 1921.

BEEKEEPING

The mild climate, the long duration of the spring and summer and the abundance of honey plants, renders Tasmania very favourable for the development of bee-keeping. The author makes practical suggestions, in an easily understood and concise manner, for the benefit of those who are interested in the industry.

E. F.

760 — **Acceleration of the Development of the Silk-Worm.** — SURCOUF J, in *Bulletin de la Société d'Histoire Naturelle de l'Afrique du Nord*, Vol XIII, No 4, pp 107-108, Algiers, April 14, 1922

SERICULTURE

It sometimes happens that silk-worms forgotten in their boxes and consequently deprived of food, yield normal cocoons, the adults are more or less atrophied, but transformation has been more rapid than in the case of worms which have received normal treatment in the matter of food and care.

Taking this fact into account, the author made experiments with *Anessa urticae*, *Spilosoma menthasstr*, and *Bombyx mori*, and discovered that through the action of the unused digestive secretion, the cuticle covering of the intestine was dissolved, the process of evolution took place and the metamorphosis was completed.

He then attempted to increase the action of the gastric juice of the worm in order to hasten its evolution. For this purpose, he sprayed water treated with trypsin and containing soluble salts of calcium on the leaves used as food for the worms. The digestive power of the silk-worm was thus considerably increased. The *B. mori* reared at a temperature of 23°-24° C, evolved in a fortnight. The number of meals was 20 during the first period of life; 17 during the second; 14 during the third; and 10 on each of the two days before the "mounting period. Generally rearing lasts from 28 to 30 days.

The author considers that by this process, the evolution cycle might easily be completed in 18 days without special preliminary treatment. The cost of the operation would thus be reduced and polyvoltine races could be raised capable of giving 4 generations in a limited period corresponding with the progress of mulberry-tree growth. At the same time an attempt might be made to accelerate the silk secretion in order to obtain a better yield.

P. C.

## FARM ENGINEERING.

AGRICULTURAL  
MACHINERY  
AND  
IMPLEMENTS

- 761 - Pump for Calzoni-Parenti Hydraulic Presses. — FREZZOTTI, G. (R. Oleificio sperimentale di Porto Maurizio) in *Il Coltivatore*, year 68, No 1, pp 12-15, 3 figs. Casale Monferrato, 1922

This new machine by the Firm Calzoni-Parenti, Bologna, for the olive oil industry, has been tested, with perfectly satisfactory results, at the experimental oil mills at Porto Maurizio (Liguria).

It is constructed with coupled pistons and may include 2, 4 or 6 pumps, capable of feeding the same number of hydraulic presses simultaneously, each pump working independently. The annexed diagram shows a cross section. There is another type working not only at high pressure, but also at high and low pressure, but in these cases each pair of pumps feeds one press only.

The special features of the apparatus are: 1) the brake system of the pump and pressure exhaust by means of differential pressure valves; 2) the control of the two pump pistons by a single eccentric, 3) automatic, continuous lubrication, 4) the power of throwing the pump-bodies out of gear by checking the counterpoise lever with a special bolt.

When the counterpoise has been correctly adjusted (after testing with the manometer scale corresponding to the maximum pressure desired), it is easy to determine the moment when the press has reached its maximum pressure, for the lever of the pump rises automatically. To lower the press, the lever of the pump is raised and fixed with the bolt; the pump is thus thrown out of gear, while the water in the press returns through the pump to the feed-reservoir.

Any recipient connected with the machine by a pipe may be used as a reservoir. (See diagram). F. D.

- 762 - Consumption of Coal and Electricity in Machine Threshing. — TABGEN, in *Die Landmaschine*, Year 11, No 17, pp 309-311 Berlin, April 29, 1922

An experiment made in Germany to ascertain whether the electric motor is more economical than the portable engine in machine threshing.

A Wolf 1908 superheated steam portable engine was used. It had formerly been used in threshing and sawing and was characterized by the following: 12 atm. working pressure, 22 HP normal, 31 HP maximum continuous, 36 HP maximum. The only repairs executed were: changing the piston rings in the summer of 1921 and soldering the superheaters damaged by rust.

The motor was a Siemens-Schuckert alternating current of 40.8 HP and 955 revolutions a minute; it was connected by a cable with a transformer placed near the high tension wire. There was an amperemeter on the carriage of the motor and a kilowattmeter on the transformer.

A Wolf 1921 threshing machine was used: the drum was 1680 mm. long and 620 mm in diameter and the threshing machine had an automatic

Cross section of the "F. N. Calzoni-Parenti" type of pump. On the left is the water reservoir S. When the levers are in the position (L) the pump bodies are in action; when they are in the position (R) the pump bodies are at rest.

feeder and large and small fans: there were no accessories, such as screens for dead leaves, chaff, stubble, etc.

The rye-threshing experiment gave good results, the straw-grain

ratio being 1: 1.3. The grain, straw and chaff were weighed and the total corresponded with the weight of the sheaf.

Four tests were made on the 12th and 13th December, 1921:

I.	A test on 12th Dec., from	1.37 p. m.	to	4.7 p. m.	by electric motor
II.	" " " 13th " "	8.24 a. m.	"	10.54 a. m.	by portable engine
III.	" " " " " "	11.30 " "	"	1.30 p. m.	by electric motor
IV.	" " " " " "	2.4 p. m.	"	4.22 " "	portable engine.

This last test really lasted 2 hours because there were two interruptions of 18 minutes (altogether) caused by the driving-belt.

The kilowattmeter was read before and after the experiment and the coal was weighed.

The straw from the 3rd and 4th tests was loaded on a separate wagon and again thrashed on the 14th December, the rye-straw first thrashed by the portable engine being worked by the electric motor, and vice-versa. No difference was observed between the two systems, the straw containing no grain in either case. The consumption of electricity was 73 kwh; that of coal containing 6900 to 7600 calories was 225 kg divided as follows:

	kg.
Lighting . . . . .	41.50
Power . . . . .	170 00
Interval of 2h 30. . . . .	12 00
Interruptions of 18 mins. . . . .	1.50

As will be seen, little power was required. This was due to the fact that the axles of the thresher were fitted with ball-bearings and that there were no accessories, which absorb much power.

The results of the experiment show for an average day's work of 9 hrs.

(1) For the electric motor:

Grain . . . . .	175	qx
Consumption of electricity. . . . .	157.5	kwh
" per quintal . . . . .	0.904	"

(2) For a portable engine of 13 years service:

Grain. . . . .	194.5	qs.
Coal. . . . .	420	kg.
Consumption per quintal . . . . .	2.16	kg.

The prices ruling at the time were:

1 ton of coal. . . . .	440 marks
1 kw . . . . .	2 mks 77 pf.

The price of the best quality of coal used in the threshing was 463 mks per ton; adding transport and other expenses, this amounted to 500 mks.

The maximum daily consumption of oil may be estimated at:

	kg.
1) for the motor and transformer. . . . .	0.3
2) " " portable engine. . . . .	1.5

Consequently the consumption per quintal amounts to :

1) by electricity .	kg 1 6
2) with coal .	8 0

At the time the experiment was made, oil cost 20 marks per kilo ; consequently the cost of threshing per quintal of grain was

(1) by electricity

			mks
Current	0 104	× 2 77	— 2 52
Oil	1 6	× 0 02	= 0 04
			—
			mks 2 56

(2) with coal

Silesian coal	1 10	× 50	1 05
Oil	5	× 0 02	= 0 10
			mks 1 4

The higher cost of threshing by electricity is not compensated in any way, for the expense of installation, sinking fund, interest, labour, etc is the same as, if not more than that of threshing with a portable engine. Even as regards the staff required, no economy can be effected, for one mechanic is always needed, whatever machine be used. In addition, in regular working, with the portable engine, a better use is made of the fuel, indeed it has been observed that in summer the consumption of coal per quintal of grain is not more than 1 90 kg. The greater consumption during the experiment is due to the low temperature in the month of December and still more to the unfavourable conditions in which the portable engine was working, 4 ½ hours in all, with 3 interruptions, the first for 2 ½ hrs the second of 5 minutes and the third of 10 minutes. In spite of this, the consumption of 2 16 kg should be considered as a proof of the economy of the portable engine, especially when it is considered that it had been working for 13 years. Further, improved portable engines now exist, with a coal consumption of about 20 % less, that is, of 1 6 kg to 1 3 kg per quintal of grain. E P

## RURAL ECONOMICS

763 - Cost of producing Wheat on 481 Farms in the States of North and South Dakota, Minnesota, Kansas, Nebraska and Missouri for the Crop Year 1919. — COOPER, M R and WASHBURN R S (Assistant Farm Economists) in United States Department of Agriculture, Bulletin No 913 Contribution from the Office of Farm Management and Farm Economics pp 1 59 figs 9 Washington D C, 1921

The authors state that to be of any real significance, cost figures must be presented in terms of the ranges that exist in the final cost per unit of production and in the various elements of cost. The variations in the cost per unit of production in any representative farming area

are so marked that they should be considered in any case where cost figures are concerned. From the presentation of the range of costs of farm products, it would appear that usually from 40 to 50 per cent of the production involves expenditure above the average. It follows that the cost that will cover the "bulk" of the production of a given product is the figure that approximates to what the price should be to maintain the industry. This consideration has led to the development of the "bulk-line" theory which has recently assumed an important place in the discussion of the relation of production costs to price. The "bulk-line" theory is a modification and an attempt at practical application of the "marginal cost" or "greatest cost" theory of the relations of cost and price. In practice, the "bulk-line" has sometimes been drawn to include 85 per cent. of the production, but this is merely a tentative and more or less arbitrary figure.

In reality the position of the "bulk-line" varies with different commodities and from time to time, according to the alertness with which farmers adjust their production to market conditions. The "bulk-line" cost corresponds to the long-period average price which is essential, one year with another, to stimulate the production of the amount of product which the market demands. What this "bulk-line" cost will be depends upon a number of factors, including the rate the farmer must pay for land, labour and capital, and the standard of living which farmers, as a class, insist upon if they are to remain on the farm.

The purpose of the present bulletin is to give a statement of facts concerning the cost of wheat production for the area and season covered by the survey: United States western and northern plains and the crop year 1919

Tabulated cost data were obtained from 481 records, of which 197 were made in five representative counties of the principal spring-wheat States, North and South Dakota and Minnesota, and 284 in nine counties in Kansas, Missouri and Nebraska, important winter-wheat States, and furnish the basis of this analysis of the average cost and variation in cost on individual farms and groups of farms in each area visited, as well as the more important reasons for the great variations in cost per acre and per bushel on individual farms. A total area of 43 940 acres sown with winter wheat, yielding 635 124 bushels, and a total area of 44 218 acres seeded for spring wheat, with a total production of 362 047 bushels for the crop year 1919, were involved. The results are summarised as follows:—

*Cost per acre* · Spring wheat, \$12.98 to \$47.84; average, \$22.40. Winter wheat, \$10.55 to \$50.23; average, \$27.80

*Cost per bushel* · Spring wheat, \$1.15 to \$14.38; average, \$2.65. Winter wheat, \$0.96 to \$8.74; average, \$1.87.

*Yield* · Spring wheat, 20.8 bushels per acre to less than 1 bushel; average, 8.4. Winter wheat, 30 bushels per acre to 2.2; average, 15.19.

The average yield of spring wheat was 9 bushels per acre in the United States as a whole in the same year, 1919, and the average yield for all

winter wheat in 1919 was 14.7 bushels per acre. The largest number of spring-wheat farms fell within the group having a yield of from 5 to 10 bushels per acre, while the largest number in the winter-wheat districts were included in the group having a yield of from 15 to 20 bushels.

The difference between the gross cost and the sum of credits for pasture and any straw utilised on the farm is taken to be the net cost of producing wheat. The average cost expense of each item was computed on a basis obtained by dividing the total cost of each item by the total wheat acreage. An analysis of the total cost for spring and winter wheat shows that labour accounts for about 32 to 35 % of the total cost of production, thrashing about 8 %, materials from 10 to 17 %, land rent from 24 to to % and other costs from 17 to 19 %. The difference in cost per bushel of producing spring and winter wheat is due to a lack of relation between the cost of producing an acre of wheat and the yield obtained, the cost per acre of winter wheat being 24 % greater than for spring wheat. In the spring-wheat area about 33 % of the production was on the farms having costs above the average ; in the winter-wheat area about 40 per cent of the production was on farms having costs above the average.

Summaries of costs by districts, range in cost per acre by counties, net cost per bushel, variations in items of cost, area of farms according to cost per bushel by counties, cumulative percentage of acreage grown at various bushel costs, cumulative percentage of total production, and individual costs per acre are tabulated and discussed. G. A. B.

764 - **The Cost of Production of Wheat, Beet, Potatoes and Milk in France.** -- GIRARD H. in *Bulletin de la Société des Agriculteurs de France, Supplément du Bulletin d'avril 1922, Comptes rendus de l'Assemblée générale de 1922, Section 2*, pp. 39-45. Paris, 1922 (1).

The French Minister of Agriculture has recently ordered a periodical enquiry to be made in order to compare the prices realised for agricultural produce and those charged by the retailers to the consumers. At the same time, the French Farmers' Association has decided to take the opportunity at their annual meeting to examine the economic situation of farmers in 1912-13 as compared with 1920-21 so far as the chief products of the soil are concerned, in order to collect information which will be of use in the Parliamentary debates.

The author has to report on wheat, beets, potatoes and milk, which together represent about a third of the area cultivated and a third of the money realised by French agriculture. He has ascertained the cost of production by adding the total outlay which is undoubtedly involved, to the general expenses (per ha), that is : upkeep of material and maintenance by the tenant of buildings and farmyards, farming, taxes, insu-

(1) See also: MINISTÈRE DU TRAVAIL, STATISTIQUE GÉNÉRALE DE LA FRANCE ET SERVICE D'OBSERVATION DES PRIX, COMMISSION CENTRALE D'ÉTUDES RELATIVES AU COÛT DE LA VIE. *Compte rendu des travaux au cours de l'année 1920*. Paris, 1921. (Ed.)

rance, power and light, paid supervision and sundry expenses. On the other hand, neither interest on capital invested, remuneration for management, nor reserve working capital has been included.

The results are as follows:—

### A. — *Wheat.*

Items of Cost of Production	1912-13		1920-21	
	Fcs.	%	Fcs.	%

700 trusses straw.	fcs. 0.20 × 700 = 140.00	700 trusses straw.	fcs. 0.80 × 700 = 560	
	Fcs. 749.50		Fcs. 2170	

1) In 1913 the cost of production of 1 hectare of wheat being 638.60 fcs., and the price realised for 1 quintal being 26.50 fcs., the latter represents 4.15 % of the outlay per hectare.

In 1921, the outlay for 1 ha. of wheat being 2122 fcs. and the quintal selling for 70 fcs., the latter represents 3.30 % of the outlay per ha.

For straw, the proportion is 3.13 in 1913 and 2.36 in 1921, per 100 trusses.

2) In 1913, the outlay per hectare was . . . . .	638.60 fcs
» 1921, » » » » » . . . . .	2,122.00 »
that is, a difference of . . . . .	1,483 40 fcs
In 1913, the quintal sold at . . . . .	26 50 fcs
» 1921, » » » » » . . . . .	70.00 »
A difference of . . . . .	43 50 »

in favour of 1921, or an increase in profit of 1,210.50 fcs. per ha. yielding 23 qx in 1913 and 26 qx in 1921

The increase in the price realised per ha. is only 81 6 % of the increase in the cost of production if the grain only be taken into account.

As regards the straw, the increase realised (prices being 20 fcs in 1913 and 50 fcs in 1921 per 100 trusses), is 14 1 % of the increase in the cost of production. Therefore the total increase in price (wheat and straw per ha) is  $81\ 6 + 14\ 1 = 95\ 7\ %$  of the increase in cost of production.

#### B. — Sugar beets

Items (of Cost of Production)	1912-13		1920-21	
	Fcs	%	Fcs	%
I. General Expenses: rent, taxes, insurance, sundries	186 00	21 08	400 00	13 74
II. Manuring & Fertilisers				
8000 kg manure				
4 for beets . . . . .	$\frac{4}{7} \times 30 \times 8 = 137\ 00$		$\frac{4}{7} \times 30 \times 514 = 834\ 00$	
100 kg. super . . . . .	4 5 85	23 40	4 30 = 120	27.30
200 kg nitrates . . . . .	2 26 20	52 40	2 100 = 200	
III Seed:				
20 kg of seed . . . . .	20 1 50	30.00	20 5 100.00	3.29
IV Cultivation				
24 days of manual labour	24 x 4 25	102 00	24 15 360.00	11 82
53 days of horse labour.	53 4 75	251 75	53 17 901.00	29 59
Plough work: and ploughing, pulling, loading . . . . .	50 + 60	110 00	—	450.00 14 77
(Total manual labour = 24 03 %).	892 55	100.00	13045.00	100 00
Yield per hectare . . . . .	29 760 kg		21 500 kg.	
Price realised . . . . .	28 65 fcs	per ton	105 00 fcs.	per ton
Gross profit . . . . .	851 00 fcs.		2257 50 fcs.	

1) In 1913, beet production costing 892.55 fcs. per ha. and the ton selling at 28.65 fcs., the latter represents 3.21 % of the cost of production per ha.

In 1921, production costing 3045 fcs. per ha., and the ton selling at 105 fcs. the latter represents 3.45 % of the cost per ha.

Appearances are in favour of 1921, but in reality the contrary is the case, owing to the poor yield of that year. With a 29760 kg. yield in 1913, the loss on beets was only 892 55 fcs — 851 fcs = 41.55 fcs, whereas in 1921, in the average yielding districts, with 21500 kg per ha., the loss was 3,045 fcs. — 2,257 50 fcs = 787.50 fcs

This proves how uncertain beet culture has been for a long time, if the returns only be considered and not the improvement in the yield of the cereals which follow this culture

2) In 1913, the returns per ha were 851 fcs., and in 1921, 2257.50 fcs., a difference of 1,406 50 fcs in favour of 1921.

The increase in price realised per ha is only 65 3 % of the increase in cost of production, this being due to the considerable decrease in yield, since the price per ton in 1921 was 3 67 times that in 1913 and the cost of production was only 3 41 more. As in the case of wheat, the final result was disastrous to the farmer, who had already in most cases lost on the previous year

### C — Potatoes

Items of Cost of Production	1913		1921	
	Fcs	%	Fcs	%
I. General Expenses rent, taxes, sund- ries . . . . .	186 00	19 20	400	12.60
II. Manuring Ferti- lisers 2000 kg. manure, 4 for potatoes 20 × 8 4 91.40 7 7 7 343 300 kg. super 3 × 5.85 = 17 55 200 » nitrates 2 26 20 52 40 206 35 21 20 2 30 = 90 200 » chloride of 2 100 = 200 737 23.00 potash. 2 22 50 45 00 2 52 = 104				
III Young plants: 1500 kg. . . . .	15 15	225 00 23 30	15 15	750 23.70
IV. Cost of cultura- tion and delivery: 36 days of manual labour 36 × 4 25 153.00 15.70 36 × 15 540 17.00 42 days of horse labour . . . . . 42 4.75 199.50 20 60 42 17 714 23.70				
		969.85 100.00		3141 100 00

Yield 12,000 kg  
At 12 fcs per 100 kg = 1440 fcs

Yield. 6000 kg.  
At 50 fcs. per 100 kg = 3000 fcs.

D) In 1913, potato production cost 969.85 fcs. per ha. and the ql. sold at 12 fr. ; the latter represented 1.24 % of the cost of production per ha

In 1921, 1 ha. cost 3 141 fcs. and the ql. sold at 50 fcs ; the latter represented 1.60 % of the cost per ha., that is, a little more than before the war.

Results therefore appear to be the same in either case, but in reality they are far from being so, owing to the wretched yield caused by drought in 1921. With 120 qx. per ha. in 1913, a gross profit of 1,440 fcs. was realised, whereas in 1921, in most cultures, 3 000 fcs. was realised. In the first case, with an outlay of only 969.85 fcs a profit of 470 15 fcs. was realised on potatoes, while in the second, there was a loss of at least 141 fcs.

2) In 1913, production cost 969.85 fcs., per ha. In 1921, it cost 3 141 fcs, a difference of 2 171 15 fcs. compared with 1921.

In 1913 the returns per ha were 1 440 fcs. In 1921, they were 3 000 fcs., a difference of 1 560 fcs in favour of 1921

The increase per ha realised is only 71 7 % of the increase in cost of production, this being due to the considerable decrease in yield caused by the drought, since the price realised per ql, was 4 1 times higher in 1921 than in 1913, and cost of production only 3 2 higher

#### D). — Milk.

fencing, fertilisers (basic slag) . .		150	
<b>II. Per cow per year:</b>			
Reserve fund for 5 years + risk of mortality 5 % . . . . .		$400 \times 130 = 530$	15.3
Cowherd: 1 per 20 cows . . . . .	(130 fcs per month)	324	9.3
General expenses: Rent, taxes, sundries . . . . .			
		400	11.5
Total cost per cow per year . . . . .		3468	100.0
Less: 1 calf . . . . .	50 fcs.		
10 000 kg. manure at 20 fcs. 200 fcs.			
	250 fcs.	250	
	Total . . . . .	3218	
Cost of production per litre of milk . . . . .		3218	= 1.10
		2920	

In 1913-14, the cost of producing 1 litre of milk was 0.22 fcs.; in 1921-22, 1.10 fr., a difference of 0.88 fcs. against 1921-22.

In 1913-14, a litre of milk on the same farm sold at 0.23 fcs.; in 1921-22, it sold at 0.90 fcs., a difference of 0.67 fcs in favour of 1921-22.

The increase in the price realised is only 76.13 % of the increase in cost of production, and by selling even at the exceptionally good price of 0.90 fcs. per l., the producer loses.

To sum up, for wheat, supposing the average price realised by the last harvest to be 70 fcs. per ql., the increase in the gross returns is only 05 % of the increase of the cost of production, and this, even with an exceptionally good harvest.

For beets used in sugar production etc., the increase in receipts is only 65 % of that of the expenses, per ha, owing to the bad harvest.

For potatoes, which also suffered from the drought the increase in receipts is only 71.7 % of that of expenses.

The increase in the price realised for milk is only 76 % of that of the cost of production, under fairly good economic conditions, and exceptionally favourable conditions for the sale direct to the consumer.

## AGRICULTURAL INDUSTRIES

765 - **Copper in Light Wines.** — PRANDI, O., in *Le Stazioni sperimentali agrarie italiane*, Vol. LXIV, Pts. 11-12, pp. 469-473. Modène, 1921.

It has now been definitely proved that copper (from fungicide sprays) is eliminated almost entirely during grape fermentation. The reduction of sulphate in sulphur is the result of a diastase produced by the ferment. As fermentation is incomplete in the sweet wines the author undertook to determine the amount of copper content in light white wines such as the muscat. An analysis of 25 samples was made in 1920, a year in which fungicides were largely employed and the results obtained are shown in the following Table :

*Alcohol and Copper in Light White Wines.*

Name and origin	Alcohol % in volume	Extract % grm.	Copper % grm.
Moscat Alba . . . . .	1.2	232.80	0.0160
» » . . . . .	4.2	187.52	0.0085
» Barbaresco . . . . .	3.4	192.60	0.0098
» » . . . . .	5.9	143.50	0.0045
» Castiglione Tinella . . . . .	1.9	202.30	0.0110
» » » . . . . .	0.5	180.10	0.0155
» Canelli . . . . .	2.8	194.40	0.0130
» » . . . . .	3.8	208.30	0.0155

The quantity of copper is therefore inverse to that of alcohol. In the wines that are very sweet and consequently very poor in alcohol, the copper content is noticeable, up to as much as 0.160 gm. per litre.

On two occasions when restarting the fermentation of the Albe Muscat which has a high copper content and scarcely 1.2 % of alcohol, half the copper disappeared and the alcohol content was quadrupled. There is therefore no doubt that the high copper content is due to incomplete fermentation. It is, however, impossible under ordinary circumstances to have recourse to renewed fermentation, as certain types of wine, should be allowed to retain their sweetness. The author has for this reason attempted to bring about a reduction of the copper by using pure potassium sulphide ; for this purpose the commercial product, which is a polysulphide is unsuitable.

According to the results obtained, and noting that the presence of copper at the rate of 9 mgm. per litre affects the taste, the author makes the following suggestions : if at the first sampling or as a result of the well-known steel blade test, an excess of copper is observed, the addition of an excess of pure potassium sulphide ( $K_2S$ ,  $5H_2O$ ) is advised at the rate, for example, of 15 to 20 gm. per hectolitre, if crystallised, and of 8 to 11 gm.

of liquid. About a week later, 6 to 8 gm. per hectolitre of metabisulphite of potassium should be added to eliminate the sulphuric acid; and the wine left for one week and then filtered. This treatment has no effect on the characteristic Muscat aroma.

Any excessive diminution in acidity as a result of the precipitation of acid tartrate of potash, may be rectified by adding tartaric acid.

766 - Administration of the Economic Poison Law in California. — See No. 679 of this Review.

767 - Distillation Experiments in the Preparation of Otto of Roses (1). — I. GADRE, S. T. (Industrial Chemist to the Government of the United Provinces, India) and MUKEJI B. C. (Chief Chemist, Office of Metallurgical Inspector Jamshedpur), Rose Otto from Rose flowers (*Rosa Damascena*) of the United Provinces, *Journal of Indian Industries and Labour*, Vol II, Pt I, pp 86-102 + Tables. Calcutta, Feb. 1922. — II. Notes on the Preparation of Otto of Rose and Advantages of Bulgarian Method, *The Cyprus Agricultural Journal*, Vol XVII, Pt. I, pp. 7-8. Nicosia, Jan 1922.

I. — Report of comparative experiments made at the Government Technical Laboratory, Cawnpore, India, with various types of stills. It is worth noting that flowers sent for distillation can apparently be stocked undamaged for 3 or 4 days after plucking, if a preservative like common salt be used.

The maximum atmospheric temperature during the period of the experiments was about 108° F and the minimum 78.5° F; the average relative humidity being 35.

Genuine samples of Bulgarian otto of rose and virgin otto of rose from Anatolia were also obtained for comparison and the constants resulting from the different products are compared with some known values of ottos from other sources. The optimum yield of otto obtainable from the Cawnpore *R. damascena* was found to be much lower than that in roses from Bulgaria etc.

As regards the evaluation of rose water in terms of otto the author gives in detail the method to be adopted for evaluation purposes following the lines of determination of the iodine absorption.

The tabulated results obtained with 11 samples of once-distilled rose water from the Indian Essential Oils Co. Cawnpore, prepared by distillation with steam at varying pressures, and the use of native (DEG) and Bulgarian stills indicate that the variation in pressure has apparently no influence on the total yield, nor on the quality of the otto. According to these results, the native DEG still has given practically similar results to the Bulgarian type.

It has been ascertained that live steam is unsuitable for otto preparation. A steam-jacketted still is however recommended as the best possible, although its practicability on rose fields and with certain grades of distillers is considered questionable.

(1) See R. Sept. 1921. No. 947. (Ed.)

The fourth type of still tested which is both portable and easily worked, was a modification of the DEG with a separate top containing a fairly wide leading tube with which a worm condenser could be connected when the still was at work.

II (1). — A detailed description of the Bulgarian system of distillation indicates the advantages of this method. A copper still, with a capacity of about 110 litres, is employed, with a mushroom-shaped head connected by a straight inclined tube with a worm condenser placed in a tub of water, the ratio being 10 kg. of flowers to 75 litres of water. An open fire is used and 10 litres of water are distilled after which the liquid in the still late is allowed to cool is separated from the flowers, made up to 75 l. again with cold water and fresh flowers added. This is repeated until up to 40 l. has been collected and afterwards distilled, and the first 5 l. set aside to allow the oil to separate. The remaining 35 l. are utilised for distilling a further quantity of flowers.

Whole flowers are generally used, the petals seldom being treated separately. The average yield is 1 kg. per 2000 kg. flowers.

A comparison is made with the steam still methods adopted in France and it appears that when the distillery is conveniently situated as regards the cultivated area, results equally satisfactory are obtained.

It appears that the best results both as regards quality and yield can be secured when :—

- 1) the roses are gathered early in the morning and the distillation of whole flowers is carried out the same day,
- 2) steam stills are employed in preference to open fires,
- 3) the head and neck of the still are very short and wide.

Speaking generally the Bulgarian method is recommended for use whenever possible. M. L. Y.

768 - Cost of Milk Production in Maryland, U. S. A. (1). — *The Creamery and Milk Plant, Monthly*, Vol. X, No. 6, pp. 56 and 72; No. 7, pp. 25-27. Chicago 1921.

I. — In 84 farms in northern Maryland, inspected in 1921 by the United States Department of Agriculture in co-operation with the University of Maryland, the average sale price is 33.2 cents per gallon, \$3.86 per 100 lb. and \$213.13 per c w per year. At an average price of 34.2 cents per gallon, 48 of the farmers (51 %), failed to make a profit, with all feed and labour charges at full current rates.

The average number of cows on the farms surveyed was 18.2; the annual production of milk per cow varied from less than 4000 lb. to over 8000 lb. with an average for all cows of 6074 lb. Practically all the milk in question was shipped either to Washington or to Baltimore.

Of the total cost of production, about one-half (\$121.38 per cow) was for feed 56.6 % of this being for farm produce.

Grain feed amounted to 2259 lb. per cow per year; 512 lb. of this being

INDUSTRIES  
DEPENDENT  
ON ANIMAL  
PRODUCTS

(1) Notes furnished by the Imperial Institute, London. (Ed.)

(2) See R. April 1922, No. 370. (Ed.)

grown on the farm. Hay feed amounted to 1793 lb., practically all home-grown. Man labour per cow totalled 291 hours; horse labour 29 hours.

II. — According to the investigations made by the Milk Producers Dairy Tariff Committee the cost of producing 100 lb. milk in various parts of the United States is as follows:—

New England . . . . .	\$	2.85
New York . . . . .	"	2.56
Philadelphia . . . . .	"	3.10
Baltimore . . . . .	"	3.12
Ohio . . . . .	"	2.86
Chicago . . . . .	"	2.53
California . . . . .	"	2.60
Average . . . . .	\$	2.80

These results were obtained as an average of costs reported by different sections. The method of determination is not identical. The New York cost is based upon the WARREN formula. For 100 lb. milk, the following are the requirements (in lb): grain 33.29 + hay 43.3 + other dry forage, 10.8 + silage 92.2 + other succulents 8.3, and labour 3.02 hours; the total representing 79 % of net cost for general expenses.

769 — Dairy Inspection in California. — See No. 679 of this Review

770 — Investigation on Lactose Ferments in Cream which has a "Yeasty" Flavour. — HAMMER, B W and CORDS, W A (Iowa Agricultural Experiment Station) in *The Creamery and Milk Plant Monthly*, Vol. X, No. 6, pp. 44-45. Chicago, 1921.

When cream is sent to the butteries without first passing through the refrigerator, it sometimes undergoes fermentation during the journey, the nature of which fermentation depends chiefly on the micro-organisms it contains and the temperature of the surroundings. One of the most frequent of these fermentations in summer is that which produces "yeasty" or "foamy" cream. This cream has the characteristic odour and flavour of yeast, and these pass into the butter; it also becomes frothy, and a part of it escapes from the jars.

The authors proposed to find out whether (1) this fermentation is always caused by the same micro-organism; (2) the micro-organisms which cause it are only found in cream which has a yeasty task, or likewise pervade fresh cream, milk, dairy utensils etc. They obtained the following results:

Lactose ferments were isolated from 21 samples of cream with a yeasty flavour, collected in five different States of the Union; from 8 out of 9 samples of second quality cream collected in Iowa; from 12 out of 72 samples of sour cream with a normal flavour collected in Iowa; from 3 samples of milk (2 from Iowa and 1 from Denmark); and from a sample of "matzum".

A comparative examination of the morphological, cultural and bio-

chemical characteristics of these 45 lactose ferments was made and led the authors to divide them into two types: *A*, much more frequent, larger and more rapid than the other, oval or elliptic, with an optimum temperature of 37° C.; capable of fermenting various carbohydrates; *B*, a true gelatine liquefier (whereas *A* is rarely so). A comparison of these micro-organisms with those described up to the present, showed that they do not correspond exactly with any of the latter; the authors therefore propose to call them respectively *Torula cremoris* and *T. sphaerica*.

Lactose ferments similar to those which cause the yeasty flavour of cream are much more common than might be supposed from the quantities of cream which undergo this change. The ordinary conditions of cream therefore do not favour the development of this change.

Besides the presence of the ferment which causes the change and the temperature which favours its development, there are other factors which cause the yeasty flavour and foam on cream; they are: the viscosity or thickening due to curdling and sufficient to prevent the gases set free from escaping rapidly; the reduced solubility of the gases when the cream is exposed to very high temperatures; the closing of the tin which contains it and shaking. Lactose ferments are widespread and it is useless to think of suppressing them in cream in order to prevent fermentation. The best the small producer can do at present is to keep the cream at a low temperature; in the case of large quantities, recourse must be had to pasteurization.

771 - **Experimental Cheese-Making Institute at Lodi.** — *Annali dell'Istituto sperimentale di Caseificio di Lodi*, Vol. 1, No. 1, pp. 44. Lodi, 1922.

By a Decree of 10<sup>th</sup> November 1919, the Royal Experimental Cheese-making Station of Lodi, was transformed into the "Autonomous Syndicate of the Experimental Cheese-making Institute". The differences between these two Institutions are, from the scientific point of view, a deeper and wider field for experimental research; and from the administrative point of view, autonomous control with a Board of Directors as the responsible head.

The Commissariat of Food Supplies granted a sum of 1 500 000 lire, raised from the "Obligatory Consortium for the Control of the Butter Trade in Milan." for the initial expenses of this Institute.

It has been deemed necessary to acquire an agricultural property, on which research work will be carried out on the alimentary and physiological factors which influence milk production, with a view to explaining phenomena of all kinds connected with dairy products.

The Institute has therefore two fields of action: experimental research, and making known the results of new investigations and those already made, in order to extend the national milk industry.

The subjects already treated or under investigation include: study of the critical temperature at which butter and its substitutes become soluble in acetic acid; chemical and bacteriological study of "hay-silage";

research on the bacteria in butter in the district of Lodi (1); research on the bacteria in butter kept at a low temperature ; mechanical milking apparatus considered from the chemical, bacteriological, technical and economic point of view , technological study of the manufacture of Asiago cheese ; preliminary experiments for improving the manufacture of Parmesan Cheese.

F. D.

772 - **A Good Type of Mixed Cheese : the " Vittoria " of the Andria School of Agriculture (Province of Bari).** — PANTANELLI, F (Director of the Agricultural Station of Bari) and VIVARELLI, L (Director of the Agricultural School of Andria), *Il formaggio misto Vittoria, La propaganda a ricola*, Vol XIII, Nos 22 23, pp 209-314, figs 9, No 24. pp 232 236 Bari, Nov and Dec 1921

For several years the Andria School of Agriculture has been making and marketing successfully a cheese made from mixed milks. This is a special device of the School for rendering butter-making possible in Apulia, by using buttermilk in cheese-making. Skimmed cow's milk is mixed with whole ewe's milk for the preparation of the so-called " Vittoria " cheese.  $\frac{1}{2}$  to  $\frac{1}{3}$  of ewe's milk is added to 1 part of skimmed milk, one hectolitre of the mixture yields 2 to 3 kg of excellent butter and 12 to 15 kg of cheese. Each cheese weighs about 5 kg and requires 40 litres of skimmed cow's milk and 19 ltrs of whole ewe's milk. This cheese which is similar to Parmesan, may be used after 6 to 7 months, but does not fully ripen until after a year.

The author describes the process in detail filtration, heating at 36°-38°c, the addition of rennet, breaking the curd, boiling the coagulum, filling the moulds, pressing, salting, ripening.

The percentage content of " Vittoria " Cheese, 6 months and 1 year after manufacture from  $\frac{2}{3}$  cow's skimmed milk and  $\frac{1}{3}$  ewe's milk was as follows: water 43.27 and 30.6, fats 12.52 and 19.08, total nitrogen 4.023 and 3.504, protein nitrogen 3.485 and 3.140, soluble nitrogenous products 0.538 and 0.364, crude proteins 25.14 and 31.90, albuminoids 21.99 and 19.63, free acids (calculated as lactic acid) 0.839 and 2.80, soluble extract (in the 6 months old cheese) 26.71, ash 2.425 and 6.10, and sodium chloride 6.579 and 4.948.

In nutritive and digestible qualities the " Vittoria " is superior to the Roman " pecorino " and " caciocavallo ", and it may be used both for the table and as grated cheese.

773 - **Bacteria in Butter** (2). — DALLA TORRE, G in *Annali dell'Istituto sperimentale di Casalecchio in Lodi*, Vol I, No. 2, pp 55-70, Lodi, April 1922.

In order that the improved methods of butter making may be properly followed, the bacterial flora of butter and the various factors which influence them must be known. With this object the author has carried out at the Experimental Cheesemaking Institute at Lodi, a series of experiments with cultures or 1) agar-agar-lactose, 2) gelatine-serum, 3) agar-agar-serum-peptone, and has noted the following facts

(1) See No 773 of this *Review* (Ed)

(2) See *R* May June, 1922, No 639 (Ed)

The number of germs contained in 1 gm. of butter varies from a minimum of 36 200 to a maximum of 7 360 000. In addition to the usual factors which affect the bacterial content of food-products, these great differences are due to the different times at which the butter is made, to the various temperatures, at which the milk has been kept and to the length of time it has been left in the receptacles before skimming.

The majority of the microbes observed were always lactic bacteria (29 000 to 7 000 000 per gram of butter); among these, the coccus occurred most frequently and was the most numerous. *Coli aerogenes* were frequently found, but were rarely plentiful. Gelatine-liquefying bacteria were often observed, and sometimes in large numbers. *Saccharomyces* and *torula* varied from 1 000 to 120 000 per gram; *Oidium lactis*, due to long standing in the receptacles for the final skimming, were often noticed and 200 to 20 000 of these germs per gram of butter were counted. In several samples, the spores of anaerobic bacteria were noticed, but generally in small numbers.

774 - **Dairy Products Investigation. Projects Carried on by the Agricultural Experiment Stations in the United States.** — POTTS, R. C. in *Journal of Dairy Science* Vol. IV, No. 5, pp. 416-425 Baltimore, 1921.

The Office of Experiment Stations of the United States Department of Agriculture has compiled a booklet of 225 pages setting out the dairy products activities now in progress. The following list has been extracted and indicates the various phases in this industry to which special attention is given, and this should be useful to experts and suggests opportunities for coordination of work and co-operation among workers :—

LIST OF STATE AGRICULTURAL EXPERIMENT STATION DAIRY PRODUCTS PROJECTS.

*Chemical studies of dairy products* (1).

1. Study of the properties of pure casein, New York State.
2. Study of the carbonic acid in milk (Ditto).
3. Study of the chemistry of butterfat and the effect of food in modifying its chemical and physical character (Massachusetts).

4. Method for detection of abnormal milk (New York State).

5. Method for determination of keeping quality of milk (Ditto).

*Nutrition Studies.*

1. Role of dairy products in practical nutrition (Oklahoma).
2. Food value of various milks for infants and invalids (Maryland).
3. Nutritive value of milk for children and animals (Vermont).
4. Minimum quantity of butterfat necessary to produce normal development in young growing animals (Oregon).

*Bacteriological studies* (2).

1. Investigations with raw and manufactured dairy products (Michigan).

(1) See No. 770 of this Review. (Ed.)

(2) See No. 773 of this Review. (Ed.)

2. Influence of barn conditions on the germ content of milk (Illinois).
  3. Species of bacteria found in dairy utensils (Cornell, N. Y.).
  4. Important factors in the production of sanitary milk and means and methods of milk testing (New York State).
  5. Bacteriological examinations of certified milk (California).
  6. Study of the true accuracy of bacterial counts as made from milk (New York State).
  7. Determination of the bacterial content of milk by a rapid method (little plate) (Wisconsin).
  8. Bacteria content of milk from milking to cooling (S. Carolina).
  9. Studies on cooling of milk in relation to its bacterial quality (New York State).
  10. High acid organisms found in American milk (Iowa).
  11. Acid production and the rate of growth of the lactic acid organisms in the sowing of milk (New York State).
  12. Studies on bacterial flavour and odour of milk.
  13. Study of the *Torula* forms causing yeasty fermentation in cream (Iowa).
  14. Effect of preservatives on the bacteria in milk (Pennsylvania).
  15. Use of available chlorine as a germicide in milk and milk products (Arkansas).
  16. Bacteriology of butter (Oklahoma).
  17. Chemical and bacteriological study of the keeping qualities of butter (Indiana).
  18. Study of the development of moulds on butter (California).
  19. Study of the types of organisms present and multiplying in cottage cheese (Idaho).
  20. Studies on the relation between the bacterial flora of good quality cheese and of good quality milk (New York State).
  21. Studies of the compounds in cheese and the changes which occur under the influence of certain classes of bacteria (Ditto).
  22. Chemical and bacteriological studies of ice cream (Indiana).
- Studies of butter and butter making*
1. Influence of acidity of cream in flavour and keeping qualities of butter (Iowa).
  2. Neutralisation of acidity of cream for butter making (Oregon).
  3. Effect of neutralisation on the quantity of butter (N. Y. Cornell).
  4. Chemistry of churning (1) (Missouri).
  5. Causes of difficult churning (Washington).
  6. Factors influencing quality of butter (Oklahoma).
  7. Study of Californian butter at the Davis and San Francisco markets (California).
  8. Comparison of creamery and market weights of butter (Wisconsin).
  9. Study of dairy records (Cornell N. Y.).
  10. Constructional improvements of creameries (N. Carolina).

(1) See No 773 of this Review (Id)

11. Keeping qualities of butter (Michigan).
12. Keeping qualities of butter in storage as affected by churning methods.
13. Chemical and bacteriological study of the keeping qualities of butter (Indiana).
14. Study of mould development on butter (California).
15. Scoring contests of commercial butter (Idaho).
16. Bacteriology of butter (Oklahoma)
- Studies of cheese and cheese-making* (1).
1. Mountain cheese work (North Carolina).
2. Making cheese (North Carolina).
3. Cheese investigations (Wisconsin).
4. A study of the manufacture of cheese and whey (California).
5. Studies of the compounds in cheese and their changes under the influence of certain classes of bacteria (New York State).
6. Factors concerned in the coagulation of milk by heat (Wisconsin).
7. Yield of cheese from milk high and low in fat (Wisconsin).
8. Pasteurization of milk for cheese making (New York Cornell).
9. The effect of clarifying milk for making Cheddar cheese (New York Cornell).
10. Studies in cheese making. Effect of temperature of cooking on texture of cheese ; effect of amount of rennet or pepsin on rapidity of curing cheese ; the possibility of curing cheese in Oklahoma factories ; controlling factors in proper handling and marketing of cheese in Oklahoma (Oklahoma).
11. The effect of separating temperatures on the loss of fat in separated whey (Oregon).
12. A study of the control of mould development in cheese-curing rooms (California).
13. The use of *Bacillus bulgaricus* starter for controlling gassy milk in the manufacture of Cheddar cheese (California).
14. The effect of washing curd on the yield and quality of Cheddar cheese (N. Y. Cornell).

(1) Cf. SAMMIS, J. L., Cottage Cheese and Buttermilk Cheese : Their Manufacture and Sale (*Wisconsin Agric. Expt. Stn. Bull.* 315, pp. 16, figs. 8. Madison, 1920).

FLEMMERGER, H. B., Cold storage of cottage and other soft curd cheeses, *Vermont Agric. Stn. Bull.* 213, pp. 2. Burlington, 1910

BAIRD, H. S., Neuchâtel Cheese, *California Agric. Expt. Stn. Circular* 207, pp. 4, figs. 2, Berkely 1919. -- Brief rules for the use of home manufacturers. It is stated that although goats' milk is preferable, a good quality Neuchâtel cheese is obtainable with cow's milk. Seeing that the outlay is small, this industry should prove profitable to cowkeepers who can thus utilise the unsold milk during the productive season.

MORLEY, I. W., Cheese Making under Missouri Conditions, *University of Missouri, Agric. College, Agric. Expt. Stn. Bull.* 164, pp. 39-40. Columbia, 1910. Study of the ripening process in cheese. An experiment is made by ripening in carbon dioxide, moulds are thus prevented. The author considers that this method should serve to solve the problem of keeping small cheeses. (Ed.)

15. The use of pepsin as a substitute for rennet in the manufacture of California (granular) and Cheddar cheese (California).
16. Studies in the manufacture of Swiss cheese in vats. (Oregon).
17. The manufacture of Camembert, Swiss, and albumin cheeses (N. Y. Cornell).
18. Cheese making (Cottage, Neufchatel, whey, Romano, etc.).  
A study of the practice of cheese making with special reference to the manufacture of foreign cheese (Vermont).
19. Relation of moisture and acidity to keeping quality of Neufchatel and cream cheeses (N. Y. Cornell).
20. The manufacture of cottage cheese from a mixture of skim milk using *Bacillus bulgaricus* starter for curdling the milk (California).
21. The manufacture of a skim milk cheese that will keep (S. Dakota).  
*Cream production studies.*
  1. A study of some factors affecting the texture of the cream (California).
  2. Losses in farm skimming of cream (North Carolina).
  3. Factors affecting the efficiency of hand separators and causes of variation in cream tests (Nebraska).
  4. A study of the efficiency of the various cream cooling tanks (Nebraska).
  5. Cream routes (North Carolina).
  6. An investigation regarding the whipping of cream (Washington).  
*Ice cream studies.*
    1. Ice cream investigations (Kansas).
    2. Studies in ice cream making (Oklahoma).
    3. Commercial ice cream making (Oklahoma).
    4. Testing ice cream for butter fat. A comparison of various acids as to time required, ease of manipulation, character and accuracy of test; comparison of different ingredients upon character of test, such as sugar, gelatin, gum, tragacanth, and ice cream powder, fruits, eggs, and color material; influence of method of obtaining samples, time cream has been packed and manner of packing; comparison of results with cream and milk bottles; effect of emulsifying and homogenizing upon ease with which tests may be made (Oklahoma).
    5. Chemical and bacteriological studies of ice cream (Indiana).
    6. A study of the factors affecting swell in ice cream (California).
    7. Factors affecting the formation of ice crystals in ice cream (N. Y. Cornell).
    8. Fillers in the manufacture of ice cream (Washington).  
*Studies of milk secretion, composition and supply.*
      1. An investigation of physiological and chemical changes taking place within the mammary gland during secretion (Maryland).
      2. Certain problems relating to the biochemistry of milk formation in the udder (New York State).

4. Synthetic capacity of the mammary gland (Wisconsin).
5. Feeding galactose to dairy cattle (Delaware).
6. The influence of barley on the milk secretion of cows (California) (1).
7. Investigations into causes of variation in milk and fat production. Effect of individuality of cows upon milk and fat yields. Influence of alimentary carbohydrates on the yield and composition of milk. Effect of proteins from restricted sources on the yield and composition of milk (Iowa) (2).
8. Factors influencing or affecting the chemical and physical properties of milk (Missouri).
9. Analysis of milk records. To determine the age changes and the duration between total solids-not-fat and milk production, per cent fat, and butter fat (Maine).
10. Factors influencing the composition of milk; the influence of the plane of nutrition of the cow (Missouri).
11. A study of the composition of milk and fat — as affected by feeds, from different breeds of cows, and with reference to the natural quantitative relationship existing between the various constituents of milk (Ohio).
12. Study of the chemistry of butter fat and the effect of food in modifying its chemical and physical character (Massachusetts).
13. The effect of peanut meal when fed to dairy cows on the qualities of the butter fat, and methods by which this feed may be fed without undesirable effects (Georgia).
14. Study of carbonic acid in milk (New York State).
15. Carbonic acid in milk under various conditions after being drawn from the udder, and carbonic acid content as a basis for distinguishing between heated and unheated milk (New York State).
16. Carbonic acid and carbonates in the udder (New York State) (3).
17. Acidity of fresh milk (N. Y. Cornell).
18. Conditions affecting hydrogen-ion concentration in milk (New York State).

(1) WOLL, F. W., The Influence of Barley on the Milk Secretion of Cows, *Californian Agr. Exp. Station, Bulletin* 305, pp. 325-331. Berkeley, 1910.

Complete data on: Quantity and nature of feeds, live weight, amount of milk and butter, obtained: 1) from a cow (half-breed Holstein), for 3 milkings, the only grain fed being barley, and for 2 milkings, when a mixture of grains was fed; 2) from a pure bred Jersey for 4 milkings, for each milking, barley the only grain fed; 3) from another pure bred Jersey for 2 milkings, when a mixture of grain was used and 1 milking using barley only. The results are compared with those for 15 other cows fed for short periods (usually 5 weeks) on barley with intervening periods of mixed grain.

As a rule, the barley feed was followed by the highest milk production, but this should not be attributed to the particular qualities of the barley, but rather to the fact that cows often consume a larger amount of barley than of the mixed grain. Consequently the idea held by certain cowkeepers that barley tends to dry the mucous membrane is unfounded.

(2) See *Review* Jan. 1920, No. 115; *Review* April 1922, No. 490. The following references are available on this subject: PEARSON, F. A., The Seasonal Cost of Milk Production, *Illinois Agr. Exp. Stat. Bulletin* 224, pp. 3-18, figs. 1. Urbana, 1919. Observations were made, monthly as to the variation in the net cost of milk (sold crude on the Chicago market) for 18 stations. During the period, viz. the years ending June 30, 1915 and June 30, 1916, the total stock is estimated as follows: 107 cows, 19 bulls, 234 calves, with a sale of 3047 lb. of milk. Two bookkeeping systems are adopted: one based on the stock as a whole, the other on the cows only (including the necessary bulls). In the latter system, the cows are graded in accordance with the value of the calf at birth; the cost of calving is debited to the cow. In the calculations, the interest is distributed uniformly for

1. Cost of milk production (Connecticut (Storrs), N. Dakota Ohio) (1).
2. Cost of milk production in Nebraska (Nebraska).

the whole year, but the remainder of the entries etc., for items impossible to estimate each month, were distributed according to the quantity of milk produced. During the winter season (November to April), the milk obtained amounted to 57 % of the total. In the following table a résumé of the more important figures is given. The author explains how sale cost can be determined on these figures; the decrease in return from pasture is also discussed.

*Variation, during the six months period (summer and winter) of amount of manual labour, and feeds necessary to obtain 100 lb of milk and the total net returns in relation to the net return at 100*

Time	For all the bulls						For bulls and cows

Cost of Producing Dairy Products. *Minnesota Agric Exp Sta Report* 1919, pp 121 St. Paul 1920. According to figures furnished by 6 Control Societies for milk production (1635 cows giving an average production of 3000 lb of milk and 114 lb of butter) it may be concluded that for 100 lb. of milk the following is required: 17.3 lb. grain + 41.5 coarse feed + 89 lb. silage and 60 days on pasture

APP, E. A., Study of the Cost of Milk Production, *New Jersey, Agr. Exp. Stat. Report*, 1919, p. 299. New Brunswick, 1920. According to the cost in 1918, the upkeep cost for 1 cow per year is estimated at \$27.60, the returns amount to 7.21 cents per quart.

(2) How to determine the Cost of Milk. *Monthly Bulletin, Ohio Agr. Exp. Station*, Vol. III, No. 12, pp 363-366; Vol. IV, No. 1, pp. 17-21, figs 1, 1919. Book-keeping model for use of milch cow stock raiser, followed by a summary of the cost price of milk, collected from 33 stations in Ohio. All the expenses, except for feeds and manual labour, are quoted in % of the value of the cow, considered as of ordinary, not pure breed. The total percentage amounts to 27.8 %, and when added to the cost of horse labour per cow (for milk transport etc.), it may be regarded as the equivalent of the value of the meat and 9 tons of farmyard manure obtained through the cow annually. As a rule, a cow remains 187 days out of the year in the meadow, but during this period, receives supplementary feeds. The cost price of equal weight in milk is estimated on the assumption that the cow is fed exclusively in the meadow for 5 months, beginning towards mid May and only given other feeds during the other 7 months.

From the figures obtained from 33 Stations in Ohio, it appears that during winter the outgoings, without equivalent returns for the production of 100 lb. of milk are: 44 lb. grain

15. Bacteria surviving sterilisation in evaporated milk.
16. Factors influencing the coagulation of evaporated milk in sterilisation.

substances 47.1 lb., phosphates 19.5 lb., potash 35.6 lb. The mean annual production of milk was 2,000 lb., butter 115.8 lb.

The return for meat, manure, and milk amounted to \$124.62 per cow per annum while the outgoings came to \$18.55. The net cost was \$1.30 per 100 lb. or \$2.87 per quintal not including expenses of management. In 1918 these were estimated at \$1.75 to 2.01 per 100 lb. The cost of milk may vary from \$2.76 to 4.5 per 100 lb.

(1) RIDDEL, F. T., *Michigan A. E. Exp. Station Quarterly Bull.*, Vol. 3, No. 2, pp. 45-46. East Lansing, 1920. For production of 100 lb. of milk, the following requirements are considered necessary (taken from a study of the net cost of milk in 225 stations (3370 cows) in 9 Counties in Michigan): — grain 11 lb. + purchased feeds 15.6 lb. + hay 31.1 lb.; other dry forage 15.9 lb.; other succulent forage (purchased) 7 lb.; maize silage 114.5 lb. litter 12.8 lb.; pasture 7 weeks; manual labour 493 hours; horse labour 62 hours. Other expenses amount to 27.7 % of the cost of feeds plus the cost of labour. In these accounts the meat and manure values etc. are not included nor the expenses of management. The net return per month is calculated, by taking the mean annual price at 100. (Ed.)

775 - **Unusual Odour of Wholesome Meat on the Refrigerator.** — MASCHERONI, E., in *Il Nuovo Frigoristi*, Year XXVII, No. 5, pp 76-77. Turin, Mar 15, 1922

The author has observed that wholesome beef and pork kept for several days in a refrigerator close to receptacles used to preserve oranges, resulted in a pronounced orange odour (especially the fatty portion), and occasionally in a bitter taste which rendered the meat uneatable.

The skin of the orange containing the essential oil (which possesses a very bitter terpene) cracks with the cold, setting free an essence which is easily absorbed by the organic liquid of the meat and especially of the fat, resulting in the odour and taste described above.

PRODUCTS  
PRESERVING,  
PACKING,  
TRANSPORT,  
TRADE

776 - **The Preservation of Forage by Means of Electric Current.** — *Rapport présenté par l'administration Centrale des Etablissements fédéraux d'essais et d'analyses agricoles de Liebefeld près Berne.* April 4, 1922, pp 1-6

The advantages of the electric current method of preserving fresh forage as compared with other processes such as ensilage and drying, are said to be the following: less loss of nutritive substances; reduction of labour; possibility of a better division of work, minimum expenditure of electric energy; the possibility of applying the process to the most varied agricultural undertakings and the preservation of all kinds of forage plants including those rich in protein substance; the forage can be carried in any weather and in any quantity; the work can easily be interrupted; good results are obtained by feeding this forage to dairy cows without affecting the quality of their milk; the electric current destroys all organic life in the mass of forage; the machines made by DERLIKON, the sole agent for this process in Switzerland, use only 1.3 to 2.0 kwh. for one hundred

kilogrammes of green forage, whereas the inventor calculated that from 2.5 to 2.8 kwh. would be required.

Electric ensilage, as far as is known at present, appears to be carried out in the following manner: the forage as soon as it is mown is cut up and put in the desired quantity into a silo of reinforced concrete. The forage mass rests between two electrodes and offers resistance to the electric current which heats it up to 50° C; the passage of the current is said to kill the plant cells and the bacteria in the forage.

During the autumn of 1921, Messrs DERLIKON carried out experiments at Liebefeld using a silo divided into three cases. The total cubage of 40.93 cub. m. was divided as follows:

Case A . . . . .	14.08 cub. m.
" B . . . . .	12.93 cub. m.
" C . . . . .	13.98 cub. m.

A three-phase electric current of 500 volts and 50 periods was employed. The questions to be considered were 4 in number.

1) The possibility of the general use of the electric silage process in comparison with the ordinary method, especially as regards labour and division of work.

2) The net cost of the preserved forage and the losses entailed during the operations.

3) The appearance and quality of the preserved forage.

4) The use of this forage by milch cows.

Equal quantities of grass of the same origin and identical botanical composition were preserved by the two silage processes. The two kinds of silage were fed to the same cattle, and in order to render the experiments more complete, the Liebefeld Federal Institute of Dairy Industry analysed the cheeses in order to ascertain whether the milk given by cows fed on electrically preserved forage was suitable for cheese-making.

The results obtained proved that electric ensilage has some advantages over the ordinary process, for it not only decreases the relative and absolute cost of labour, but requires no special knowledge on the part of the Staff. The chief advantage, however, is the better distribution of labour.

The chief obstacle to the general adoption of the new system is the present high cost of the plant and of the electric force required which is 5.7 kwh. per 100 kg., a figure exceeding the maximum estimated by the inventor.

Electrically preserved forage was taken from the silo between December 27, 1921 and January 15, 1922 and was found equal in quality to the ordinary product. It has, however, been noticed that the keeping qualities of electrically preserved silage, when once the pressure has been removed are inferior to those of silage made in the usual manner. The differences in the colour, taste and smell of the successive layers of electrically prepared silage are much more marked than in the case of ordinary silage which explains the preference or aversion shown by the animals to

forage taken from different strata. The appearance of electrically preserved forage is unattractive.

The annexed Table shows the content in nutritive substances of electrically preserved forage and ordinary silage respectively.

The results of the chemical analysis were taken as a basis for the calculation of the daily ration of the milch cows. A group of 4 animals were used, all of which were in the decreasing phase of the lactation period. The experiment lasted from the evening of December 5, 1921 to the morning of January 27, 1922. The live-weight of the cows remained practically stationary throughout the experiment, as also the milk secretion.

	Sg 5	5.7	1.2	16.4	7.5	5.6	63.6	4.7	1.0	

Note. Es represents the layers of electrically prepared forage and Sg those of forage made in the ordinary way

It was not possible to make experiments with any other kind of animal, or to discover the effect of the new forage upon the production of any other substance than milk.

The animals did not show much appetite for certain layers of electrically preserved forage although they always ate readily silage prepared by the ordinary method.

No ill effects or disturbances of the general health of the cows were however, noticeable during the experiment.

It may further be stated that the general and approximate nutritive value of 1 kg of hay was equal in round figures to that of 2 kg. of ordinary silage and of 4 kg. of electrically prepared silage.

To sum up, the conclusions to be drawn from the first experiments are as follows. although the hopes of the advocates of the new process were realised to a certain extent, the high cost of the electric method is

not in proportion to the advantages to be derived from it. Further, the forage does not keep well, and its general appearance, the losses during preservation, and the amount of electrical energy consumed do not tally with the statements made by its advocates. This remark also applies to the bacteriological properties of the forage.

This report makes it clear that exhaustive researches and very careful experiments are necessary before it will be possible to arrive at any definite conclusion regarding the practical value of the new process of preserving forage by electricity.

E. P.

## PLANT DISEASES

### DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

#### GENERAL

777 - **Fungi in Catalonia, Spain.** - FERNANDEZ, RÍOFRÍO, B., in *Boletín de la Real Sociedad Española de Historia Natural*, Vol XXII, No. 1, pp. 200-204. Madrid, Apr. 26, 1922.

In addition to the various species of micromycetes, mostly parasites of cultivated plants which have been already recorded for the Catalan flora, a further list has been made including other species found between 1912 and 1921 in different districts of Catalonia.

These species are not only new for this region, but they are to a certain degree, new also to Spain, and to the Iberian Peninsular.

*Uromyces Pisi* (Pers.) De Bary, although previously observed in Catalonia, has been observed for the first time as host for the leaves of *Pisum sativum*.

*Ustilago Panici-miliacei* (Pers.) Wint, on the panicles of *Panicum miliaceum*, is a fungus new to Spain.

Although *Exoascus deformans* (Berk.) Fuck. is probably very widely spread throughout Spain, it has, according to the author, never been notified in Catalonia. At the present time it has been observed on the leaves of *Amygdalus communis*.

In Pedralbes (Catalonia), *Uncinula necator* (Schw.) Burr has been observed on the leaves and fruits of *Vitis vinifera*. This is the second time it has been noted in Spain; this ascophore was found for the first time in Seville (Andalusia).

*Podosphaera tridactyla* (Wallr.) De Bary, found recently on the leaves of *Prunus Armeniaca* has not previously been recorded in Spain. *Septoria Lycopersici* Speg. var. *europaea* Br. and Cerv. on leaves of *Lycopersicon esculentum* and *Sept. Petroselinii* Desm. var. *Aprii* Br. and Cav., host of leaves of *Apium graveolens*, are also newly recorded species for Spain.

G. T.

778 - **The Mechanism of the Parasitic Action of *Penicillium glaucum* and of *Mucor stolonifer*.** - NOBÉCOURT, P., in *Comptes Rendus hebdomadaires des séances de l'Académie des Sciences*, First Half-year 1922, Vol CLXXIV, No. 26, pp. 1720-1722. Paris 1922.

*Penicillium glaucum* Lk. and *Mucor stolonifer* Ehrb. are two very common saprophytes living on a great variety of substances; these fungi are also sometimes found parasitic on a certain number of ripe or green fruits which they cause to rot more or less rapidly.

The author decided to ascertain the means by which the parasites produced the changes he had observed in the infected fruit.

He therefore inoculated fruits with spores from pure cultures of *Penicillium* and of *Mucor*. The rot spread with rapidity around the point of inoculation varying according to the kind of fruit inoculated. Tomatoes even when green are very quickly attacked by *M. stolonifer* and more slowly by *P. glaucum*; pears are very susceptible to *M. stolonifer*, while apples are most easily infested by *P. glaucum*.

When the fruits were completely rotten, the author took great care to prove that their condition was due to the fungus with which they had been inoculated.

The fruits after inoculation become more or less soft, and their disorganised tissues lost all cohesion owing to the dissolution of the middle lamellae connecting the cells. Microscopic examination shows the shrunken, granular, opaque protoplasm to be dead.

The juice of these soft fruits is easily expressed. After filtration, a rather dark yellow, slightly opalescent liquid with acid reaction is obtained. If different fragments of plant tissue such as peices of apple, pear, bean stalk, Jerusalem artichoke tuber, carrot, onion etc. are introduced into the liquid, the author found that after a certain time they became soft and their cells were plasmolysed and killed, that is to say, they had the same appearance as the tissues of the fruits parasitised by the fungi in question. The time necessary for the complete disorganisation of the fragments, or preferably of slices of plant tissue varies according to the nature of the plant, their thickness and the temperature. At 20° C, slices of carrot about 160  $\mu$  thick become completely softened and their cells are killed in about 3 hours. The short duration of these experiments show that the effects observed are due to substances present in the juices used and not to any micro-organisms that have developed in them subsequently to their preparation. Further, the same effects are produced in the same space of time if substances such as chloroform or toluene, which prevent the growth of micro-organisms, are added to the juices. The extracted juice of sound apples, pears, or tomatoes does not disorganise plant tissues.

The author thinks he has thus proved clearly that the deleterious effect produced on fruits by *P. glaucum* and *M. stolonifer* is due to substances secreted by these fungi which permeate the pulp of the fruit infected and are found again in the expressed juice. These substances, which may be called fungous toxins, are of an enzymoid nature and only act in an acid medium. The toxins secreted by *P. glaucum* and *M. stolonifer* act also upon the tissues of plants which the fungi themselves are unable to parasite such as carrots, Jerusalem artichokes, beans, etc.

The conclusion therefore seems justified that the immunity against these two fungi which is possessed by some plants is not due to the resistance of their tissues to the secretions of the parasites, but to other causes which the author intends to try and ascertain.

G. T.

MEANS  
OF  
CONTROL

779 - Control of Diseases and Pests in California. — See No. 679 of this Review

780 - The Control of Pear Scab in the Cape Province, South Africa. — PUTTERILL, V. A., in *Union of South Africa, Journal of the Department of Agriculture*, Vol. IV, No. 5, pp 430-431, figs 2. Pretoria, May 1922

Report of spraying experiments on the control of pear scab (*Fusicladium pirinum*) carried out in 1922 at Stellenbosch and in Somerset West (Cape Province). These experiments among other things have proved the importance and the necessity of spraying the trees four or five times at least during the season, either with Bordeaux mixture or with lime sulphur.

The following sprayings should on no account be omitted : — 1) when the buds are breaking and leaves just showing ; 2) when the flower buds have opened, but while the individual blossoms are still closed, that is, about 10 days later than the first spray , 3) when the last petals are falling, that is, about 10 days later than the second spray , 4) ten days to 2 weeks after third spray , 5) five weeks later

In orchards where the disease is particularly virulent, an extra spray might be given between sprays 1 and 2 and between sprays 4 and 5

Late susceptible varieties, if the summer season is wet, might with advantage be sprayed again 3 or 4 weeks after spray 5. Spray 3 coincides with the first spraying for codling moth (*Laspeyresia pomonella*), and the fungicide in this and other subsequent spraying can be applied with arsenate of lead for codling moth. Experiments have shown that no diminution either in *Fusicladium* or in codling moth is effected by using the combined mixture.

Spraying has resulted in a gain of about 60 % of clean fruit, and a net profit of at least 4s per average tree. In addition to this, there was a marked increase in the vigour of the tree.

The ascophore stage of the fungus (*Penturia pirina*) was discovered in South Africa in September 1921, for the first time. The fungus passes over from season to season in the fallen leaves, so that to obtain satisfactory control it is essential to have a knowledge of the stage when the fungus in such leaves is in a condition to infect the tree. The ascophore stage was found also in 1921 for the first time in New Zealand. G. T.

DISEASES  
OF VARIOUS  
CROPS

781 Wart Disease of Potatoes (*Synchytrium endobioticum*), observed in South Africa. — DOIDGE, E M, in *Union of South Africa, Journal of the Department of Agriculture*, Vol IV, No. 5, pp 117-151, figs 3. Pretoria, May 1922

In spite of the precautions taken since 1921 to prevent the introduction of wart disease of potatoes (*Synchytrium endobioticum*) into South Africa, the disease has been detected recently in one locality, in the Impendhle Division (Natal).

Immediate steps are being taken to discover the extent of the infection and to prevent it from spreading to other parts of the Union.

A detailed description is given of the disease, and the control methods so far adopted. G. T.

- 782 - *Urocystis Bolivari* n. sp. a Ustilaginea Parasitic on Perennial Ray-Grass in Spain. — BUBÁK, F., in *Boletín de la Real Sociedad Española de Historia Natural*, Vol. XXII, No. 4, pp. 205-207, figs. 2. Madrid, April 26, 1922.

This article gives a description of a new species of Ustilaginea, *Urocystis Bolivari* Bubák and Fragoso, found towards the end of May 1921 near Algodor (Prov. of Toledo), on perennial ray-grass (*Lolium perenne*).

This fungus attacks all the organs of the plant, so that it never heads, or else produces defective florets.

This new species of Ustilaginea recalls by its external characters *Ur. occulta*, while in the form assumed by its clusters of chlamydospores it much resembles *Ur. Agropyri*.

G. T.

- 783 - *Fomes* sp. Root Disease of Rubber in Malaya. — See No. 716 of this Review

- 784 - *Sclerotium cepivorum*, a Garlic Disease called "boixat" in Catalonia, Spain (1). — CABALLERO, A., in *Boletín de la Real Sociedad Española de Historia Natural*, Vol. XXII, No. 4, pp. 210-212. Madrid, April 26, 1922.

For the last twenty years, the large garlic fields in the district of Bañolas (Prov. of Gerona), have been seriously attacked every season by a disease known to the local agriculturists under the name of "boixat" ("boixadura"). In 1914, the losses occasioned amounted to three hundred thousand *pesetas*, about 30 % of the total value of the crop.

Although first attributed to the presence of a bacterium, and afterwards to the attack of a Nematode, sometimes in association with other animal or plant parasites, the chief cause of the malady as has been repeatedly proved by the author, is a fungus, *Sclerotium cepivorum* Berk.

In order to control this pest, it is necessary to burn all infected plants; to suspend the cultivation of garlic in the places most contaminated by the disease, and to immerse all suspected bulbs before planting in a  $\frac{1}{3}$  % solution of formalin.

G. T.

- 785 - American Gooseberry Mildew (*Sphaerotheca mors-uvae*) reported from Piedmont, Italy. — GABOTTO L., in *Il Coltratore*, year LXVIII, No. 17, pp. 522-525, 1 fig. Casale Monferrato, June 20, 1922.

American Gooseberry Mildew (*Sphaerotheca mors-uvae* [Schw.] Berk. and Curt.), which was recorded for the first time in Italy in 1914, in the Province of Pavia (2) was also found in 1920-1921, in the Province of Novara, and is now attacking gooseberries in the districts of Asti and Casale-Monferrato (Prov. of Alexandria).

The author gives advice as to the control measures to be adopted against this Frysiphaea.

G. T.

(1) See also *R.* Oct. 1920, No. 1048. (Ed.)

(2) See *R.* Dec. 1914, No. 1188. (Ed.)

786 - *Fusicladium* sp. and *Entomosporium* sp. on Loquat in the Cape Province, South Africa. — PUTTERILL, V. A., in *Union of South Africa, Journal of the Department of Agriculture*, Vol. IV, No. 4, pp. 332-337, figs. 7. Pretoria, April 1922.

Towards the end of 1920, it was noticed that leaves of the loquat (*Eriobotrya japonica*) from Kenilworth (Capetown), were attacked by a disease resembling that caused by the apple and pear scab (*Fusicladium dendriticum* and *Fus. pirinum*). In October 1921 half-ripened fruit showed similar signs of decay. On the leaves, the diseases is seen on the under side as olive-green velvety spots; usually the leaves so affected become misshapen. On the fruits similar spots are produced. The outer layers of the fruit develop radiating fissures. The disease is thus very similar in appearance to apple and pear scab, especially the former (1). In some cases the fruits were totally destroyed and the leaves and branches badly attacked.

This disease has not been previously recorded in South Africa but probably it has been in existence there for about nine or ten years. It is not known if this fungus forms an ascophore in old leaves as is the case with *Fus. pirinum* and *Fus. dendriticum*, although such a means of hibernating is hardly necessary as the loquat is an evergreen.

Although no definite measures have yet been taken to combat these attacks, the following suggestions, if carefully followed, should give satisfactory results: 1) Old leaves and fruits should not be permitted to remain under the trees, but should be collected at frequent intervals and burnt; 2) badly diseased twigs should be cut and burnt; 3) the disease is not likely to spread much during the dry summer months, so that the trees should not be sprayed more than every two months, from November to April. If the trees show only slight symptoms of attack, two or even one spraying during this period should be sufficient. More frequent spraying from thence onwards up to the time the fruit is of a fairly large size is essential. The number of sprayings will depend largely on the intensity of the disease. As the rainfall is fairly high during the winter months, the amount of rain is another factor which will have a bearing on the number of sprays necessary; Bordeaux mixture 4:4:50 or lime sulphur 1:45 should prove satisfactory. Good results have been obtained with lime sulphur in Rondebosch (Capetown).

Another disease has been observed in only one locality, viz. at Wynberg (Cape Province) on loquats badly attacked by *Fusicladium*, though it is known to exist in other parts of the Union. This disease appears on the fruit as small, circular, shiny black spots, somewhat convex in shape. When these spots are very numerous and aggregated into patches, the disease looks, at first sight, very much like *Fusicladium*, though when they are isolated the two diseases are readily distinguishable. On the leaves

(1) Probably the present disease notified in the Cape Province is identical with loquat scab (*Fus. pirinum* var. *Eriobotryae*), already reported several years ago in Italy by SAVASTANO See R May 1918, No 599 (Ed.)

the disease is much less noticeable than *Fusicladium*; small, circular, reddish brown spots surrounded by yellow are formed.

This disease is caused by *Entomosporium* sp. In South Africa, a very common disease of the quince and the pear known as "leaf blight" does much damage, especially in Natal and in the Orange Free State; it is caused by a similar if not identical *Entomosporium*. The ascophore (*Fabræa maculata*) is found on the old fallen leaves. The winter ascophore stage is not known in the case of loquat blight.

The measures taken against loquat *Fusicladium* should be equally effective against *Entomosporium* on the same plant G. T.

787 - *Cenangium Abietis*, Ascomycete injurious to Spruce Pine in Switzerland. BADOUX, H., in *Journal forestier suisse*, Year LXXIII, No 6, pp 101 104 Berne, June 1922

*Cenangium Abietis* Duby, which as a rule is a simple saprophyte found fairly often on the branches of various Conifers, has been noticed sometimes to behave as a parasite, fatal to large trees and capable of spreading rapidly. Attention is drawn to the serious damage caused by this fungus in Germany (especially from 1891 to 1895) to pines of all ages, from about 5 years onwards.

In 1921 (Pomerania), saplings of 1 year were noticed to be attacked. *C. Abietis* was observed between 1914 and 1918 as a dangerous parasite on the white Pine in several parts of Switzerland (Zurichberg, Horgen, Rothenbourg) and in 1921 was found in the Hinterholz forest, in a closely packed stand of Pines of 60 years old, on alluvium of medium depth. Within a radius of 100 ares the trees died off from the top downwards and decayed rapidly. The attacked trees were cut down. The contaminated wood appeared to be very brittle, a transverse section showed a blackish tint which would render the timber useless for commercial purposes. Only 90 cub m of the 587 cub m felled in 1921 have been utilised for building purposes etc.

In order to stop the spread of this attack the stand in question has been well cleared in certain places G. T.

## WEEDS AND PARASITIC FLOWERING PLANTS

788 - Control of *Orobanche crenata* on Beans. MATTEI G. I., in *Allgemeine Year III*, pp 86 87 Palermo, March 1922

Small scale practical experiments covering a period of two years. In a series of pot experiments the author used identical quantities of the same type of soil and made comparative trials with guano coming from the Dalak islands distributed in minute and larger quantities in the various pots together with beans damaged by *Orobanche crenata* (= *O. speciosa*). Results show that guano if not applied too vigorously, hinders the development of *Orobanche*, without detriment to the bean.

Although up to the present, it has not been possible to determine the amount of guano required to obtain the best results, the author considers that further experiments should be made on a large scale, to ascertain the

practical value of this discovery and this applies especially to the Sicilian farmer who as is well-known, suffers great loss as a result of Orobanche attacks on the bean. G. T.

789 - **Mistletoe on the Spruce Pine in Switzerland.** — DELACOSTE, F., in *Journal forestier suisse*, year LXXIII, No. 5, pp. 90-91, figs. 1. May 1922.

In a forest near St. Maurice (Canton Valais), in March 1922, an unusual variety of the mistletoe (*Viscum album*) was observed slightly below the top of a pine, some 60 years old.

This Loranthacea is found in large and numerous clumps on the silver pine and white pine in the same forest, and on the fruit trees on the neighbouring plain.

The form of *album* observed on the pine may be distinguished by the yellow, narrow-shaped leaves when compared with other varieties, found on white pines and fruit trees.

In 1918 the mistletoe had already been noticed in Valais on pines in the forest of Saxon. G. T.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS

### GENERAL

790 - **Some Injurious Neotropical Weevils (*Curculionidae*).** — MARSHALL G. A. K., in *Bulletin of Entomological Research*, Vol. XIII, Pt. I, pp. 59-71, figs. 4, pl. 2. London, May 1922.

Amongst the species of Curculionidae here described for the first time as new to science, or only casually mentioned are the following:

1) *Diaprepes capsicalis* n. sp., observed in Rio Piedras (Porto Rico); the adult of this species has been observed feeding on leaves of pepper (*Cap-sicum* sp.).

2) *Exophthalmodes roseipes* Chev. (hitherto described as a *Pachnaeus*); the adults attack the leaves of cotton at Isabella (Porto Rico), but the species is more abundant on citrus trees.

3) *Lachnopus coffeae* n. sp., observed at Rio Pedras; the adult feeds on young leaves of coffee.

4) *Lachn. coffeae montanus* n. subsp., found at Yauco (Porto Rico); feeds on young leaves of coffee.

5) *Cholus wattsi* n. sp., collected in Grenada where the larvae and adults cause serious damage to the pine apple. The chief injuries result from attack of the fruit stalk. The control of this pest lies in clean weeding and removal of bushes and cultivation away from the influence of shade. Pineapples should be planted in straight and regular rows with sufficient distance between the rows to permit clean weeding. If properly planted and carefully tended plantations are attacked by the weevil, it should be possible to check such an attack without much loss, by collecting the weevils found hiding in the axils of the leaves and by cutting out and destroying any infested fruit, to remove any hidden larvae.

6) *Conotrachelus psidii*, n. sp. found in Bahia (Brazil); attacks the fruit of *Psidium Guayava*.

7) *Coelosternus granicollis*. Pierce ; attacks stems of cassava (*Manihot utilisima*) in Bahia.

8) *Piazurus papayanus*, n. sp., also found in Bahia, the larvae bores into the leaf stems of the papaw (*Carica papaya*).

9) *Lechriops psidii*, n. sp., collected in Mayaguez (Porto Rico) ; the larvae feed on the fruits of *Ps. Guayava*, which shrivel up as a result of attack.

G. T.

791 - Observations on *Tortrix viridana* in Spain. — AULLÓ, M., in *Revista de Montes*, year XLVI, No 1067, pp 10-11, figs 1. Madrid Jan. 1, 1922.

Observations were made during the first part of 1921, in the oak woods at Villaneuva de Cordoba, where the *Tortrix viridana* has been seen in abundance, in conjunction with the Macrolepidoptera, *Malacosoma neustria* and *Lymantria dispar*. Mating of the adults of this Microlepidopteron starts in the warm early hours of the morning, and continues for about 3 hours ; eggs are not laid at once, but two or three days later, after the female has had time to choose the most advantageous spot for the purpose.

According to the observations made both of captive specimens and during several hours watching in the open it has been noticed that frequently after remaining for a long time on the branch, the female goes away without laying. When, and however, and laying takes place, the female after going the length of the branch, places herself in an attitude parallel to the axis, bends the abdomen at the lower end, sways backwards and forwards moves herself along the branch leaving a mass of small scale sand scraped bark where finally lays the eggs, these are thus lightly covered, but under such conditions that they can only be distinguished with difficulty.

The number of eggs found in each spot is variable ; on the branches examined, from one to four have been counted ; the eggs when recently laid were of a light yellow colour.

The fact which has often been observed that it is at the beginning of the growth period that the caterpillars of *T. viridana* make their appearance, may be attributed to the method adopted by the female in laying, namely placing the eggs on the host plant where the new shoots should develop the following year. In this way, the caterpillar becomes enveloped at its birth by the plant nutritive organisms. It should not therefore be supposed that the caterpillar migrates from the trunk to a fixed point at the tops of the trees, which would be the case only if the trunk bark was, as is sometimes believed, the normal place for the egg-laying.

792 - Meade Cotton resistant to Boll Weevil (*Anthonomus grandis*) in the United States. -- See No. 713 of this Review.

793 - *Upupa epops indica*, And its Utility in India --- FLETCHER, T. B. and INGLIS, C. M., in *The Agricultural Journal of India*, Vol. XVII, Pt. II, pp. 113-118, figs. 1, pl. 1. Calcutta, 1922.

Except in Sind and Western Punjab, the Indian hoopoe (*Upupa epops indica*) is one of the most familiar of the birds living in the Plains of India.

RESISTANT  
PLANTS

MEANS  
OF  
CONTROL

It occurs abundantly in suitable localities in India, Burma and Ceylon. It is found chiefly in open country and is essentially a ground bird, only occasionally perching in the trees. Its food consists of insects, sometimes of cutworms found chiefly below the surface of the ground and rarely in the trees.

The young nestlings are fed almost entirely on caterpillars (probably all of *Noctuidae*), and on larvae of *Melanthinae* and *Gryllidae*. The quantity of food consumed during the day by half-developed nestlings is considerable.

From an examination of the stomach contents of 24 birds at Pusa, C. W. MASON found that these had swallowed 278 insects of which the majority belonged to injurious species.

In recognition of its agricultural utility, this bird is protected throughout the year in Bombay, Delhi, United Provinces, Bihar, Bengal, Assam, Burma and in Madras (Shevaroy Hills).

G. T.

**INSECTS, ETC.  
INJURIOUS  
TO VARIOUS  
CROPS**

794 - **Unidentified Dipter on Lucerne in Italy.** DRAGHETTI, A., in *L'Italia agricola* Year LIX, No. 3, pp. 82-83. Piacenza, March 15, 1922.

Misshappen inflorescences exactly similar to those observed by DENATIFFE and COLLE (1) on lucerne in Carignan (France), have been reported near Forlì (Romagna) in 1920, on selected parent plants, and scattered here and there over a series of plots, also serious damage is reported in a lucerne area in 1921.

Examination of flowers attacked showed that the damage is caused by a gall insect which changes the flowers into actual galls. The author is led to believe that the real agent responsible for attack is the same Dipterous, or a species very similar to that which injures the flowers of the lotus (*Cecidomyia loti*).

With lucerne the attack coincides with the appearance of the first flowers of the May and June-July crop, but hypertrophied flowers are also to be found in the following crops. The damage is not limited to undeveloped flowers, which, however, may be a serious matter, but may also affect a small proportion of normal flowers, delaying flowering time and attacking the upper portion of the inflorescence, and resulting in a decreased quantity and an inferior quality of seed.

G. T.

795 - **"Murda", a Disease of Pepper Plants, caused by an Unidentified Mite.** — KULKARNI, G. S., in *The Agricultural Journal of India*, Vol. XVII, Pt. I, pp. 51-54, pl. 2. Calcutta, 1922.

The most outstanding pest associated with the pepper plants (*Capsum*) in the Pres. of Bombay is a form well known to planters under different names, "murda", "goja", "macoda", mirya (in the Deccan), chandiroga or mnt lagariroga (in the Karnatik), "kokadva" (in Gujarat).

(1) See R. Jan 1922, No. 129. (Ed.)

The symptoms appear first on the terminal and axillary shoots. The leaves attacked curl up at the edge and wither; they often become twisted, curled and crumpled and gradually dry up and fall off. New shoots are formed and are attacked in the same way, and the development of the plant is hindered. The symptoms are noticeable at all stages of growth. If attacked when very young, no flowers or fruits are produced; if later and during the flowering period, the larger proportion of flowers attacked fade and fall off, and the small number left give fruits which rot quickly. The fruits attacked are much smaller than the normal and are curved. The disease spreads gradually to the lowest branches and as the internodes are shortened, the leaves appear to be aggregated in patches and the structure resembles scale formation. The plant is therefore seriously misshapen, and is hardly recognisable. A serious attack was reported in 1920, near Poona, in the Baramate valley, where there was a crop failure in nearly all the fields. Damage was recorded also in Byapour, Gokak, Kolhapour, Khed, Amalsad and Anand.

The cause of this disease is attributed to the same mite which attacks the potato, and is known as "tambera" (1).

In June 1920, the mite was found on the diseased pepper plants in all its stages and corresponding to that already observed on the potato. The exact cause of the two diseases was soon discovered after practical experiments were made by placing diseased portions of pepper on potato plants, and by inoculating *Capsicum* plants with mites living on the potato plant.

Preliminary control measures undertaken in seven different centres in the Presidency, have shown that a lime sulphur spray is sufficient to combat this pest, if it is used directly the first symptoms of attack are shewn.

The mite limit its attacks to the potato and the pepper, but also infests *Cyamopsis psoraloides*, *Zinnia*, *Dahlia*, *Tagetes*, *Mirabilis Jalapa*, *Physalis minima*, *Phys. peruviana*, *Amaranthus polygamus*. The effect on *Zinnia* is especially serious and frequent. Cross inoculation experiments made with the mite found on this Composita, with other *Zinnia* spp. have in every case given positive results.

As regards its identity the mite corresponds exactly with the description and photographs of the yellow Acarien belonging to the *Tarsonemus* found by WATT and MANN to be harmful to the tea plant. It is considered probable therefore that the mite found on the pepper plant is a *Tarsonemidae* species. G. T.

**796 - The Gall Form of Vine Phylloxera, observed for the first Time in New South Wales.** — PROGGATT, W. W., in *The Agricultural Gazette of New South Wales*, Vol XXXIII, Pt. 5, p 360, pl 1 Sydney, May 1922

In the Hawlong nurseries, the leaves of *Riparia* × *Rupestris*, planted several years ago were observed recently to be covered with "phylloxera" galls.

(1) See R. June 1921, No. 696. (Ed.)

According to the author it is the first time that a gall form of *Phylloxera vastatrix* has been noticed in New South Wales. G. T.

797 - "The Tukra" Disease of Mulberry caused by *Phenacoccus hirsutus* in Bengal. — MISRA, C. S. (First Assistant to Imperial Entomologist), in *Agricultural Research Institute, Pusa, Bulletin* No. 109, pp. 610-618, pl. 1, Calcutta, 1921.

The disease of the mulberry, locally known as "Tukra" in Bengal is caused by the coccid *Phenacoccus hirsutus* Green, and not by *Dactylopius bromeliae* Bouché as hitherto believed.

It was noticed for the first time in Pusa in 1908, and was seen later in the Murshidabad, Marda and Ban-Kura silk-producing districts. In the first mentioned area the disease was already very widely distributed in 1900 and the damage serious. Probably it is to be found in other mulberry-silk-producing districts in Bengal.

The shoots of the affected plants first turn coppery green, then pale yellow and ultimately become so hard and compact that it is not possible to open them without breaking off the shrivelled leaves. With the appearance of the malformed shoots, the lower lateral leaves become seared and fall off prematurely. In cases of severe attack, the bare stems are left. The apical leaves, if they do not turn pale yellow, become so crisp and devoid of nutrient constituents that they become unfit for the silkworms. The disease is very widespread during some years and considerable damage is done to the leaf crop, and consequently there is a heavy loss to the cultivator.

The disease seems to have obtained a footing in the silk-producing districts of Bengal for the following reason: the remedies hitherto adopted for eradicating the pest consisted in the collection of affected shoots and throwing them outside the infested fields into a neighbouring ditch or pool; the nymphs as well as the mature females crawled from these and invariably infested the succeeding crop. In addition this, the nymphs and the gravid females were blown away by the wind with fallen leaves, and nymphs and females of *Phen. hirsutus* have also been transported to new places by means of the nymphs and females of *Pseudococcus virgatus* Ckll as well as other insects.

At Pusa, *Phen. hirsutus* has been found on *Morus* spp., on cotton, and on potted *Ficus religiosa* plants kept near the potted mulberry plants. Close to these were also *Eugenia jambolana*, *Ficus glomerata*, sugar cane, rice and *Citrus decumana* plants, but none of these were attacked.

The author has been able within a short time to reproduce the disease on healthy potted mulberry plants which showed all the usual symptoms noted in the field. In addition to this he succeeded in rearing one complete cycle of *Phen. hirsutus* on *Ficus religiosa* plants in pots.

On mulberry plants in pots, *Pseudococcus virgatus* has been found to occur along with *Phen. hirsutus*, but experiments have shown that nymphs and females of the former may easily be distinguished from the eggs, nymphs and adults of the latter. *Phen. hirsutus* occurs also on cotton

along with *Ps. corymbatus* and *Ps. virgatus*, but in this case also they may be easily distinguished.

The nymphs and females of *Phen. hirsutus* are parasitised by 3 unknown species of Chalcidae, one of which is very widespread. A Cecidomyad fly, *Diadiplosis indica* E. P. Felt is parasitic on the eggs, nymphs and gravid females. The larvae of *Eublemma* sp (allied to *quadri-lineata*) also feeds on the nymphs and females

Colonies of *Phen hirsutus* living on the mulberry and on *Ficus religiosa* are also attacked and devoured by the larvae of *Spalangia epus*, a very effective agent for destroying this pest.

ORIGINAL ARTICLES

**Problems of Cotton Growing (1)**

by Dr. FABRIZIO CORTESI

*Professor of pharmaceutical Botany at the Royal University of Rome,  
Consulting Botanist at the Italian Colonial Institute*

On the eve of the international cotton Conference which will be held at Rio de Janeiro in October, it may be useful to give certain information corroborated by biological and statistical data, regarding some of the more important fundamental questions relating to cotton growing.

This article is divided into three chapters; in the 1st the present possibilities of developing the growth are examined; the 2nd is devoted to the study of the seed, and in the 3rd a rapid survey is made of the diseases which injure, and often destroy this important crop.

I. -- PRESENT POSSIBILITIES OF DEVELOPING  
THE GROWTH OF COTTON.

If the statistics of the cotton production of the world are examined, it is seen that, on the whole, it has decreased chiefly owing to a decline in the United States yield

The data published in the *Annuaire International de Statistique Agricole* from 1909 to 1921, give the following totals for the different parts of the world (Table I)

TABLE I. — *Total production of cotton in the world from 1909 to 1922.*

Regions	Area (ha).			Production of ginned cotton (qx)		
	1909-10 to 1913-19	1914-15 to 1918-19	1919-20 to 1921-22	1909-10 to 1913-14	1914-15 to 1918-19	1919-20 to 1921-22

Oceania . . . . .	150	45	3 140	163	72	735
Grand Total . . . . .	24 183 763	24 219 212	23 671 948	40 730 911	38 786 870	36 849 345

Table I, which gives the averages of these recent years, shows also that the decrease in the area cultivated, which in round numbers is about one and a half million hectares, does not correspond with the decrease in production, which exceeds four million quintals; the latter being much greater in comparison with the decrease of the area cultivated, since according to Table II in the above-mentioned *Annuaire* the average of production per hectare varies between 1.6 q. and 1.7 q. Other causes have therefore influenced this decrease, which will be examined later in considering certain fundamental questions in the world's cotton problem.

If the figures relating to the statistics of the world's production in various countries are examined in detail, we see that there are at present three principal cotton centres in the world, all situated in the Northern hemisphere, namely — the United States of America, which produced in 1909-10/1913-14, 28 258 194 qx., in 1914-15/1918-19, 26 937 344 qx., in 1919-20/1921-22, 23 994 679 qx.; British India, with the following pro-

duction :— in 1909-10/1913-14, 7 770 220 qx., in 1914-15/1918-19, 7 785 099 qx., in 1919-20/1921-22, 8 391 671 qx. ; Egypt, with the following production :— in 1909-10/1913-14, 3 149 782 qx., in 1914-15/1918-19, 2 462 037 qx. in 1919-20/1921-22, 2 232 576 qx

Brazil, chiefly in the Southern hemisphere comes next with —

1919-10 — 1913-14	611 900 qx.
1914-15 — 1918 19	675 460 »
1919-20 — 1920-22	1 045 304 »

Regarding the yield per hectare, which is a very important coefficient, it is given, according to the above-mentioned *Annuaire*, for a number of countries in Table II (p 930)

These figures are very important, because they show that, except in Peru, where the average production per hectare is the highest, Egypt and Japan, where the averages always exceed 3 qx per hectare, in the other countries (including the United States which is the greatest cotton centre in the world), the averages are very low and in certain countries almost negligible. These figures indicate that the chief cotton region of the Northern hemisphere is Egypt where the averages always exceed 3 qx and often 4 qx. per hectare, while in the Southern hemisphere, the averages reach and exceed 3 qx. per hectare in South America. The Southern hemisphere has higher averages than the Northern hemisphere, indeed almost double.

Apart from the decrease in the total area cultivated, the decrease of the world's cotton production is due also generally to the almost continuous decrease in the production of cotton per hectare, which is shewn in Table II.

\* \* \*

The above paragraphs give the present position of the world's cotton production and the question of the future possibilities of development next arises.

In certain countries, such as Brazil, in certain central and eastern parts of Africa and in certain parts of Asia, the production of cotton is susceptible of great extension and probably this is the case for China, Manchuria and Korea.

J. A. TODD in a very interesting article published in a recent number of *The Agricultural Journal of India*, recognises that Brazil is a very important centre of cotton production capable of very great development. Further, it should not be forgotten that the *International Federation of Master Cotton Spinners* has recently sent representatives to Brazil to investigate and study on the spot the possibilities of cotton production ; and that this mission, which is composed of members of unquestionable authority, has recognised that Brazil possesses most favourable conditions of climate and soil for becoming a centre of cotton production. of the highest importance. It is certainly necessary that all measures calculated to encourage planters as effectively as possible should be taken and that all modern

cultural methods directed towards industrialisation and high production should be introduced.

In the report presented by Dr. DE CAMPOS to the VIth General Assembly of the International Institute of Agriculture it is stated that in certain regions of Brazil, such as the State of São Paulo and in the North-East, there are very high unitary yields of cotton, which exceed the averages of any other country

Local varieties are very important and have a great future. The variety Riqueza has a very fine fibre, strong, flexible and glossy. "Mocó" (which can be grown very successfully in Seridó) produces a fibre 45 mm long and, in that region, the plant becomes perennial, producing bolls for 10-15 years, while in Egypt a somewhat similar species is annual, requiring more labour, and giving a smaller yield of fibre. Another important variety is "Rim de Boi" the herbaceous short stapled cotton plant has the advantage that it can be grown in places which are unsuitable for other species and that it develops very rapidly thus, at Alagôros and Sergipe, only 3 months elapse between planting and picking, while at Maranhão one month and a half is said to suffice

In recent years the cotton production of Brazil has increased considerably, as the following statistics, taken from the previously mentioned *Annuaire*, show. On the other hand it has decreased very much in other countries

Years	Quintals
1915-16	611 900
1916-17	608 327
1917-18	747 154
1918-19	734 461
1919-20	832 971
1920-21	977 842
1921-22	1 326 000*

\* The figures 1921-22 are approximate

According to HIMBURY, quoted by Prof RICCI in his report, there are distinct possibilities for the development of cotton growing in British Colonies in Africa and especially in Nigeria, whence 16 000 bales (of 400 pounds each) were exported in 1920, and some day there may be a production of one million bales, in Uganda, a country where cotton was unknown 16 years ago, the production was 53 000 bales in 1920 and anticipations of the future point to 500 000; in the Sudan 22 000 bales were obtained, and there is a possibility of favourable development up to 1 500 000. Altogether Great Britain might possibly obtain from these three colonies, after a lapse of years 3 million bales of 400 pounds, which would represent  $\frac{1}{7}$  of the present total production of the whole world.

There are also certain possibilities for the development of cotton growing in Erythrea, in the districts situated on the Anglo-Egyptian frontier and along the coast; but it will be necessary to bring to a conclusion

the experiments in selection of some American varieties of the "American Upland" type, and especially of the variety "Triumph" and of some short stapled "Orleans" kinds which have given excellent results. Italian Somaliland, especially the region of middle Ouébi Schébé, where the Duke of the Abruzzi has started a large farm and extensive irrigation works are being carried out, contains plains where by means of irrigation cotton planting could be considerably developed.

Before the war the Russians were investigating, the possibility of intensifying and extending the growth of cotton in Transcaucasus and in Turkestan.

The following figures have been quoted for Russia in Asia :—

Years	Quintals
1909-10 . . . . .	906 967
1910-11 . . . . .	1 500 787
1911-12 . . . . .	1 604 945
1912-13 . . . . .	1 134 225
1913-14 . . . . .	1 449 747
1914-15 . . . . .	1 574 605
1915-16 . . . . .	2 145 209

Unfortunately the present conditions exclude the possibility of any reliable forecasts or estimates.

In the United States, which is the greatest centre of world cotton, production has decreased, both on account of some reduction in area under cotton and of the significant decrease in the unitary yield. In fact from a maximum production of 34 983 423 qx. obtained in 1914-15 production went down to a minimum of 18 082 538 qx. in 1921-22.

The case of Egypt is similar and the decrease has been equally marked. Egyptian production reached its maximum in 1913-14 with 3 443 193 qx. and its minimum in 1921-22 with 1 482 624 qx. One of the principal causes of this decreased production in Egypt is to be found in infections, especially the "pink bollworm", while other contributory factors are want of manure, continuous cropping, and too long continued growth on the same ground and the state of the soil in relation to irrigation and drainage.

A region which may perhaps have some future for cotton planting, when the political problems and those of irrigation and labour have been solved, is Mesopotamia, where there is a possibility of utilising more than 121 000 ha., along the banks of the Tigris and the Euphrates. Experiments, undertaken by Capt. R. THOMAS in 1918 and continued in the following years, gave promise of eventual, good results.

\* \* \*

From this rapid examination the following conclusions may be drawn.

1) The growth of cotton in the different countries of the world is susceptible of substantially increased development, especially through

encouragement in those new countries in which conditions are particularly favourable.

2) The causes of the present decrease in the world's production of cotton are due to the decrease in the area cultivated and especially to the decrease in the unitary yield.

3) The decrease in yield is due to complex causes, among which are — deterioration of the species grown in the absence of good selection methods, the still imperfect cultural methods followed in many regions and the insect pests which in certain countries destroy a large portion of the crops.

4) The unitary yield probably depends on a combination of geographical and ecological factors which require detailed study and exact determination in the interest of the world's future cotton production.

5) In cotton statistics, it is necessary to distinguish between the production of long stapled and short stapled species, the more so because, from the standpoint of manufacture and market prices, these two types of cotton may be considered in many respects as different products

## II — THE PROBLEM OF SEED

Another problem of capital importance in the cotton question is that of seed. The success or comparative failure of cotton crops depends specially on the quality of the seed used.

The most serious fact which impairs both the quality and quantity of the product originates from the mixing of the seed which takes place during the operation of ginning the cotton. If the ginning machines are not perfectly cleaned, a small quantity of the seed of one variety remains, and gets mixed with the next variety. The impurity of the seed results in the mixture of varieties in the crop and, owing to the facility with which cotton plants cross-fertilise, considerable quantities of natural hybrids are produced which impair the homogeneity of the crop and the quality of the produce. This phenomenon is most evident in the

United States and is one of the principal causes of the deterioration of varieties of cotton plants and their low yield. An interesting study has been made on this subject in Texas by SAUNDERS and CARDON, and has shown that the mixture of seeds takes place in the case of the drum of ginning machines, that the ginned seed contains not less than 14 to 16 % of seeds from the lot of cotton previously ginned and that it contains also a small percentage of the previous lot.

To avoid this mixing the ginning apparatus must be carefully cleaned before proceeding to gin each new lot; these precautions require longer time which slightly increases the cost of the operation, but the advantages obtained are well worth the expense and result in an improved cotton crop.

Selection carried out by scientific methods is of very great importance for improving the seed. Researches on this subject have been undertaken for many years in British India at the experimental agricultural stations of Akola, Sindenahi, Ljallpur, Mirpurkas and in Burma. These researches have for object the isolation of the most productive and most important types, from an agricultural standpoint, from the mixtures of forms which constitute the local varieties or types and also the study of those exotic species which are most suitable for growing. The results obtained should encourage perseverance in this line and also might serve as an example to other Governments to carry out similar investigation and research in their countries.

The work of selection by pure lines carried out by B. C. BURT and HAIDIR NIZAMUDDIN at the Kaliempur Station (British Indies) and which deals with the type of acclimatised cotton plant known under the generic name of "Cawnpore American", may yield some important results. The quality and quantity of the produce in the selected forms have always been superior to that of the original mixtures and may open the way to further improvements.

\* \* \*

In Egypt, where the deterioration of cotton has been very marked in recent years, very searching investigations have been made regarding the causes of this deterioration which entails enormous economic injury to the country. The article by VICTOR MOSSERI on this subject, seems to be most interesting; he notes in Egyptian cotton plants, not a true degeneration, but a deterioration due to essential and accidental causes which affect the quantity and quality of the produce. To remedy it, especially so far as quality is concerned, it is necessary to isolate and purify the cultivated types or to select the most suitable plants and shield them during propagation from all other pollination.

Three methods can be used for this object — the first, employed by BALLS at the Laboratory of the Khedivial Society of Agriculture, consists, after having isolated a type, in adding, by means of crossing and methodical elimination, the advantageous specific characters desired. This

is the *method of addition or synthesis*. The second consists in isolating the types which present the specific advantages desired, eliminating those which do not offer the advantage wished for, the (*method of analysis or of elimination*). The third method is that of the *selection of advantageous mutations*.

The most difficult thing is to propagate the seeds of pure types and keep them free from all contamination, and this can be done by care when ginning; by not growing different varieties too near each other in order to avoid hybridisation, by eliminating undesirable plants from the plantation and by rigorous control of the seed. It is only in this way that the best Egyptian types can be saved from inevitable decadence.

This rapid study of cotton seed may be concluded by the following recommendations. —

1) That all cotton growing countries should carry out investigation and research on the genetics of local and imported species of cotton plants, following the methods used in India and Egypt, with the object of isolating the best pure lines

2) That, as soon as these pure types are obtained and established, every effort should be made to keep them free from all degeneration, especially by avoiding the cultivation of various species in adjacent areas.

3) The greatest care and cleanliness should be used in ginning cotton for seed purposes so as to avoid the mixture of seeds of different varieties, which takes place, as has been clearly proved, in the ginning machines.

### III. — DISEASES OF THE COTTON PLANT

See also the collection of *Monthly Bulletins of Agricultural Intelligence and Plant Diseases* of the International Institute of Agriculture which contain, under the heading *Plant Diseases*, much information on the diseases of the cotton plant and their remedies

The cotton plant, like all cultivated plants, is subject to numerous diseases, some of which are very destructive to the crop. These diseases may be grouped in 3 classes. — The first includes those which are due to physiological causes, the second deals with diseases due to vegetable parasites, the third includes all diseases caused by animals, especially by insects.

#### (A) DISEASES DUE TO PHYSIOLOGICAL CAUSES

(a) "Mosaic disease or Yellow leaf blight". — This is characterised by yellow spots which are arranged more or less regularly on the surface of the leaves and cause withering and fall of the leaves. This disease

is often aggravated by the simultaneous attack of some fungus. It is due to the weak constitution of the plants attacked and the remedy lies in better cultivation such as the addition of kainit to the soil which is always beneficial

(b) "Red Leaf Blight" — This is shown by a red margin of the leaves; the growth of the plant is gradually arrested and the leaves fall. This disease is due to scarcity of some fertilising elements of the soil and can be controlled by means of manures, in order to supply the elements which are lacking (potash, nitrogen and phosphoric acid).

(c) "Shedding of Bolls". — Disease due to unfavourable climatic conditions and which is frequently noticed during periods of drought or excessive rain.

#### (B) DISEASES OF CRYPTOGAMIC ORIGIN.

(a) "Anthracnose". — This disease is caused by *Colletotrichum Gossypii*, and it attacks the stems and the leaves. No direct remedies against this disease are known; phosphate and potassic manures render the plants more resistant to attack. Where the disease has shown itself, all the refuse remaining in the field after the harvest should be collected and burnt and cotton should not be grown there in the following year.

(b) "Wilt or Trenching" is produced by *Neocosmospora vasinfecta*: the fungus enters the plant by its roots and gradually invades the whole vegetative system. The first indication of the disease is the turning yellow of the under part of the lowest leaves. On examination of the stem after breaking, it will be seen that the fibrovascular bundles are dark brown. The only remedy for this disease is selection, which enables resistant varieties to be obtained; in the United States the "Sea Island" cotton industry which was threatened with extinction, has been saved by this method.

(c) "Root Rot" is due to a species of *Ozonium*, a fungus which also attacks other plants besides cotton, such as lucerne, apple trees etc. The fungus attacks the roots and lives on the soil at the expense of the plant. The only means of control is a scientific rotation, by following cotton crops with cereals which are resistant to this disease; cotton should not be grown for three or four years on land where the disease has shown itself.

(d) "Cotton Leaf Blight" This is the most common disease of the cotton plant. The fungus (*Sphaerella gossypina*) usually attacks the oldest leaves and predisposes the plant to attacks by other diseases, particularly "Mosaic disease". The infected leaves are characterised by spots, white or light brown in the centre and reddish on the edges.

(e) "Cotton Mildew". Due to *Ramularia areola*, this disease shows itself on the leaves by small zones bordered by marbling.

(f) Angular Leaf Spot. — The disease is shown by dark angular spots on the leaves of the less vigorous plants; good cultivation is the best means of prevention.

*Heteroderma radiculicola* causes swellings on the roots and diseases of bacterial origin also attack the cotton plant.

### (C) DISEASES OF ANIMAL ORIGIN.

(a) "Cotton Boll Weevil" (*Anthonomus grandis*). This is the greatest enemy of cotton crop. This beetle, a native of Mexico was reported in 1892 in Southern Texas, and has spread to such an extent that it has invaded almost the whole cotton growing area, and causes enormous damage. The eggs are laid in spring on the flower buds or on the young capsules; the larvae feed on these parts of the plant and the insect multiplies so rapidly that five generations occur between the 1st May and the 1st December. Control by means of its natural enemies has been tried, among which are some hymenoptera (*Ectatomma tuberculatum*, *Braccon mollitor*, *Cotolaccus incertus*, *Eurytoma tylodermatis*, etc.) DWIGHT PIERCE has tried to limit the development by placing beside it other anthonomes but with little result.

Insecticides, arseniate of lead among others, have proved ineffective. The best means of control is to prevent the normal evolution of the species by adopting the following measures — (1) selection of varieties which ripen very early, (2) sow as early as possible, (3) hasten growth by all means. Furthermore, as the insect hibernates on the leaves and on debris of the soil, they should be burnt. Rotation also decreases the damage. In zones with a dry climate (East Texas, California, etc.) the plant is protected to some extent from the attacks of the "boll weevil".

(b) "Cotton Boll Worm" or capsule worm. This is the larva of a micro-lepidopter (*Heliothis armigera* or *Noctua armigera*) which is very common and feeds on the leaves, flowers and capsules of the cotton plant and causes great damage. As it also attacks other plant, it is recommended to sow catch-crops, especially maize sown late in the middle of the cotton fields to attract the insect at the time when the larvae develop. Insecticides made with Paris green and arseniate of lead have given good results. In Egypt the "Cotton boll worm" is the larva of *Earias insulana*, which behaves like the former and causes enormous damage, it also attacks hemp and *Hibiscus esculentus* (gombo, chindi) which is used in India as a trap-crop. An analogous species (*Earias tabia*) has been noticed in Egypt, India, Ceylon and Java.

The "Egyptian Boll Worm" is *Prodenia littoralis*.

(c) "Pink Boll Worm" or "small boll worm" is the larva of another micro-lepidopter very common in Europe, Asia and Africa (*Gelechia gossypiella*) which causes such great damage to cotton plantations that it destroys them completely, as has happened in India and in Egypt, where it is one of the causes of the decadence of cotton growing. The capsules attacked should be carefully collected and burnt, the use of lamps to attract and capture the insect, which is nocturnal, also gives good results. To destroy the larvae in the seed, which is the principal cause of propagation of the disease, the following methods may be employed:

1) treatment of the seed with hot air at 80° C ; (2) fumigation with bisulphide of carbon or hydrocyanic acid or sulphurous anhydride ; (3) immersion for 24 hours in a 0.1 % solution of "cyllin".

(d) "Cotton Worn" (*Alabama argillacea*) is another micro-lepidopter whose larva is a troublesome enemy of the cotton plant in the South of the United States and in the West Indies. This larva first attacks the topmost leaves and then descends towards the base of the plant destroying everything in its course, including young buds, flowers and young capsules.

In the United States good results have been obtained from an insecticide composed of powdered arseniate of lead mixed with Paris green, slaked lime and flour. In the West Indies the larva is destroyed by a wasp (*Polistes annularis* or "Jack Spaniard").

The "Leaf Roller" of different cotton countries is *Sylepta derogata*.

(e) "Cutworms" are the larvae of certain insects (*Feltia* sp., *Agrotis ypsilon*, etc.), which attack the young cotton plants after the germination of the seed. The best means of control is to place poisoned cabbage leaves in the infected plantations.

(f) "Cotton Aphid". This is *Aphis gossypii* which attacks a large number of young plants and the buds. The best remedy is the use of emulsions of soap and creoline.

(g) "Cotton Stainers". The worst are — *Dysdercus* (the American "red bug") and the *Pentatomia* (*P. ligata*), the "conchuola" of Mexican planters.

Locusts also cause much damage to cotton plantations.

\* \* \*

As is seen from this brief review, the diseases of the cotton plant are many and often very serious. To control them it is indispensable to take international and national measures. These measures should prohibit the transport of seed of infected regions, unless disinfected and carefully controlled, into regions free from disease, methods of control should be studied and the most resistant types should be selected. It has been proved, for instance, that the resistance of Indian cotton plants to certain parasites is due to abundant resinous secretions which cover the valves of the capsules. This course, namely the study of types resistant to and free from disease, which has already given such excellent results with cereals for resistance to rust, will give important results provided that the investigations are undertaken with adequate means and a clear idea of the ends to be attained.

AGRICULTURAL INTELLIGENCE

CROPS AND CULTIVATION

798 - **Phenological Observations in Holland in 1921.** — Bos, H., in *Cultura*, Year 34, No. 400, pp. 2-13. Tiel, Jan. 1922

AGRICULTURAL  
METEOROLOGY

Results of observations made in 1921 at the stations organised by the writer in Holland. Noticeable points:—

(1) The great abundance of flower buds of the ash (*Fraxinus excelsior*);

(2) The severe frost ( $-7^{\circ}\text{C}$ ) of 15th-16th April which damaged the flowering of cherry and pear trees and destroyed the shoots of acacias and plane trees;

(3) The early flowering and ripening, 10 days earlier than usual, of autumn rye;

(4) The severe drought in spring-summer caused a series of interesting phenomena: --- there was a partial fall of leaves in the summer, followed, in certain plants (*Syringa*, *Jesulus*, etc.) by a fresh foliation and flowering; pear and apple trees blossomed for the second time at the end of June and commencement of July, and produced, generally, fruit half the size of normal fruits, but which in some cases attained remarkable size; most of them had no pips.

The drought also caused the leaves to turn yellow and wither, but this phenomenon should not be considered as an anticipation of the normal process of fading and fall in autumn. This process in fact, took place as usual in autumn, but notably late, due, according to the writer, to excessive exposure to the sun.

799 - **Data regarding the Distribution and Intensity of Hail in Bulgaria.** — GREGOROV, G. in *Semkdelie*, year XXV, part 8, pp. 121-122. Sofia, Aug. 1921.

Data collected during the decennial period 1911-1920 warrant the statement that the greater part of Bulgarian territory is subject to frequent and severe hailstorms. The phenomenon has an essentially local character; cases however of extensive hailstorms, such as that of the 18th June, 1915, which raged over 164 communes, are not lacking. In most

[Abstract No. 798-799]

*Distribution of hail in Bulgaria.*

Year	Date of the first hail	Date of the last hail	Duration of the hail Season	Maximum quantity of hail		Number of days on which hail fell	Number of Communes in which hail fell					
				Date on which it fell	Number of communes in which hail fell		Total	Once	Twice	Thrice	Four times	Five times or more
1911	3 III	27 IX	200	15 VI	15	29	108	89	16	3	—	—
1917	27 IV	27 IX	154	9 VII	52	39	281	232	38	8	2	1
1913	22 IV	1 IX	131	10 VI	70	55	352	264	61	17	8	4
1914	3 V	9 IX	130	3 VI	90	63	441	315	94	23	5	4
1915	14 IV	23 IX	162	18 VI	164	60	455	328	81	36	6	4
1916	25 IV	23 IX	151	13 VI	93	65	470	358	148	43	13	9
1917	19 IV	30 VIII	134	18 VII	60	49	281	227	47	5	2	—
1918	23 IV	10 IX	141	27 VII	57	47	369	302	54	11	2	—
1919	9 IV	18 X	193	25 VII	43	54	322	257	50	11	3	1
1920	24 IV	7 IX	137	19 VII	49	54	316	245	44	17	8	2

cases the hail clouds come from the west or north-west, and the phenomenon ordinarily is seen between 2 p. m. and 6 p. m.; it is very rare in the morning, the evening and at night.

The annexed Table contains the following data:— 1) duration of the hail season; 2) number of days on which hail fell; 3) number of communes in which hail fell, on the average, once, twice, or more often.

During the period dealt with, the duration of the hail season was 154 days (5 months). There were, on the average, 52 days of hail, and hail fell in 340 communes or  $26\frac{3}{4}\%$  of the insured communities. The co-operative Bank had to indemnify 18% of the insured (47 166) and pay 17 997 416 lei ( $9\frac{33}{64}$  pence at par). G. A.

## SOIL PHYSICS

800 — **The Soil Fauna of Agricultural Land.** — BUCKLE, P. (Department of Agricultural Entomology, Victoria University of Manchester), in *The Annals of Applied Biology*, Vol 8, Nos. 3-4, pp. 135-145, bibliography of 10 works. London, November 1921.

It is well known that cultivation has a detrimental effect upon the soil fauna, and various cultural operations are strongly advocated as preventive and remedial measures against the depredations of soil insects. However, it is not known whether arable land possesses a characteristic fauna apart from species peculiar to certain crops.

Hence, the survey was carried out on three types of agricultural land and the author studied the fauna of: a) land continuously under the plough for a number of years; since 1916, the rotation of crops included oats, potatoes, turnips and mangels and wheat; a dressing of farm-yard manure was given preparatory to the root-crop; 2) pasture land that had been broken up not less than three years previously; 3) permanent pasture, or meadow-land. The author gives all the characters of these

three types. In studying the fauna, 9-inch cube samples were used; the soil was allowed to dry and then passed through sieves of different degrees of fineness. The arthropoda thus collected were carefully classified. The researches lasted from October 1919 to May 1920; during this time viz., nine months, the soil fauna were more stable and numerous on the grassland than on the arable land, probably because grassland bears a vegetative covering, while little if any vegetation exists on arable land; further, the ploughing and working of the ground brings the fauna to the surface and exposes the animal life, not only to bird attack, but also to harsh climatic conditions, especially in the winter and early spring, thus disturbing many hibernating species. There was a corresponding increase in the fauna on all the three types of land as the vegetative growth increased. No characteristic fauna of arable land could be discovered; the predominant species were those commonly found on pasture.

The author has, however, not made any quantitative determinations, as these investigations are of a preliminary character. L. V.

801 - **Influence of Salts on Bacterial Activities of Soil.** — GREAVES, J. P. in *The Botanical Gazette*, vol. LXXIII, No. 3, pp. 161-180, bibliography of 29 works. Chicago, March 1922.

A study has been made of the influence of 24 salts on soil microflora and the minimum amount of solution required to effect certain forms of bacterial activity, such as ammonification, nitrification and nitrogen fixation. The results are tabulated clearly, showing the six cations of the different salts employed and the 4 anions and the measure of toxicity of the resulting 24 salts.

As regards ammonification, the maximum retarding effect was noted with potassium chloride and sulphate of iron (vol. mol. =  $625 \times 10^{-7}$ ); then in order of sequence is placed calcium chloride and magnesium nitrate ( $156 \times 10^{-7}$ ) etc. The toxicity of a compound is regulated by both anion and cation; almost without exception the chlorides are more toxic than the corresponding nitrates. The sulphate varies according to the cation with which it is combined. The relative toxicity for the anions can be written as follows:  $\text{Cl} > \text{NO}_3 > \text{SO}_4 > \text{CO}_3$ , and the results for the cation:—  $\text{Mn} > \text{Mg} > \text{Fe} > \text{Ca} > \text{Na} > \text{K}$  or the monovalent anion is more toxic than the bivalent and viceversa for the cation.

Results obtained with nitrification indicate that the nitrifying organisms are more sensitive than the preceding; toxicity of salt increases with concentration much more rapidly than in the case of the ammonifiers:—  $\text{CO}_3 > \text{NO}_3 > \text{SO}_4 > \text{Cl}$ ; and of the cations  $\text{K} > \text{Mg} > \text{Fe} > \text{Mn} > \text{Ca} > \text{Na}$ .

As regards nitrogen fixation, the organisms concerned, are on the contrary very resistant, so that the concentrations employed were hardly ever strong enough to act as a retarding agent; the results do not therefore allow any definite conclusions to be drawn as to the degrees of toxicity of the various salts.

It appears, however, that toxicity is due in a large measure to osmo-

tic influences. Thus with 24 salts, 16 became toxic when the osmotic pressure ranged between 1.43 and 1.96 atmospheres. But other factors intervene; for example the range of toxicity for cations on ammonification organisms shows a similarity to that due to protoplasmic formation; it is very probable that the cations modify the proteins forming the protoplasm and in such a way as to incapacitate them for their normal functions.

All except 6 of these salts acted as stimulants of bacterial activity, measured by the quantity of ammonia, nitrates and nitrogen fixation.

In the investigations made on bacterial activity it was discovered that assimilation of part of the organic material occurs. This influence is well indicated in the solubility of the rock phosphate; to identify the changes due to bacteria, organic phosphorus has been treated with water-soluble phosphorus. The results obtained show that certain salts, for example manganese carbonate, increased bacterial activity (135.1 % compared with the control), whilst with others such as magnesium carbonate a contrary effect was obtained (85.1 %).

L. V.

**802 - Influence of *Azotobacter* added to the Soil on the Plant-growth. —**

FOUASSIER, M. and L'HOMME, J., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol 8, No 7, pp 155-159 Paris, Feb 15, 1922

The writers recall that since 1877, SCHLOESING and MUNTZ, on the basis of Pasteurian ideas, had shown that the processes of nitrification of nitrogenous matter are in correlation with the existence in the soil, of living agents, whose action is arrested by sterilising agents such as chloroform or heat. Later nitrification and the fixing of nitrogen were the object of researches on the part of BIRTHLOT, JOULIE, A. GAUTIER, BRÉAL, ANDRÉ, etc. In 1893 WINOGRADSKY noted the symbiosis of Leguminosae with the nitrogen-fixing microbes, later he isolated one of the most active agents of this phenomenon, the *Azotobacter*, DÉHÉRAIN studied the action of *Azotobacter* on the soil in different conditions.

Meanwhile, methods were sought for favouring the multiplication of nitrogen-fixing microbes in the soil, for increasing their power, and for determining their solution by means of suitable sterilisation. LAPPARENT and RABATÉ observed that by spraying the soil with a  $\frac{1}{10}$  solution of sulphuric acid to the extent of 1 cub m per hectare an increased crop was obtained. In America and England sterilisation of the soil is practised in market gardening. In France TRUFFAUT and BEZSSONOFF after having studied the action of aromatic carbides fixed on calcium sulphide as sterilising agent.

The writers have made similar experiments, but for sterilisation they have used formol in doses of 3.45 per cub. m.; they abandoned the use of calcium sulphide because TRUFFAUT, who had recognised it as one of the best soil sterilisers, had also proved that the sulphur in its composition is a fertiliser. As nitrogen-fixing agent the writers used *Azotobacter agilis*, isolated to a pure state, and then cultivated in non sterilised, aqueous extract of earth, to which a little glucose was added: in this non-nitrogenous medium the *Azotobacter* soon got the upper hand while the other

germs perished. The experiments were made on 5 plots of ground in the open field, 1 sq. m. each and arranged in a similar way: one remained as control plot, two were sterilised, two not; in the case of each of these two pairs, to one plot was added mould containing 1.5% of organic nitrogen; 24 hours after sterilisation broadcast sowing was made with clover seed; then over all the plots, except the control plot, the liquid containing the *Azotobacter* was poured using  $\frac{1}{4}$  of a litre per sq. m., diluted with 5 litres of ordinary water. The differences in growth, at first imperceptible, became well marked towards the 20th day in favour of the *Azotobacter*, it is strange to record that the growth was greater in the sterilised plot to which no mould was added. Without wishing to exaggerate the importance of these researches, the inference is that *Azotobacter* is able to cause the fixation of nitrogen even if it is added directly to the soil L. V

803 - **Nitrogen Fixation in Ericaceae.** - RAYNER, M. C., in *The Botanical Gazette*, Vol. 73, No. 3, pp. 226-235, figs. 4 Chicago, March 1922

The article gives a general review of the subject together with some new data.

It has been known since the middle of the nineteenth century that plants belonging to the Ericaceae form characteristic mycorrhiza, but it is only recently that some light has been thrown upon the relations between the plant-host and the endophyte.

In 1907 TERNETZ succeeded in isolating from the roots of certain Ericaceae several pycnidia-forming fungi which were all referred by LINDAU and HEMMINGS to the genus *Phoma*. They differed from the species previously found associated with Ericaceae in the small size of their pycnidio-spores, and though isolated from plant species growing in close proximity, are specific strains, distinguishable by definite morphological and physiological characters. The most distinct forms were named *Phoma radialis Ericae*, *Ph. r. Tetralicis*, *Ph. r. Vaccini*, *Ph. r. Oxycocci*, *Ph. r. Andromedae* respectively. It should be noted that the isolation of fungi endophytic in the roots of plants is very difficult, and the identity of the fungi can only be proved by inoculation from pure culture into the roots of sterile seedlings and the consequent formation of the mycorrhiza typical for the species. TERNETZ's work in this connection is open to criticism, for he never succeeded in obtaining sterile Ericaceae seedlings, and hence there was no proof that the mycorrhizal condition was due to the inoculated fungi.

TERNETZ also tried to discover whether the *Phomae* he had isolated could fix atmospheric nitrogen. He therefore cultivated them in nitrogen-free media with all due precautions as to purity of materials, adequacy of controls and methods of estimation. The cultures were carried over a period of several years, and frequently repeated. It was found that none of the five strains investigated required a supply of combined nitrogen for healthy development or growth. They all fixed atmospheric nitrogen, but in very different degrees. From his own comparative experiments, which agreed in this respect with the results obtained by other investi-

gators, TERNETZ found that the strains of *Phoma* are much less energetic nitrogen fixers than *Azotobacter chroococcus*, *Clostridium pasteurianum* and *C. americanum*, but more economical as regards the amount of dextrose consumed to obtain the energy necessary for the process; for example, the maximum amount of nitrogen combined for each mg. of dextrose used by them was 22 gm. as against 10.6 gm. in the case of the nitrogen-fixing bacteria. The values obtained for *Aspergillus* and *Penicillium* were too small to have any serious value.

In ignorance of the work of TERNETZ, the author made an exhaustive experimental study of an Ericacea, *Calluna vulgaris* and published the results in 1915. He showed that the fungus is already present in the testa of the seed and infects the young seedling immediately after germination. A pycnidia-bearing fungus was eventually isolated with comparative ease from unopened fruits. Proof of the identity of this fungus was provided by reinoculation into seedlings raised from sterilised seed. The author tried to detect the symbiotic relation between *Calluna* and the endophyte, and found that the former could not grow in a sterile medium, thus proving that a remarkable case of *compulsory symbiosis* existed between the two organisms. The hyphomycete is distributed throughout the plant tissues of the host including the seed-coat and eventually reaches the ovary; the mycelium spreads to the seed-coat, so that the seedling become infected. Root-formation by the seedlings is dependent upon early infection by the endophyte; if this does not take place, development ceases and the young plant perishes. It is probable that the same conditions exist in the whole family of Ericaceae and in fact ovarial infection has been reported for many species, and the inability of seedlings to complete their development without infection has already been proved in a number of cases.

Similar conditions are also to be found among the Orchidaceae, but here the endophyte is localised in the root-cells, so that the infection of the seedling is not insured. There is visible evidence in orchids of the digestion of the mycelium by the cells of the root, and it is clear that by this means the plant can draw indirectly upon organic compounds of carbon and nitrogen in the soil.

In the chlorophyllous orchids the endophyte can utilise the products of photosynthesis, otherwise the higher plant lives as a parasite at the expense of the fungus. This condition has been fully demonstrated for *Gastrodia elata*, a Japanese orchid, parasitic upon a fungus, *Armillaria mellea*. It is certain therefore that one at least of the so-called "saprophytic" orchids is to a certain extent parasitic. This is the more interesting because the fungus in its turn has parasitic habits and invades the tuber of the orchid in the first instance in exactly the same manner as it attacks the tubers of the potato, it is only afterwards that the fungus supplies the orchid with food. These facts explain the ecology of *Calluna*. There is no indication in this Ericacea of digestion of the *Phoma* mycelium by the root, nor are there any obvious symptoms of attack or defence beyond the fact that the hyphae effect an entry and spread from cell to cell. It is

only in the mesophyll cells of the leaf that the mycelium undergoes digestion. The mycelium in its turn draws its supply of organic compounds from its host ; as is proved by the cultures in solutions of mineral salts and the power it possesses of hydrolising arbutin. This being so, the question of the use of the endophyte to the Ericaceae naturally presents itself. There is abundant evidence that the fungus can fix atmospheric nitrogen in a greater or less degree and supply it to the host in return for the organic compounds it obtains from the host. Of this fact the following proofs have been obtained : 1) infected *Calluna* seedlings, germinated on filter paper moistened with distilled water are vigorous and longlived ; 2) the endophyte is widely distributed through the plant tissues, develops in the intercellular spaces of the leaves and emerges into the air from the surface of the shoot, as if to obtain nitrogen from the atmosphere ; 3) the mycelium is afterwards digested by the mesophyll cells in which the fixation of oxygen takes place. On the other hand there is no evidence that the endophyte of Orchideae can absorb atmospheric nitrogen, for it does not spread into the chlorophyllous tissues

In 1916, DUGGAR and DAVIS made an experimental survey of previous work on nitrogen fixation by fungi and extended the observations of earlier investigators, taking special precautions to avoid dubious experimental methods. They tried many species and varieties of fungus, among which was *Phoma Betae* which has the power, common to all the *Phomae*, of fixing atmospheric nitrogen. In this manner an indirect proof of nitrogen fixation on the part of Ericaceae by means of endophytes was obtained

The author has recently provided a further experimental proof. He has already grown two sets of *Calluna* seedlings, the one in agar-agar free from combined nitrogen, and the other in the same medium, but with the addition of a 0.5 % concentration of potassium nitrate as being the solution most suitable for the purpose. No special precautions were taken beyond the use of pure chemicals and freshly distilled water. The seedlings grew equally well in both cases, and those not supplied with nitrate were of a brighter green.

The experiments have since been repeated using every possible precaution to avoid contamination by traces of combined nitrogen. A similar solution of inorganic salts was made up in silica jelly prepared from specially purified materials and ammonia free water. The results obtained confirmed those already described, although owing possibly to mechanical difficulties offered by the silica jelly, the seedlings did not take root freely.

It may be objected that the seeds used their reserves of nitrogen, but when sterilised seeds were employed and no nitrates given, the seedlings turned yellow and the leaves became discoloured, these symptoms being relieved by inoculation with a pure culture of the endophyte. The fixation of nitrogen by Ericaceae through the medium of species of *Phoma* has thus been clearly demonstrated and with their aid Ericaceae can grow and thrive in soils deficient in nitrogen.

These researches have in part been carried out at the Pilcher Research Laboratory, Bedford College, University of London.

804 - **The Micro-organisms of Sulphofication** (1). - I WAKSMAN, S A (New Jersey Agricultural Experiment Station, Department of Soil Chemistry and Bacteriology), Micro-organisms concerned in the Oxidation of Sulphur in the Soil, I. Introduction, *Journal of Bacteriology*, Vol VII, No 2, pp 231-238 Baltimore, March 1922 — II WAKSMAN, S A, and JOFFE, I S (Id) Id, II. *Thiobacillus thiooxidans*, a New Sulphur Oxidising Organism isolated from the Soil, *Ibid* pp 239-256, figs 2, 1 pl, bibliography of 36 works

The micro-organisms of sulphofication have been very carefully studied by OMELIANSKY, DUGGELLI, and KRUSE. The author takes up the subject with the object of establishing the present state of knowledge of the question and of using the data collected as a starting point for further investigation

Hydrogen sulphide, sulphides and thiosulphates undergo a spontaneous oxidation process resulting in the separation of sulphur. The sulphur thus produced, like natural sulphur, if finely subdivided, is further oxidised with the production of sulphuric acid; the latter, reacting with carbonates and other salts, forms sulphates

The process takes place very slowly as a result of the action of simple physical and chemical forces, but is greatly accelerated by specific bacteria; this was pointed out for the first time by WINOGRADSKY who referred to them under the name of *sulphur-bacteria*. In the transformations which sulphur and its compounds undergo, two types of bacteria are concerned, the one being a reducing, the other an oxidising agent. The sulphur-bacteria belong to the second class and are very energetic in their action. The first sulphur-bacteria studied by WINOGRADSKY contained granules of sulphur resulting from the oxidation of the hydrogen sulphide dissolved in the medium, subsequently, many other micro-organisms were found to possess the power of oxidising hydrogen sulphide, sulphides, thiosulphates and sulphur, some of them being able to accumulate sulphur in their cells. These microorganisms are very heterogeneous in character.

In nearly all the work which deals with the oxidation of sulphur by bacteria the point of departure of the process was not regarded as sulphur, but as hydrogen sulphide, sulphides and thiosulphates, the oxidising power of these bacteria not being estimated by the oxidation of the sulphur and hence by the production of sulphuric acid and sulphate or the change in the reaction of the medium, but only by the appearance and disappearance of the granules of sulphur. This was due to the fact that the sulphur-bacteria were studied in sulphur springs, mud baths, sea-water, drinking-water and drainage-water, very little attention being paid to the micro-organisms that oxidise the sulphur of the soil. It was only later that these micro-organisms aroused interest, as a result of the researches of JACOBSEN and other writers. It has also been recognised that the oxidation process takes place in two stages; the sulphur is produced first and afterwards transformed into sulphuric acid. Two large classes of micro-organisms are

(1) See R 1919, No 693 (Fd)

especially concerned in the work. The bacteria of one class oxidise the hydrogen sulphide, sulphides and thiosulphates removing the sulphur which they accumulate internally and subsequently oxidise. These bacteria cannot oxidise external sulphur, and are therefore of little importance as regards the chemical changes which take place in the soil; they have, however, been more completely studied than the bacteria of the second class. These are either unable to bring about the preliminary changes, or can only carry them out unsatisfactorily; they alone, however are, capable of oxidising external sulphur. These bacteria are the more important to agriculture, but scientific knowledge of them is still incomplete.

Each of the two large classes can be further subdivided into smaller groups according to their morphological characters and physiological properties. The micro-organisms capable of storing up sulphur in their protoplasm consist of 3 groups: 1) colourless and filamentous; 2) colourless and non-filamentous; 3) purple rhodobacteria. The micro-organisms that cannot accumulate sulphur within themselves, but are able to oxidise external sulphur, can be divided into 2 groups according as: 1) they themselves deposit the sulphur externally and separate it from the other compounds; 2) they do not deposit sulphur. The latter group is the more active. There are thus 5 groups of sulphur-bacteria each of which can be studied separately.

1st GROUP. — This is the best-known, for it has been the longest investigated. It includes three genera; *Beggiatoa*, mobile forms of bacteria; *Thiothrix*, immobile forms of bacteria (both of these have no sheath), and *Thioploea* composed of bacteria covered with a gelatinous sheath. The *Beggiatoa* are the classic sulphur-bacteria. As long ago as 1870, CRAMER recognised that the granules they contained were sulphur; later, COHN was of opinion that the *Beggiatoa* and the purple bacteria reduced the sulphur they contained and produced hydrogen sulphide. WINOGRADSKY subsequently showed that exactly the opposite process takes place, the sulphur accumulated in the protoplasm of these bacteria which is present in the form of soft globules incapable of cry-tallisation is the product of the oxidation of hydrogen sulphide; when subsequently oxidised, it produces sulphuric acid, which is neutralised by the carbonates and bicarbonates, and liberates carbon dioxide; hence the medium never becomes acid. These processes are exothermic, that is to say they entail a certain production of heat, thus supplying the bacteria with the energy they require for living and building up their organic substance. If these micro-organisms are deprived of hydrogen sulphide, they burn up all their accumulated sulphur and then perish. Traces of nitrates or of other simple nitrogenous substances are all they need for the construction of their plastic materials, but peptone, sugar, etc. which promote the growth of other bacteria are useless or injurious to *Beggiatoa*. KEIL believes himself to have obtained pure cultures of *Beggiatoa* and *Thiothrix*. He clearly recognised that both species can live in media containing no organic matter, for which reason he called them autotrophic. KEIL showed that these bacteria can obtain from carbon dioxide all the carbon they require for

the formation of organic matter, and he states that the presence of carbonates is necessary for the neutralisation of the sulphuric acid. The different species of *Thioploea* have been studied by WISLOCK and by KOLKWRZ.

2nd GROUP. — This is very heterogeneous and artificial. It contains most dissimilar forms, bacilli like *Thiobacterium*  $\alpha$  and *Thiobacterium*  $\beta$  described by JEGUNOW; spirilli like *Spirillum agilissimum* and *Microspira vacillans* described by GICKLEHORN, and even flagellates like the *Monas Mülleri* of HINZE.

3rd GROUP. — The rhodobacteria are characterised by two pigments distributed irregularly throughout their protoplasm: bacterio-purpurin, which is red, violet-red, or brownish red, and bacterio-chlorine which is green. Although these micro-organisms occur in large numbers in the water of sulphur springs and in mud impregnated with sulphur, they are unable to isolate the sulphur present. MOLISCH succeeded in obtaining pure cultures of some of these forms, but they were not sulphur bacteria. According to MADSEN and MOLISCH, sulphuric acid is not necessary to keep them alive, and they contain no sulphur granules; this statement, however, does not agree with the preceding observations made by WINOGRADSKY and others. The behaviour of these bacteria as regards sulphur is therefore an open question.

4th GROUP. — The bacteria composing this group were observed for the first time in sea-water by NATHANSON and subsequently found in drainage water, and in the soil. They oxidise hydrogen sulphide, sulphides and thiosulphates and accumulate sulphur externally forming a thick surface film containing sulphur which they can ultimately break through. The bacteria of this group are also able to use the carbon of carbon dioxide for the manufacture of organic matter. NATHANSON has cultivated them in liquid media containing, amongst other substances, thiosulphates and carbonates; BEIJERINCK has generally confirmed these results, and recognised that no other source of carbon is capable of replacing carbon dioxide. He isolated a very mobile, non spore-forming type of *Thiobacillus thio-parum* and a very similar form of *Bacillus denitrificans*, capable also of liberating the nitrogen of nitrates. JACOBSEN has carried out some quantitative experiments to determine how far *Thiobacillus* is able to oxidise external sulphur. LIESKE and GOEHRING have found *Bact. denitrificans* in many soils, while GICKLEHORN has met with bacteria of the same group in garden mould, but has never isolated them.

5th GROUP. — Although the first four groups are well-known and have been described in microbiological treatises and in special studies on sulphur-bacteria, little attention has been paid to this last group, although it includes some of the bacteria that are most active in oxidising the sulphur of the soil. These are very common in soils to which crude sulphur has been added, and they obtain from it large quantities of sulphuric acid. The bacteria of the 5th group also oxidise thiosulphates to a slight extent, but cannot break up hydrogen sulphide or sulphides, and do not liberate sulphur, they form no surface film on the liquid on which they are growing, but are distributed equally throughout the mass; they extract all the car-

bon from carbon dioxide. These micro-organisms, though excessively minute, are the most active sulphur oxidising agents and acid producers known. The group has but one representative *Thiobacillus thioxydans*, which is very common in the soil, and has been the object of preliminary studies on the part of the author in collaboration with JOFFE and LIPMAN.

II. — In a mixture of soil, mineral phosphate and sulphur, the sulphur is quickly oxidised into sulphuric acid, which converts the basic lime phosphate into neutral phosphate, then into acid phosphate and finally, if the phosphate supply is exhausted, it accumulates it on its own account unaltered. These facts were discovered by MACLEAN in 1918.

The authors have succeeded in isolating from the mixture a micro-organism which oxidises sulphur. They employed the dilution method, adding to the substance sterilised water in the proportion of 1 : 10 up to 1 : 10 000 000 ; and then added 1 cc. of the liquids thus obtained to 100 cc. of the cultural medium. This consisted of a suspension-solution in distilled water, of sulphur (1 %), basic phosphate of lime, ammonium sulphate and other mineral salts. The authors also tried adding glucose, but had to abandon it, as this carbohydrate encouraged the growth of moulds. By means of successive transplanting the cultures became gradually purified, as was ascertained under the microscope, and proved by the sterility of cultures grown in ordinary nutritive media.

The micro-organism isolated is a very minute bacterium with rounded extremities, gram positive, and non-spore producing ; most of the individuals measure 10.5  $\mu$ . In its morphological characters it much resembles the two species of *Thiobacillus* identified by BEIJERINCK. For this reason, the authors have included it in the same genus under the name of *Thiobacillus thioxydans* n. sp. ; it is however very different in its physiological behaviour, and has therefore been placed in a separate group. Unlike the two forms separated by BEIJERINCK, which liberate sulphur from hydrogen sulphide, sulphides and thiosulphates and deposit it externally, the new bacillus only attacks thiosulphates, and does not deposit sulphur, but oxidises the surrounding sulphur.

From sulphur, *Thiobacillus thioxydans* obtains all its life-energy. Its activity can be accurately gauged from the amount of sulphur oxidised ; the quantity of sulphuric acid thus produced, or the amount of basic calcium phosphate dissolved by this sulphuric acid. Impure cultures have proved the more active ; they have oxidised as much as 20-30 % of the sulphur. The original acidity of the cultural medium was  $\text{pH} = 5.6-6.2$  ; during the growth of the culture, it continually increased up to 2.8-2.6 where it remained stationary (this being the optimum growth acidity), until all the tricalcic phosphate had been dissolved by the sulphuric acid and transformed into bicalcic phosphate, monocalcic phosphate and phosphoric acid, the calcium being however precipitated in the form of the sulphate. The further oxidation of the sulphur resulted later in the production of free sulphuric acid which increased the acidity, the latter reaching values of pH ranging from 1 — 0.8 — 0.6. This high acidity hindered the further development of the culture, producing an auto-regulation of the acid content. If

much tricalcic phosphate was present, a larger amount of sulphur was oxidised, because the acid produced could be neutralised during a longer period without impeding the growth of the culture. An excess of tricalcic phosphate (as well as of carbonates), was not, however, easily tolerated.

The micro-organism obtains all its carbon from the carbon dioxide of the atmosphere. It has no need of carbonic acid obtained from carbonates by the action of sulphuric acid; carbonates never increased its growth and sometimes they were even found to hinder it, as occurred when the medium was rendered alkaline. The reason is that sulphur-oxidising bacteria prefer an acid medium, whereas nitrifying bacteria flourish in an alkaline medium. Bi-carbonate of sodium is not only useful to the nitrifying micro-organisms as affording a supply of carbon, but also and chiefly, because it renders the medium alkaline (MEYERHOF). For the same reason it may have an injurious effect on sulphur-oxidising bacteria. The latter are not tolerant of calcium oxide, for it has the power of producing too sudden a change in the reaction of the medium, whereas tricalcic phosphate is very useful in neutralising the sulphuric acid formed, owing to its insolubility and the acid compounds and insoluble deposit to which it gives rise.

The best source of nitrogen proved to be the inorganic salts of ammonium, but other compounds can also be used.

In conclusion, *Thiobacillus thioxydans* (which is doubtless the first recognised individual of a group of energetic sulphur-oxidising bacteria), is distinctly autotrophic, that is to say able to live and grow at the expense of organic matter alone; it derives its energy from sulphur, the carbon present in carbon dioxide, and the nitrogen of mineral salts. Glucose is not injurious to the bacterium, but has no effect upon the production of sulphuric acid. Autotrophic microorganisms possessing the power of manufacturing organic matter from mineral substances in the same manner as higher plants, but without the aid of sunlight, or chlorophyll are not only of considerable agricultural importance, but also of great general biological interest, as probably being the earliest representatives of organic life upon the globe.

805 - **Researches on the Efficacy of Deep Tillage and on the Distribution of the Roots of Certain Plants in Different Strata of Soil.** — AVANZI, E. (Istituto agrario della R. Università di Pisa), in *L'Agricoltura Italiana* Year XLV, parts 1-3, pp 41-56 Pisa, 1922.

Preliminary researches commenced in May 1920, with the object of determining the influence which the depth of preparatory tillage might have on different crops grown in succession on the same soil. In a preliminary experiment frames 10 cm. in height were placed one on top of another and sunk on garden soil normally dug with the spade; each series of 5 frames was filled with soil which had been dug over and exposed to the sun. An analysis of the soil was made and the fundamental manuring consisted of mineral superphosphate and nitrate of soda; buckwheat and millet were sown in two series, succeeded by autumn wheat and white

mustard; the second season was particularly dry, for which reason the humidity of the different boxes and the different strata of soil was determined at the end of the experiment.

It is easily understood, after what has just been stated, that the results of the researches made cannot be applied in practical cultivation. However, these researches allow certain conclusions to be drawn which confirm the general rules regarding the influence of the depth of tillage in regard to different crops.

If the produce obtained with the various plants used in the experiment is examined, it is noticed that the increased production due to greater depth of tillage was realised, as is easily supposed, with the crops which were formed immediately after the execution of the tillage. It is next noted that the increased production has not taken place in proportion to the depth of the tillage, since this increase after reaching its maximum for the first deepening of the tillage (from 10 to 20 cm), has then become less accentuated, and, after having attained a maximum, instead of continuing to grow in proportion to the depth, has, on the contrary, decreased in a sudden and marked manner; and it has done so very probably owing to the intervention of injurious actions exercised by the mineral and organic matter situated in the deep strata and brought to the superficial strata. It is further remarked that the favourable effect of deep tillage was particularly manifest with millet, which, on account of its great vegetative activity and its rapidity of growth, consumed a greater quantity of fertilising substances and water for the production of a much greater quantity of organic matter than that produced by the buckwheat. The crop of wheat which followed that of millet and buckwheat also felt the effects of the different depth of tillage previously done, but the effect in its case was much less; to such an extent that if there was a noticeable increase in the production of grain there was often a reduced production of straw.

Another fact which this crop has brought into prominence concerns the slightly smaller quantity of grain obtained from the wheat which followed the millet compared with that yielded by the wheat which followed the buckwheat. The white mustard, having gone through a period of scarce rainfall, felt the effects of the tillage also in a notable manner, and its increased production was similar to those recorded for the former crops.

A final remark concerns the smaller amount of humidity in the upper layer of soil where the tillage was only 10 cm, in comparison with the humidity contained in the soil of the corresponding layers where the soil had been more deeply turned up; and this will seem all the more remarkable if it is remembered that in the former case there was also a smaller consumption of water, owing to the smaller amount of organic matter produced.

Other researches on the distribution of the roots of certain crops in the different layers of soil accompanied the former; they were made with rules and methods similar to those above mentioned, with this difference

that the frames were 15 cm. high. In five parallelepipeds of soil formed of five frames superimposed, indigenous selected maize, millet, hemp, giant sunflower, and Kentucky tobacco in transplants were sown on the 25th May 1920. The vegetative phases passed regularly and, in October when each species had finished its vegetative cycle, the roots were examined.

The writer concludes from that examination that the greater part of the root-system of the species considered was found in the most superficial part of the soil, to the extent that about 90 % of the weight of the roots are in the first 23 cm. of depth. However, it should not be forgotten that a good part of the weight of the roots found in the upper layers is constituted the taproots or by the thickest roots while the deeper layers only contain the capillary roots.

As is easily supposed each plant is distinguished by a characteristic root system. Maize has strong principal roots to which are attached numerous capillary roots, very largely found in the first and second layers.

Millet has a root-system very similar to maize ; but it is much more abundant and formed of more resistant and more pliable roots.

Hemp has a root-system which may be considered as typical of plants with tap-roots : from the taproots start more or less stout secondary roots to which are attached the system of capillary roots formed of very fine rootlets. The sunflower is indicated, as is well known, as a taprooted plant : it has, it is true, a very strong taproot which buries itself beyond the third layer ; but, differing from true taproots, it has a capillary system of very fine rootlets which spreads out mainly in the more superficial layer.

Tobacco, owing to transplantation, has not a true taproot, since at a depth of a few centimetres (4 to 6) the taproot is replaced by very strong secondary roots spreading chiefly in the lower layers and bearing capillary rootlets which reach a considerable depth.

The form and distribution of the root-system may serve to justify the various exigencies of plants in the matter of soil, preparation, tillage, manuring and cultural care. In any case, we should never neglect the direct or indirect influences which tillage exercises on the physical, chemical, and biological properties of the soil and which are expressed by greater or less vegetative activity of the plants cultivated.

Another fact, which we must beware of neglecting in the matter of tillage and manuring concerns the rate of growth of the root-system ; it probably is very different in various plants. In fact, the above-mentioned researches have given prominence only to the final conditions, but it would not be without importance, especially in connection with the application of quick acting manure, to follow the development of the root-system of different species of plants in their most typical vegetative phases.

806 - Application of Electricity to Cultivation. - See Nos. 814 and 867 of this *Review*.

807 - **The Effect of Gypsum on Soil Reaction.** — ERDMAN, I. W. (Iowa Agricultural Station) in *Soil Science*, Vol. 12, No. 6, pp 433-448, bibliography of 32 publications. Baltimore, Dec. 1921.

Gypsum has been used as a fertiliser for many years and has often proved to be valuable when applied to small grains and clovers.

The early investigators claimed that gypsum increased crop yields for a time, but its continued use failed to maintain those increases, and, as it contained no nitrogen, phosphorus or potassium, it was regarded as a soil stimulant. Recent investigations have shewn that the value of gypsum is probably due to its sulphur content, as many soils have been found to be deficient in this essential plant-food element, which is more important in the case of certain crops than was formerly supposed. As gypsum supplies sulphur in a form available to plants it may play an important part in the fertility of soils which are deficient in this element. It is believed also that gypsum has an indirect action in modifying other soil constituents. Gypsum cannot replace lime as a means of correcting soil acidity, but opinions differ as to whether or not when applied to soils it tends to make them acid. Gypsum is a neutral salt and on dissociation ought to give rise to hydrogen and hydroxyl-ions of equal concentration, which might modify soil acidity; at the same time there may be secondary reactions, which theoretically may cause a certain amount of acidity.

The author decided to test as far as possible the effect of gypsum on soil reactions.

The literature on the subject contains references to experiments dealing with gypsum itself, and also with superphosphate which contains about 60 % of gypsum, consequently the effect of the fertiliser may be partly due to this substance. The work of GARDNER and BROWN in 1910 on plots which had received gypsum at the rate of 320 lb per acre every two years for a period of 30 years, showed that these plots were slightly more acid than those which had received none, but the difference was so little that FREAK concluded that gypsum did not add to soil acidity.

SCHOLLENBERGER found that gypsum applied to manure decreased acidity; CONNOR obtained similar results; on the contrary, LIPMAN stated that it did not correct acidity; SKINNER and BEATTIE maintained that it added to acidity; SINGH the same. VEITCH and CONNOR applied superphosphate and found acidity decrease. BROOKS, PLUMMER AMES and SCHOLLENBERGER found no appreciable difference. These experiments were carried out by various methods.

The author used TACKE's method, as slightly modified by STEPHENSON: it consisted of treating the soil with an excess of calcium carbonate and estimating the volume of carbon dioxide evolved.

The results were checked by the method of MACINTYRE and WILLIS, based on the determination of the residual carbonate; a direct evaluation was also made of the hydrogen-ion concentration.

To summarise the results, it may be concluded that gypsum applied in amounts up to and including 500 lb. per acre does not increase or decrease the soil-reaction as determined by the TACKE-STEPHENSON meth-

od. An application of 1000 to 2000 lb. per acre causes a slight increase in hydrogen-ions in an acid or neutral soil, but very little in the case of a basic soil.

Gypsum added at the rate of 500 lb. per acre to a neutral soil made to vary in degrees of acidity by additions of HCl and Ca CO<sub>3</sub> had no effect on the hydrogen ion concentration of the soil, and did not show sufficient lime requirement by the STEPHENSON-TACKE method to justify the conclusion that gypsum had any effect on soil acidity. 808 - **Herbaceous Growth of Arborescent Plants for the Production of Manure and Forage in Cuba.** — CALVINO, M., in *Boletín N. 47, Secretaría de Agricultura, Comercio y Trabajo, Estación Experimental Agronómica*, 16 pp., fig. 6. Habana, 1922

By sowing very thickly the "gelso bianco" (*Morus alba*) or still better *M. multicaulis* and cutting it level with the ground several times a year, a sort of meadow is obtained which can be mown with the same apparatus and machines as herbaceous plants (1).

The writer proposes the adoption of this method for the growth of two arborescent leguminous species of tropical regions introduced into Cuba:— *Cassia siamea* Lamk. (*C. florida* Vahl) and *Albizia Lebbeck* Benth. The former called "Cassia del Siam" in Cuba, "Kassod tree" in the Hawaii islands and "wa" in India, is a native of Southern India, Burma, Ceylon and of the Malay peninsula and Siam. Grown in its natural form it furnishes a good firewood and cabinet wood, grown as a hedge it serves as a wind screen, if sown thickly and cut often it gives a large quantity of herbaceous material rich in nitrogen and suitable for use as green manure.

In the experiments made by the writer at the Havana Experimental Station with seed obtained from the Philippines, by sowing on the 7th May 1920, transplanting at a spacing of 60 cm. × 60 cm. on the 2nd June of the same year and cutting for the first time on the 8th July 1921, the second on the 17th November 1921 and the third on the 31st March 1922, he obtained respectively, without any irrigation, 1212 — 572 — 320 qx. per hectare of tender leafy branches, easily decomposed, each 1000 kilogrammes made up of 498 kg. of leaves and 502 kg. of branches.

The leafy branches at the time of cutting contain in their leaves 52.4 % of moisture, 44.33 % of organic matter and 3.27 % of mineral matter and in the branches respectively 49.85 — 48.64 — 1.51 %. They contain nitrogen in the proportion of 1.88 % in the leaves and 1.3 % in the branches. By drying at 30°, the moisture is reduced to 9.7 % in the leaves and to 7 % in the stems; the nitrogen becomes respectively 3.57 % and 2.40 %. The ash of the leaves contains:— 27.05 % of lime, 12.8 % of potash, 6.12 % of phosphoric acid; the ash of the branches contains respectively 8.78 — 10.63 — 5.05 %. For the purpose of comparison, the writer recalls that the "cowpea" (*Vigna Catjang*) contains in the fresh leaves 0.33 % of nitrogen, the "velvet bean" (*Styrolobium* spp.)

(1) See: R. FORLANI, *Il prato gelso*. Catane, Battiato, 1920. (Ed.)

0.37 % and the "fandul" (*Cajanus indicus*) 1.12 %, that is to say they are all inferior to *Cassia siamea*.

As 1000 parts by weight of fresh leafy branches contain 15.88 of nitrogen, 2.89 of potash, 1.134 of phosphoric acid and 5.03 of lime, if 50 tons of these branches are applied to 1 hectare of land, as green manure, it is furnished with 794 kg of nitrogen + 114.5 kg. of potash + 67 kg. of lime. *Cassia siamea* is not eaten by animals; it is not subject to diseases, nor attacked by insect pests.

For use as transported green manure the writer recommends as follows:— before spreading and burying the cut branches, let them steep in water in which farmyard manure in fermentation has been soaked (as is done in India) and to which has also been added 2 % of phosphate of ammonia or 1 % of superphosphate and 1 % of sulphate of ammonia; much more rapid decomposition is thus obtained. One of the systems suggested in England for the production of artificial manure (1) may also be adopted, that is to say mixing the plant with ground limestone and sulphate of ammonia or simply with cyanamide of calcium and let it ferment by watering from time to time. The writer recommends mixing 100-160 kg. of cyanamide of calcium and an equal quantity of Cuban bats phospho-guano with 2000 kg. of leafy branches.

*Albizia Lebbek*, called "algarrobo de olor" in Cuba, "blackwood" in French Colonies and "women's tong tree" in British Antilles, may be used with the same object. This plant is a native of tropical Asia where it is much used as shade trees for coffee. Compared with *Cassia*, *Albizia* has one disadvantage, it drops its leaves in the middle of the dry season, in spring; but if it is sown very thickly and cut very low it remains always in leaf. It is moreover well liked by cattle and can therefore also be used as forage; its leaves contain 1.19 % of nitrogen and are rich in mineral constituents. As is the case with the "Cassia del Siim", it shoots again rapidly after cutting and grows quickly. Previously the writer had recommended, as a plant for green manure in Mexico, the herbaceous growth of "mezquite" (*Prosopis juliflora*) which is spontaneous in the barren and semi-sterile soils of the "Mesa central".

809 - **Sweet Clover as a Green Manure.** — WHITTING, A. L., and RICHMOND, T. E. in *University of Illinois Agricultural Experiment Station, Bulletin No 233*, pp 255-267. Urbana, May 1921.

Sweet clover (*Melilotus alba*) should prove a promising source for supplying nitrogen to the chief farm crops. Certain characteristics give it a marked superiority over other crops as a green manure. The most important of these are:

Adaptability to a wide range of climatic and soil conditions, if the soil is not acid and inoculation is assured; hardness to cold and drought, resistance to disease and damage from weeds; vigorous growth; rapid decomposition whilst green; deep-rooting habit which renders impervious sub-soils more porous and of higher nutritive value.

(1) See *R. March* 1922, Nos. 236 and 237. (Fd)

A crop that possesses the combined capacity to grow rapidly in early spring and to decompose readily, makes an ideal green manure. Owing to its rapid growth clover conserves large amounts of soluble plant food, utilisable when the soil would otherwise suffer heavy losses. Similar to other legumes, when properly inoculated, the plant can utilise atmospheric nitrogen which it stores in its roots as reserve food material. The leaves are very tender and decay immediately after the crop is turned under green. The roots and stems decay more slowly; thus the different parts represent three sources of nitrogen which furnish three rates of nitrate production.

Hitherto considered as a weed, the sweet clover is now coming to be regarded as the best crop for soil improvement. As it will supply nitrogen at a low cost, it could be employed on a large scale.

The literature concerning sweet clover as a green manure and as a source of nitrogen is very limited. Having been classed for some time as a weed, it has received very little attention by investigators. ORTH in 1890 was the first to test the value of this crop as a green manure and proved its superiority over farmyard manure for the production of potatoes, oats and maize. G. B. HOPKINS recognised the possibilities of this plant as a green manure and in his book on "Soil Fertility and Permanent Agriculture", he states that 6 ½ tons of dry matter furnish as much humus and nitrogen as would be furnished by 25 tons of average farmyard manure. The appreciation of the importance of this crop is evident in that he introduced it into the rotations on several experiment stations and also selected sweet clover as the crop upon which to base his foundation work for restoration of the soils of Greece. In 1917, MAYNARD studied the decomposition for nitrate formation under glass and found it to be very rapid. He mentions that no record has been found of any study of the rate of decay of sweet clover as a green manure.

The work of MERTZ deserves attention, especially designed to compare the value of various green manures, leguminous and non-leguminous, the latter being reinforced with artificial nitrogenous fertilisers. The experiment was conducted in South California. The crops grown for green manures in the winter were followed by maize, potatoes, cabbage, beets, sorghum and Sudan hay, for six successive years. The legumes proved much superior to the non-legumes and amongst the former the bitter clover (*Melilotus indica*) an annual variety of sweet clover was the most promising, both from the standpoint of vigour, of seed supplies and as a green manure. The use of *M. indica* resulted in a gain of nearly 20 bus of shelled maize per acre. This compares favourably with results obtained with an annual application of sodium nitrate giving 1080 lb. per acre of maize and of dried blood giving 1200 lb., taking into account also the cost of these fertilisers.

The advantage of utilising the crop as a manure has been proved by the authors in their experiments made (1918-19) on 5 specially selected fields in northern, central and southern Illinois, in connection with the University Farm, Urbana. A series of plots was arranged as follows:

sweet clover; green manure; control; to the sweet clover and manured plots, rock phosphate or bone meal was added once in four years. On the sweet clover green manure plots, residues were added to compensate for corn stubble. A distinction should be drawn between available and non-available nitrogen as it is most important to keep as much nitrogen as possible in the available form. This is exactly what happens in the case of leguminous crops, which help to contribute large quantities of available nitrogen. The results obtained by the authors indicate that after digging in, the sweet clover tends to increase the proportion of nitrates in the soil, even more than heavy applications of manure. In poor soils the effect is even more marked. The maximum nitrate production was noticed in August which suggests the advisability of ploughing under at an earlier date, and so avoiding any detrimental effect (due to decomposition) on the germinating maize. Another suggestion is the utilisation of the surplus nitrate by sowing a catch crop. When maize is the main crop, the value of the additional nitrate remains although quickly utilised by the crop. Even when manure, lime and phosphate have been used in large quantities (5 times normal application), the yields were not equal to those obtained after sweet clover.

The average for the 2nd year sweet clover crop was 87.6 lb nitrogen per ton of dry matter, the cutting was made before sowing the maize. The subsequent advantage was evident.

These results furnish positive information concerning the value of sweet clover when used as a green manure, for adding to, conserving and making available for crop purposes the nitrogen of the soil. It is well-known that, except for manure, the animal sources of nitrogen (dried blood, tanning residue, guano etc.) are scarce and costly and therefore unsuitable for use on a large scale. This applies also to the use of nitrogenous fertilisers (sodium nitrate, sulphate of ammonia, ammonium phosphate and calcium cyanamide). On the other hand, the leguminous crops offer an exceptional advantage, and sweet clover in particular may in the future occupy a prominent position as a green manure. L. V.

810 - **The Nitrogenous Compounds in Lucerne Hay.** - MILLER, H. C. (Chemical Division of the Oregon Experiment Station), in *The Journal of the American Chemical Society*, Vol. 43, No. 12, pp. 2656-2663. Easton, Pa., December 1921.

The author has succeeded in isolating from lucerne hay certain non-protein nitrogenous compounds containing 40.7% of nitrogen; most of them can be easily extracted with water. Purins make up 3.2% of the total nitrogen. The author has determined the percentages of the different constituents of the protein compounds, and in particular of the amino-acids: arginin, hystidin, lysin, cystin, etc. He finds that they contain 13% of nitrogen, whereas the amount of this substance present in the proteins of lucerne seed is as much as 15.6%, owing to the different percentages of the various constituents, and especially, to the larger quantity of arginin which is very rich in nitrogen. The author describes a new method for the further study of the non-protein substances. This consists

AGRICULTURAL  
BOTANY,  
CHEMISTRY  
AND  
PHYSIOLOGY  
OF PLANTS

in the precipitation of the aqueous solution by chloride of mercury and the subsequent removal of the mercury. L. V.

811 - **The Chemical Composition of Plants as a Basis for the Estimation of their Water Requirements.** - NOYES, H. A. (Mellon Institute of Industrial Research, Pittsburg, Pennsylvania), in *The Journal of Industrial and Engineering Chemistry*, Vol. XV, No. 3, pp. 227-228. Washington, March 1, 1922.

The author refers to the results of field and greenhouse experiments carried out at the Agricultural Station of Purdue, La Fayette U. S., which prove that the direct, or indirect, manuring of the soil causes a decrease in the water requirements of growing plants and also changes their composition. Working the land has the same effect, for the soil is thereby more exposed to the air which increases the bacterial activity and this, in its turn, brings about the greater concentration of the soil solution.

By the application of a suitable fertiliser and the timely working of the land all danger from drought could be greatly reduced in the case of crops growing in the wet zones of the United States, for by these means the plants are enabled to enter upon the dry season with an accumulated store of moisture. The manuring of the soil will therefore have to be studied from another point of view viz., the water requirements of the crop.

The author is of opinion that the old advice given to farmers, "work the soil well so as to retain its moisture and the best crops will be obtained", might be modified as follows: cultivate the land thoroughly so that the soil may be well ventilated, because air increases bacterial activity and enables the plants to obtain a larger amount of nutritive substances and to grow with less moisture.

The following data confirm this statement. In the course of his field and orchard experiments made at the Agricultural Experiment Station of Nebraska, KRISSELBACH obtained the results given in the appended Table.

	Cleaned land cover crops	Land dressed with straw	Land untilled for several years
Increased girth of trees from 1911-1916 in cm.	25.5	25.9	17.1
Nitric nitrogen in the soil during the vegetative season per thousand parts of dry soil	57.5	47.0	14.5
Water at beginning of vegetative season, kg. in 30.5 cm. x 30.5 cm. x 22.9 cm	5.12	5.24	5.37
Water at end of vegetative season <i>idem</i>	3.83	5.10	3.66

Greenhouse experiments on *Capsicum annuum* var. *abbreviatum* and lettuce have shown that by the application of dung and of a complete chemical fertiliser the water units required to produce one unit of green

substance are reduced by more than a half, while the plants themselves are 4 times as heavy as the controls. Further, the water requirements estimated by the water content of plants treated in different ways (controls, limed, manured with phosphatic, and nitrogenous fertilisers dung, or complete fertiliser), as well as their nitrogen content (green portions and roots), and the amount of phosphorus and calcium present in their ash all show the existence of a correlation between the composition of plants and their need of water

**812 - Influence of Conditions of Humidity on the Growth of Sainfoin Seeds respectively Unhusked and Husked.** RIVIERA, V. (R. Stazione di Patologia vegetale Rom 1)

in *Rivista di Biologia* Vol 1 No 1 pp 11 Rome 1922

In the working of meadows of sainfoin (*Onobrychis sativa* All.) the results obtained are very variable, which has led the writer to study closely the growth of the seed of this leguminous plant under the experimental conditions of the laboratory.

For each experiment a portion of the seeds were husked and the others left in their pods. In a first series the seeds were placed in various conditions of humidity by forming 4 groups in Petri capsules: (1) capsules containing water in which the seeds were kept immersed by means of a glass; (2) capsules containing blotting paper abundantly soaked in water; (3) capsules containing blotting paper soaked to a limited extent; (4) capsules in which a humid atmosphere was produced by moistened blotting paper placed inside the cover. The first two groups of seeds behaved in an identical manner: they are therefore considered together, in them the absorption of moisture was very rapid: after 42 hours the maximum was reached and then weight was almost doubled; on the other hand it required 90 hours for the seeds placed on the paper slightly moistened to absorb about half their weight of water and those placed in a humid atmosphere absorbed about one third.

It is interesting to note that the seeds on slightly moistened blotting paper germinated first: it is clear that in the other cases the seeds found themselves in conditions less suitable for their growth owing to excess or deficiency of moisture: the delay has a distinct biological significance but it is evident that excessive conditions of moisture cannot be prolonged beyond a certain limit.

Regarding the different behaviour of unhusked and husked seeds, one of the effects of the presence of the pod is a delay of a few days in the beginning of germination; this delay may be caused by the fact that the soaking of the seed is retarded since the pod first imbibes the water and the seed afterwards; it may also be attributed to the pressure which the pod exerts on the swollen seed.

The amount of water absorbed by the pod is maintained in the same proportion as that absorbed by the seed: in fact the difference between the percentages of water absorbed by the unhusked and husked seeds are negligible, especially after 90 hours. The pod therefore stores much moisture and can restore it later, by its structure, which makes it like a

sponge, it creates an ideal humid chamber for the seeds which it contains. The power of disposal of moisture is therefore, superior in the unhusked seeds than in the naked seeds.

If the seeds are next placed in a dry medium, those which are unhusked lose less moisture than the naked seeds. The writer assured himself of this in a second series of experiments in which he exposed seeds swollen with moisture, to a drying action, obtained by means of chloride of lime. For example, in one of his experiments, after two days drying the unhusked seeds still contained 0.32 gm. of moisture and the naked seeds only 0.19 gm. If the environment becomes suddenly dry, the pod protects the seed from excessive siccation.

When the radicle has developed, it suffers less from dryness in unhusked seeds than in the husked seeds : thus in two lots of 27 seeds each, 10 and 21 radicles respectively were injured. With a return of humidity, even seeds which had their radicles destroyed could protect themselves by sending out fresh lateral roots.

From the above it follows that the pod performs complex functions : it not only favours a wide distribution of the seeds owing to its conformation (wings, prickles, hairs, etc., which, however, vary much in different species of *Onobrychis* and also in varieties), but also forms a mechanical protection to the seed which it covers, and stores moisture which helps the growth of the seed ; the seed enveloped in its pod absorbs moisture and swells more slowly, but more surely.

The pod equalises the variations of humidity in the environment ; sudden differences are borne by the pod, while the seed only feels their mitigated effect. The moisture which is collected through the pod and passes into the seed, serves the latter specially when it grows under dry conditions in the soil.

This behaviour throws light on some vicissitudes in the growth of peas, especially in southern, dry regions, where, it often happens that the seedling, especially if sown in spring and in ground which dries up easily, can only benefit by a single fall of rain, some times even a very slight fall, and that followed by a prolonged drought. The difficult period for plants of this kind is almost always the beginning of the development of the seed, because when in full growth the plant no longer suffers from the dryness of the soil. Now it is precisely at the critical period of need of moisture, however slight, that the function of the pod is useful, for it stores up a greater amount of moisture than the husked grain could absorb and gives it up to the seed later. Furthermore it prevents, in the period which precedes germination and at the beginning of the period which follows it, a sudden and rapid loss of moisture by the seed, when the conditions of environment become suddenly and markedly dry ; lastly it is sometimes useful in retarding germination until the conditions of humidity improve, while the husked seeds which have already germinated perish.

Such are the reasons why, while meadows sown with husked seeds do not succeed, especially if the dry season hinders the first development of the seed, the chance of the meadows is more certain when the seed has

not been husked : this the writer has been able to prove in a series of experiments in the open field, and therefore concludes that it is not advisable to husk the seed.

L. V.

813 - **Absorption of Ions of Aluminium through the Root System of Plants.** — STOKLASA, J. in collaboration with SEBOR, J., TYMICH, P. and GWACHA, F. (Biochemische Abteilung der Staatl. Versuchstation an der böhmischen technischen Hochschule, Prag) in *Biochemische Zeitschrift*, Vol. 128, Nos. 1-3, pp. 35-47. Berlin, March 7, 1922.

The absorption of aluminium was studied for the first time by the Russian physiologist W. ROTHERT, in collaboration with BOROWIKOW and SCHIMKINE: all the plants tested absorbed the element, which was furnished in the form of soluble compounds and even certain insoluble compounds. These researches were followed by those of the writer, of BERTRAND, AGULHON and SZÜCZ.

At present the author has undertaken the analytical study of the problem, using aqueous solutions: he employed a mineral solution of definite composition in which he plunged the roots of young robust plants after careful washing. The aluminium was added in the form of sulphate and control cultures were not neglected. The writer has experimented with two hygrophytes, two mesophytes and two xerophytes.

In a preliminary experiment the sulphate of aluminium was used at a strength of 0.001 gm-atom of aluminium per litre of solution. The xerophytes and several of the mesophytes developed badly. For the analyses, made after 26 days, the writer chose the most healthy samples. All the plants absorbed much aluminium, especially the hygrophytes; the mesophytes absorbed less and the xerophytes still less. The greatest amount of aluminium was found in the roots.

By increasing the concentration of sulphate of aluminium 15 times (0.015 of the atomic weight of aluminium expressed in grammes, per litre of solution), all the plants died: first of all the xerophytes in 7-11 days; then the mesophytes beginning from the 17th day; lastly the hygrophytes as from the 23rd day. The proportion of aluminium absorbed was much less in this than in the previous experiment: aluminium is absorbed to the greatest extent when the solutions are weaker: it is therefore clear that it is not a simple diffusion which takes place, but that a *specific* permeability of the rhizicome is produced, associated with phenomena of absorption and reactions which develop in the intracellular colloids. The aluminium which has penetrated into the cells causes contraction of the protoplast; then, if in strong concentration, it softens and dissolves it (STOKLASA, BERTRAND, AGULHON, SZÜCZ). In the xerophytes, this plasmolysis is more rapidly accomplished; more slowly in the mesophytes and only with strong concentrations in the hygrophytes. The degree of reversibility of the process is conditional on the concentration of the ions of aluminium and on the duration of their action.

Hydrolysable compounds of iron, manganese, copper etc., show themselves still more toxic than those of aluminium; compounds of aluminium can even reduce their poisonous effect, because they take the place

of others in the cells, which causes an exchange and a new balance of cations.

The writer had previously noted this protective action of aluminium but he has now made a more complete study. He selected, with this object, the three species of plants, which in his previous experiments had absorbed the largest amounts of aluminium and he put them to grow in four mineral liquids of identical composition, but one of which being without aluminium or iron, served as control; another contained aluminium; a third contained iron; a fourth both these elements. In the second and third of these nutrient liquids, the absorption of aluminium and of iron were accompanied by an abundant elimination of magnesium, calcium and sodium; that elimination was however, much more marked in the liquid containing iron, evidently because iron exercises a more intense toxic action than aluminium and consequently kills and dissolves the protoplasts, setting free almost all the salts. In the liquid which contained iron and aluminium, the latter diminished the penetration of the iron and, consequently reduced the harmful action; it prevented plasmolysis and limited the loss of mineral principles. The analysis of the plants grown in the four liquids showed that the addition of iron alone sensibly reduced the total ash content while the addition of aluminium and of aluminium and iron increased it, while reducing the content of potassium, sodium and phosphorus.

The three plants studied are plants of peat bogs: they therefore grow well in relatively acid media and are not tolerant of bases. The author has remarked that very many cryptogams behave similarly. He gives the analyses of some of these plants: — ferns, lycopods, horsetails, etc.; their ash is rich in silica, aluminium, iron and sometimes in lime; it is probable that they have adapted themselves to this kind of mineral exchange from the remotest time; it suffices to consider that most coals were formed by these hygrophytes, which utilise the most common mineral elements in the soil:— silica, iron and also sulphur (ferrous and ferric sulphates); it is probable that aluminium had already the power to neutralise the injurious action of iron present in the ground in the form of oxides and hydrates and especially of ferrous and ferric sulphates: it thus limited the absorption of potassium and phosphorus in which, as a matter of fact, coals are poor.

814 - **Experiments on the Use of Artificial Light in the Growth of Plants, in Germany.** — HÖSTERMANN, in *Verein Deutscher Ingenieure*, Vol. XVI, No. 21, pp. 523. Berlin, May 27, 1922.

The first experiments on the use of electric light for inducing the growth of plants were made in 1880 by Wilhelm SIEMENS, with a 1600 candle-power arc lamp; these experiments were next reproduced at Bromberg by means of arc lamps and mercury lamps with unsatisfactory results; on the other hand experiments made in England and Ireland in 1919 by TJEHRES and UTHOFF induced an increased yield up to 50 %. In the buildings of the Experimental Station of plant physiology at Dahlem (Germany),

experiments were made during the winter of 1921-22, to ascertain the influence of artificial light on the growth of plants in glass frames ; in winter, in a heated place, the difference of growth of plants, compared with the summer, is determined not only by the temperature and by the manuring which may be the same at both seasons, but also by the duration of day light ; in fact, it is the light absorbed by the chlorophyll which furnishes the energy required for the reduction of carbonic acid into carbon, from which carbohydrates are produced through assimilation. But it is not only daylight which exercises a beneficial action on the process of assimilation ; this action can also be exercised by light coming from another source, provided that it is comprised in the category of wave lengths in the compass of which the colouring matters of the leaves have a power of absorption. The question is to select the light which will give the best return.

According to what can be deduced from researches on the physiology of plants, with a luminous intensity of about 1000 Lux, the assimilation may be considered as proportional to the illumination, while with a more intense light, assimilation is less and less accelerated and thus is why artificial light was not used simultaneously with the winter light, but the day's light was prolonged from dusk by means of an electric current

Over a plot 5 m long by 1.50 m broad were arranged 5 "Nitra" lamps of 200 watts, in such a way that the light could be diffused as uniformly as possible ; the lamps were placed 0.70 m from the edge of the plot, at a distance of 1.20 m from each other at a height of 0.60 m above the plot, and were furnished with WISKOTT reflectors. The intensity of the illumination of the plants varied over different points of the surface of the plot from 300 to 900 Lux, and was exactly 900 Lux under the lamp and 300 at the edge of the plot. The daily consumption of electric power by the lamps, lighted for about 6 hours every day commencing at dusk, amounted to 4.8 kilowatt-hours for lighting a surface of 7 sq. m. Forced cultures were made on that surface, the preceding period of vegetation of some of them had already made it possible to have an idea of the principles assimilated ; others, having just germinated had still to construct their vital elements. Close to the plot of illuminated plants was the control plot, with the same plants and separated from the former by a partition of white wood ; this plot, except for light, received the same care as that of the illuminated plants.

Cabbage-lettuces, illuminated from mid-November, had after 12 days on an average about two and a half times as many fresh leaves as those not illuminated ; moreover, the leaves of the former were larger and firmer, so that after 18 days the plants had developed like lettuces sold at 2 marks each. Plants exposed only to daylight required from 4 to 5 weeks, or double the time to attain this degree of development ; it would therefore be possible, in practice, to obtain in the same period of time two crops of lettuce instead of one. In 18 days the consumption per lamp was 21.6 kilowatt-hours ; the price at the time of the experiment being 1.20 mark per kilowatt-hour, it cost 26 marks for illuminating a surface of 1.2 sq. m. But as (with a doubled crop) 480 marks instead of 240 is drawn from a

surface of 1.2 sq. m., there remains, at this price of electric current, a surplus gain of 214 marks per 1.2 sq. m.

To examine its subsequent growth, the lettuce was left in its place, since it did not flower but continued only to grow. However this very probably, should not be attributed to lack of power of the electric light relatively to solar light, but more especially to the richness of the artificial light in red rays, compared with daylight. The crop was gathered after 7 weeks of prolonged illumination; a comparison was then made between the plants of the illuminated plot and those of the plot not illuminated: a superiority of weight of the former over the latter of 50 % in the green state and 68 % in the dried was found.

The effect was equally good on beans and vetches. *Lathyrus odoratus* grew much more vigorously under the influence of the illumination, and it flowered earlier and more abundantly. Strawberry plants illuminated yielded, as early as the middle of March, very sweet and scented fruit, while those not illuminated were 4 weeks later. The favourable effect of electric light in the prolongation of the short daylight from November to May, was very clearly shown on all greenhouse crops and especially on lilac which gave very fine inflorescences under this treatment, with more intense perfume and brighter colour. But certain data are lacking regarding — 1) the most correct and suitable illumination for certain species of plants, 2) the duration of illumination, 3) the most favourable colours of the light, hence without exact knowledge of the sources of light and of the physiological effects of the light, it is not yet possible to form a correct judgement. P.

815 - Influence of X-rays on dry Seeds and germinating Seeds. - PI TRY, I (Zentral-Institut des Landeskrankenhauses Graz) in *Biochemische Zeitschrift*, Vol 128, Nos. 1-6, pp 326-353. Berlin March 25, 1922.

G. SCHWARTZ has already stated that dry seeds stand, without damage, an intense application of X rays up to 40 times as strong as those to which germinating seeds show themselves sensible. The writer has noted also that, even when respiration is lessened, for example by means of cyanic compounds, sensibility to X rays continues. He has now observed that a rapid hydration of dry seeds or of dried germinating seeds was sufficient to stop or renew this sensibility, which is therefore due to the water and, in this respect, may be compared with the sensibility to heat ferments and proteins. But the water acts not only as such; it causes also the chemical changes inherent to germination. In fact, if the supply of oxygen is suppressed, and germination is thus hindered, sensibility to X rays decreases; on the other hand, germinating seeds which have been dried are always much more sensitive to X rays than dry seeds. Chemical changes therefore intervene which modify the environment; they may consist in the stimulation of the proferments, in hydrolytic splitting up of reserve materials, in oxidising processes, in processes of assimilation and breaking-down. Notable differences are remarked with different seeds; for example, seeds of leguminous plants are much more sensitive to X rays than the seeds of cereals. L. V.

816 - **The Applicability to the Problems of Plant Genetics of Morgan's Theory of the Mechanism of the Chromosomes.** — JONES, D. F., in *The American Naturalist*, Vol. LVI, No. 645, pp. 166-173. Lancaster, P. A., April 1922.

The data so far collected are sufficient to justify the supposition that the chromosome theory postulated in the case of *Drosophila* is equally applicable to plants. The pea, primrose and maize have all furnished excellent material for studying the linkage of genetic factors in the plant world. Owing to the ease with which maize can be cultivated the large number of grains it produces, and its great variability from the genetic standpoint, this plant has been the special object of investigation.

Owing chiefly to the work of EMERSON and his school it has been possible to distinguish in maize 6 groups of linked factors, and in the case of most of these factors their relative position in the chromosome has been determined. Therefore from the study of the genetic phenomena in this plant an indirect proof of the mechanism of the chromosomes has been obtained.

If two families are taken that have been long enough self-fertilised to have become almost, if not quite, homozygous, on crossing an absolutely uniform  $F_1$  is obtained. This is then repeated with two further families and another  $F_1$  is produced. When this point has been reached, the work is carried on in two directions: 1) the two  $F_1$  generations are crossed together and produce  $F_1 \times F_1$ , a double hybrid of the 2nd generation; 2) an  $F_2$  is obtained by the self-fertilisation of the  $F_1$ . Each line of maize so far produced by self-fertilisation has hitherto always been found to differ in many of its characters from any other line no matter whether it is descended from the same variety or from a different original variety. The self-fertilised lines when crossed show a remarkable increase in growth and, if again selfed, a rapid decrease in vigour, together with greatly increased variability in the following generations.

It may therefore be assumed that the greater number of self-fertilised lines differ from one another as regards many of the genes in each chromosome. If this be the case, the double combination  $F_1 \times F_1$  should have a much more complex structure than the  $F_2$ , and a critical comparison of these double hybrids with the hybrid parents of the first generation and with their  $F_2$  by self-fertilisation, if based on the variability of their different characters, ought to afford some indication of the distribution within the chromosome of the genetic factors influencing growth. As regards the other factors, the variability of the double hybrid should be almost the same as that of the 2nd generation obtained by self-fertilisation, though in the characters which are in direct connection with the vigour of the plant, the double hybrid ought to resemble the  $F_1$ , which has lower variability coefficients. To decide these questions, the following characters were investigated: number of rows of grain per cob; the nodes of the plant; the height of the plant; length of the cob; grain production, the weight of the whole female fructification with its ripe grains.

The preliminary study of the 1st generation resulting from the cross of two self-fertilised lines of maize showed that the number of rows of

grain in the hybrid was 5.29 % larger than in either of the parents. As regards the other characters, the percentage increase observed was as follows :

Number of nodes per plant	6 43
Height of plant . .	27.44
Length of cob . .	28 57
Total grain yield . .	180 00

The vigour of the plant therefore has much less effect upon the number of rows and of nodes than upon other characters, especially grain production. Assuming the vigour of the hybrids to be due to the complementary action of the dominant factors, the combination  $F_1 \times F_1$  (the double hybrid), if the factors essential to growth are numerous and distributed uniformly through the chromosomes, ought to be *less variable* than the  $F_2$  obtained by self-fertilisation. On the other hand, characters that are entirely or almost independent of growth vigour (number of rows of grain and number of nodes), should present almost the same variability as the  $F_1$ .

The data given in the annexed Table confirm this hypothesis. The variability of the families  $F_1 \times F_1$  as regards the number of rows and nodes is almost identical with that found for the  $F_2$  families. On the other hand, in all that concerns the characters in correlation with the vigour of the plant, the families of the  $F_1 \times F_1$  show a decreased variability. Further, the fact that all the plants are uniformly vigorous and that their high averages are not to be attributed to the presence of some individuals of exceptional development, proves indirectly that the hereditary factors which control the growth of the plants are very numerous and distributed widely through all the chromosomes, or at least a large number of them.

From the point of view of improving maize, it certainly would be most desirable that all the factors which control the superiority of a hybrid over its parents should be present in a homozygous condition in a single individual. The latter would be in a more stable condition than an individual possessing heterozygous combinations of the factors in question, given that the factors determining growth vigour rarely attain to complete dominance. The recombination of the linked factors is a problem deserving the most careful attention of those interested in genetics. In any case, linked factors are not two paired factors present in the same chromosome but two factors situated in the same chromosome at a distance from one another of less than 50 units. When the distance between the two *loci* is 50 length units (1) or more, factors situated in the same chromosome at a greater distance apart are as independent of one another from the point of view of transmission, as if they were in different chromosomes. The number and arrangement of the genes themselves therefore appear to be of

(1 By 1 2 3 etc., units of length is understood 1-2 3 etc. % of the crossing over. Thus, in the case of two linked characters with a crossing over percentage of 24, it would be said that their genes are situated in two *loci* of the chromosome 24 length units apart (Ed.)

greater importance than the number and arrangement of the chromosomes. When each gene is independent of all the others situated at a distance exceeding 50 units and therefore behaves according to Mendel's law, the author proposes the term of *mendel* for a chromosome segment of a length equivalent to 50 % of the crossing-over.

*Comparative data showing the variability of the 1st generation, of the double 1st generation and of the hybrids of the 2nd generation.*

(CV = Variability coefficient; PE = probable error).

817 - Genetic Selection of the Wheats "Bianchetta" and "Gentil rosso", at Andria in Apulia (Italy). - VIVARELLI L., in *La Prova andia 1 raccolto*, 2nd Series, year XIV No 1, pp 115, No. 2, pp 27-31, 2 figs Bari, Jan 1922

Genealogical selection of the wheats "Bianchetta di Puglia" and "Gentil rosso" begun in 1916.

The work was done in three stages. —

1st year: Selection of ears as founders and starting of pure strains.

2nd year: Comparative test of the descendants of these ears.

3rd and following years: Multiplication and propagation of the selected plants.

In the course of these experiments the following characters were specially considered; number of stems; number and length of internodes; average quotient; length of ears; large or small number of leaves, intensity of colour; time of ripening; resistance to lodging and rust, etc.

Among the numerous families thus isolated, the following 4 deserve special attention: — 1) "Bianchetta" fam. A; 2) "Gentil rosso" fam. A.; 3) "Gentil rosso" fam. B.; 4) "Gentil rosso" fam. C. To give an idea of the effect of selection on the morphological and physiological characters the following comparative data relating to unselected "Bianchetta" and "Bianchetta" of the fam. A, are given.

In the average proportion or biometric value of the grain  $\frac{L}{D}$ ,  $L$  represents the length and  $D$  the maximum diameter of the grain, placed groove downward. This proportion indicates that the grain of the selected variety tends sensibly to elongate.

	« Bianchetta » common	« Bianchetta » fam. A
Average height of the plants, in cm. . . .	92	120
Average length of the ears, in cm. . . .	8.5	14.5
Average number of grains per ear . . . .	23	40
Weight of grains of 100 ears, in gm. . . .	101	246
Average proportion, in gm. . . . .	1.90	2.00
Average quotient, in gm. . . . .	0.32	0.20
Aborted spikelets at the base of the rachis.	4	2
Stalks and ears per plant . . . . .	2-3	6-8

In the average quotient or biometric value of the stalk  $\frac{S}{R}$ ,  $S$  represents the thickness of the wall of the stalk in the middle part of the mean internodes and  $R$  the radius of the cavity.

This proportion indicates that the stalk varies in length but that the thickness varies little; there is therefore no reason to fear that the feeding qualities of the straw might decrease by selection, nor that it might become weak and liable to lodge.

The difference in favour of the selected families (see Table below) shows clearly and it has been maintained throughout the three years of the experiment, in spite of great variations in meteorological conditions during the same period.

*Production of grain and straw during the triennial period 1919-1921  
(in quintals per hectare).*

818 - **Natural Hybrids of Wheat Rye at Saratov (Russia).** - MEISTER, G. K., in *The Journal of Heredity*, Vol. XII, No. 10, pp. 467-470. Washington, December 1921

In 1918, a well authenticated and unusual occurrence was seen at the Agricultural Experiment Station of Saratov (Russia) viz., the existence of a large number of natural hybrids (in the  $F_1$ ) between wheat and rye.

These hybrids made their appearance in some plots sown with winter wheat: *Triticum vulgare* v. *erythrospermum*, v. *Hortianum* and v. *pyro-*

*thrax*. The number varied in the different plots; sometimes they were entirely absent, or very rare; in other plots, they occurred in considerable quantities; plot No. 828 sown with var. *erythrospermum* contained 20 % of the hybrids, while their total number reached several thousand.

The plots containing the largest number of these hybrids were characterised by their early ripening, so that the flowering phase coincided with, or at least overlapped, the flowering phase of the rye. The glumes of these varieties of wheat are very widely open and far apart at the flowering season which facilitates cross-pollination. Owing to the continental, dry climate of Saratov and its low rainfall (about 380 mm.), crosses between different varieties of wheat are of practically habitual occurrence.

In 1917, the year preceding the appearance *en masse* of the wheat  $\times$  rye hybrids, the season had been drier than usual.

The hybrids in question belong to the  $F_1$ , and occupy an intermediate position between *Secale* and *Triticum* with a slight predominance of the characters of *Triticum*. In general habit, the plant is more like wheat than rye, in most of the culms however the upper part of the rachis near the base of the ear is hairy, as is the case in rye.

The seed of the first year ( $F_1$ ) produced 209 plants and these may be divided into 4 groups:

I) Two individuals of the *Secale* type with a tendency to self-pollination

II) 87 individuals of the *Triticum* type. In these, frequent morphological traces of *Secale* were noticeable. buds coloured by anthocyanin — elongated glumes — keel-shaped glumes, etc.

III) 12 plants of entirely new type with long ears and glumes, and a large number of spikelets. In these forms, the rye characters were predominant although the grains were typical wheat grains.

IV) 102 plants of intermediate character.

As regards fertility 29 of the plants were completely sterile, 42 % had only one grain each, 11 % were normally fertile 18 % occupied an intermediate position.

Among the hybrids, new characters, quite different from the characters of either parent, made their appearance as for instance narrow pointed leaves resembling the leaves of certain wild *Gramineae* thick leaves; very brittle rachis; very rough awns culms, with thick walls. In the 3rd and 4th generation, there are typical wheat and typical rye individuals with very few intermediate forms.

When this point was reached it was useless to continue the analysis.

The chief fact to be learnt from the examination of the data collected is that the characters of the hybrids of the first generation, whether the latter are of the typical wheat, or rye, type (or even intermediate), remain fixed in the succeeding generations.

The following question may now be asked. since in the segregation processes there is a clear distinction between the two fundamental forms *Triticum* and *Secale*, what are the characters regulating their resistance to low temperatures? If it be conceded that opposite morphological

characters exist, surely the presence of similarly opposite physiological characters cannot be denied.

As regards the resistance to *Fusarium nivale* evinced by wheat × rye hybrids, distinct segregation has been observed resulting in their division into very resistant and highly susceptible families respectively. This indicates the possibility of obtaining resistant types by means of crossing and selection.

The low temperature resistance of some families of the rye type was found to have diminished, as if they had been forfeited as a result of taking on certain wheat characters.

On the other hand, many of the hybrids of the *Triticum* type showed increased resistance to cold. G. A.

819 — A Study of the Hybrids, Red Rustproof (*Avena sterilis*) × Black Tartarian (*Avena Orientalis*), in the United States. — WAKABAYASHI, S., in *Journal of the American Society of Agronomy*, Vol. 13, Nos. 6-7, pp. 259-266. Washington, October 1921.

This paper gives the results of experiments on the inheritance of resistance to smut (*Ustilago leavis Avenae*), sterility, panicle shape, colour of glume, and correlations among these characters in the  $F_2$  and  $F_3$  of Red Rustproof (*Avena sterilis*) × Black Tartarian (*Avena orientalis*).

TABLE I. — Comparison between the chief characters of the two Parents.

Characters	Red Rust proof	Black Tartarian
Average height, inches . . . . .	32	2.3
Average number of culms per plant . . .	83	2.3
Average number of kernels per panicle . .	45	169
Susceptibility to smut . . . . .	Immune	Susceptible (av. 34%)
Percentage of sterile flowers . . . . .	25	14
Shape of panicle . . . . .	Pyramidal	One-sided
Average length of panicle (in ches) . . .	5	11

The most important results obtained may be summarised as follows :

I. — SMUT RESISTANCE. — Red Rustproof has never shown a single indication of smutting, whereas the percentage of rust infected Black Tartarian plants ranged from 25 to 40. The  $F_1$  and  $F_2$  have never shown a trace of smut. In the  $F_3$ , there were 12 infected lines, while 95 remained immune. In the 12 infected lines, the percentage of diseased plants was 15 — 12 — 9 — 8 — 4 — 4 — 4 — 3 — 3 — 2 — 2 — and 0.1 respectively, thus the most susceptible row produced less than half as much smut as the susceptible parent.

The cause of immunity up to the  $F_2$  and the pronounced resistance in the  $F_3$  indicate the existence of multiple factors. Since the susceptible parent showed smut on less than half the plants, the behaviour of the  $F_3$  is nearly what is to be expected if the immunity of Red Rustproof

is caused by 3 independent dominant factors any one of which would prevent the appearance of *Ustilago*.

The fact that resistance is dominant is unusual, inasmuch as it has been reported recessive in wheat yellow rust (BIRKEN and NILSSON-EHLE) and in stinking smut of wheat (GAINES)

II — STERILITY — The record shows Red Rustproof to be higher in sterility than Black Tartarian. Their crosses are comparatively high in sterility, although this sterility decreases in successive generations because the sterile strains eliminate themselves. Great differences were observed between one panicle and another, some being 100 % sterile, while a few were less than 5 % sterile.

Table II shows the sterility in the parents and the  $F_1$ ,  $F_2$  and  $F_3$ . It proves the progressive decrease of sterility in the successive generations when averaged, but the increased fertility of some of the  $F_3$  rows suggests multiple factors and is of economic importance.

TABLE II — *Comparative Sterility of Red Rustproof and Black Tartarian oats and their Hybrids of the First Three Generations*

Variety		Number of fertile flowers	Number of sterile flowers	Sterility percentage
Red Rustproof		454	112	25
Black Tartarian		1 452	246	14
Red Rustproof	Black Tartarian $F_1$	122	197	62
"	" $F_2$	2 802	3 663	57
"	" $F_3$	39 721	23 935	38
Black Tartarian	$\times$ Red Rustproof $F_1$	68	167	71
"	" $F_2$	1 158	620	35

III — COLOUR OF THE GLUMES — Red Rustproof has white glumes slightly tinted with red (**bb**); Black Tartarian has dark brownish or black glumes (**BB**). It is difficult to distinguish **Bb** from **BB**. If, however, the two classes are combined, the proportion is 72 % of plants with coloured glumes and 28 % with white, which approaches the monohybrid ratio 3 : 1.

IV — SHAPE OF THE PANICLE — The author spent much time in trying to classify the  $F_3$  and  $F_2$  panicle types segregating in 1919, but owing to the rapidity with which the material ripened and the changes produced by different stages of maturity the classification was unsatisfactory. It was, however, sufficiently accurate to show that the inheritance of the asymmetrical or horsenane type of panicle is recessive, but produced by multiple factors.

V. — DWARFNESS. — In most cases, plants which were below 24 inches in height were counted as dwarf. The production of dwarf plants was interfered with by sterility, and it is therefore difficult to state whether it is a simple Mendelian character.

TABLE III. — *Correlation between Colour of Glumes, Shape of Panicle and Height of Plant.*

Black asymmetrical panicle		Black pyramidal panicle		White asymmetrical panicle		White intermediate panicle		White pyramidal panicle	
No of plants	Height in inches	No of plants	Height in inches	No. of plants	Height in inches	No of plants	Height in inches	No of plants	Height in inches
I	15	I	70	I	45	3	50	I	45
I	40	—	—	2	50	—	—	I	67
I	45	—	—	2	55	—	—	—	—
I	60	—	—	I	65	—	—	—	—
I	67	—	—	I	67	—	—	—	—

VI — CORRELATION — Table III classifies the smutted oat plants according to colour of glumes, shape of panicles and height

There seems to be some correlation between dwarfness and sterility, and between smut susceptibility and dwarfness. There may also be a correlation between smut susceptibility and the white colour of the glume, and between susceptibility and asymmetrical panicle.

Sterility is not correlated with the colour of the glume or the shape of the panicle.

820 — **The Improvement of Sorghum by Crossing and Selection in the United States.** — VINHALL, N N, and CRON, A B, in *The Journal of Heredity*, Vol XII, No 10, pp. 435 443 + figs 6 Washington, December 1921

Until recently, all the studies on the hybridisation of sorghum in the United States have been confined to the subject of natural hybrids. Now, however, that the separation and isolation required to obtain pure lines is finished and the pure lines have not proved as satisfactory as was expected, the investigators are persuaded of the necessity of having recourse to crossing, if any further improvements are to be attained.

In the hybridisation experiments carried out by the Office of Forage Crop Investigations in greenhouses in Washington, and in experiment fields at Amarillo (Texas), the following system is adopted.

1st Generation. — The grain obtained by cross fertilisation is sown in rows and the  $F_1$  plants bagged to prevent the access of foreign pollen.

2nd Generation. — The grain produced by the  $F_1$  plants is sown in rows. The best plants of the  $F_2$  are chosen when they are well developed and their inflorescences are isolated in order to carry out comparative tests with their parents and other commercial varieties.

3rd Generation — The grain of chosen individuals from the  $F_2$  is sown in rows, one row being reserved for each plant (Head to row). The best individuals of the  $F_3$  are chosen out and isolated, enough seed being taken if possible to sow a whole experiment plot next year. When the rows are very uniform they are regarded as units.

**4th Generation.** — The best lines of the  $F_3$  are sown in duplicate plots protected from cross-pollination by high rows of maize.

The forage and grain yields are taken as a basis for estimating the quality.

**5th Generation.** — The best rows of the 4th generation are propagated more extensively in order to obtain a supply of seed for comparative experiments on a large scale.

**FETERITA × KAFFIR.** — Contrary to all expectation the plants of the  $F_1$  had panicles with brown seeds whereas the seeds of Kaffir are white slightly spotted with brown, and those of Feterita are bluish white with a slight brown tinge on the glume.

In general appearance the hybrid chiefly resembles the Kaffir parent.

In the  $F_2$ , the segregation phenomena are very complicated owing to the appearance of extreme types ranging from a dwarf form, 60-70 cm. in height, to a tall form over 2 m. high. The plants vary also in the development of the leaves, the shape and density of the panicle, the size and colour of the grain, the succulence and sweetness of the stem and in many other characters.

The types chosen for the subsequent experiments are intermediate between their two parents in most of their characters and resemble in many ways "Dwarf hegari".

Many types selected according to the system described above remained fixed from the third generation.

The following Table gives the comparative data for the type F. C. I. 8921, the parents and two other hybrids: 9917 and 8929.

*Forage and Grain Yield of the varieties Feterita and Kaffir as compared with the Yield of the Three Hybrids Feterita × Kaffir.*

No. of series	Varieties	Forage quintals per hectare		Grain quintals per hectare		Relative forage yield Kaffir = 100	Relative grain yield Kaffir = 100
		1920	1921	1920	1921		
811	Feterita	50.1	29.1	19.7	13.2	97	104
8917	Feterita × Kaffir	26.4	20.1	21.6	18.3	57	127
8921	" "	56.4	30.0	21.3	19.9	105	128
8929	" "	—	34.2	—	18.7	—	—
24983	Kaffir (Dwarf)	52.6	29.7	18.9	12.5	100	100

These figures show the superiority of the hybrid 8921 over its parents, both as regards grain yield and forage production. The object of this work was not only to increase grain crop, but included more strictly genetic aims such as the study of the heredity of grain colour, of the colour and shape of the glumes and of awn development.

**COLOUR OF THE GRAIN.** — *Feterita × Red Amber.* The kernels of Feterita are bluish white with narrow brown zones; in the Red Amber kernels, brownish-red predominates. In the  $F_1$ , the brown-red colour

appears while the segregation phenomena in the  $F_2$  show that there are 2 genetic factors coming into play, R (red) B (brown). Feterita should have the formula  $rr\ bb$ . Red Amber  $RR\ BB$  and the hybrid of the first generation  $Rr\ Bb$ .

*Feterita*  $\times$  *Kaffir* and *Kaffir*  $\times$  *Feterita*; here again there appear to be 2 factors, but they are not the same as those in the preceding case.

*Blackhull Kaffir* seems to have the factor B for brown, while in *Feterita*, a factor S breaks up the uniform brown of *Kaffir* into dots and patches. The formulae thus are as follows: *Feterita*  $SS\ bb$  and *Kaffir*  $ss\ BB$ .

COLOUR OF THE PALAE. — *Red Amber*  $\times$  *Feterita*:  $F_1$  is uniformly red like Red Amber. The brownish-red of Red Amber is dominant as regards the black of *Feterita*. In the  $F_2$ , red and black appear in the ratio 759:241.

AWN DEVELOPMENT. — *Dwarf Milo*  $\times$  *Feterita*. — Milo is awned, *Feterita* is awnless. The 1st generation is awnless; in the 2nd generation there were 183 awnless and 68 awned plants.

Thus the awned character is recessive

SHAPE OF GLUMES. — *Dwarf Milo*  $\times$  *Feterita* — Milo has large, truncated glumes, while the glumes of *Feterita* are slender and pointed. The Milo shape is dominant in fact, in the  $F_1$ , there were 187 plants with blunt glumes and 64 with pointed glumes.

G. A

821 - Correlation between the Colour of the Spermoderm in Peas and the Shape of the Seeds. — PAERLES, J. J. TJBELLS, K., UPHOFER, J. C., in *Genet.*, Vol. IV, part 1, p. 23-31. The Hague, Jan. 1922.

Results of some crosses between Dutch and American varieties of peas.

"Blauwpeul" has large seeds of a brown-yellow colour, flat in shape. The pigment is situated in the spermoderm, it lacks the genetic factor which determines the concentration of the pigment into spots. "Krombeck" is a variety with crooked pods, yellow cotyledons and unpigmented spermoderm; but it has the factor which determines mottling.

By crossing "Blauwpeul" with "Krombeck", hybrids with the spermoderm mottled or spotted with brown were obtained in  $F_1$  "Kroonerwt", a green pea with large round seed also possesses the factor which induces the concentration of the pigment into spots.

From "Blauwpeul"  $\times$  "Kroonerwt", hybrids were obtained in  $F_1$  with flat seed with brown-yellow spermoderm spotted dark violet. "American Wonder", has large, green wrinkled seeds; it lacks the factor for spottedness and, crossing it with "Blauwpeul" plants with flat seeds of plain yellow-brown colour were obtained.

These experiments show the correlation which exists between the presence of pigment and the shape of the seeds; coloured seeds are always flat and wrinkled and round seeds always have a spermoderm lacking in pigment.

G. A.

822 - **Self-Pollination and Cross-Pollination in the Coconut Palm.** — ALDARA, V C., in *The Philippine Agriculturist*, Vol X, No 5, pp 195-207, Plates 2 Los Baños, Laguna, December 1921

The results of the author's researches and experiments have shown that self-pollination and cross-pollination are both possible in the case of the coconut palm

The majority of the male flowers in one cluster begin to open about 6 o'clock in the morning, but the anthers do not dehisce before 8 o'clock. The female flowers in the same cluster become receptive after 2 or 3 weeks from the time of the appearance of the inflorescence

Insects and wind may serve as agents in pollination. Amongst such insects are *Lucilia* sp (Diptera) — *Sarcophaga* sp — *Vespa luctuosa* Sauss., *Rhynchium atrum* Sauss., *Apis indica* Fabr., *Trigona biroi* Fabr. (Hymenoptera) — *Prenocerus caeruleipennis* Peity (Coleoptera)

The positive results obtained by artificial cross-pollination are also very interesting from the standpoint of applied genetics (see following Table)

*Artificial Cross-Pollination in the Coconut Palm*

Set No	Designation of cluster and tree	Date when cluster appeared	Date when male flowers were removed and the cluster bagged	Date when female flowers were pollinated	Polliniser	No of female flowers pollinated	No of nuts formed	Percentage formed
1	C <sub>7</sub> T <sub>1</sub>	Oct 10	Oct 10	Nov 4	C <sub>8</sub> T <sub>1</sub>	10	0	0
2	C <sub>8</sub> T <sub>1</sub>	Nov 4	Nov 22	Nov 24	C <sub>1</sub> T <sub>6</sub>	6	0	0
3	C <sub>3</sub> T <sub>2</sub>	id	Nov 5	Nov 11	C <sub>1</sub> T <sub>6</sub>	4	2	50
4	C <sub>4</sub> T <sub>3</sub>	Oct 10	Oct 20	Nov 4	C <sub>8</sub> T <sub>1</sub>	7	2	28
5	C <sub>5</sub> T <sub>3</sub>	Nov. 3	Nov 19	Nov 27	C <sub>2</sub> T <sub>4</sub>	6	1	16
6	C <sub>1</sub> T <sub>4</sub>	id	Nov 21	id	C <sub>1</sub> T <sub>6</sub>	6	1	16
7	C <sub>1</sub> T <sub>5</sub>	id	Nov 29	Dec 13	C <sub>2</sub> T <sub>6</sub>	4	0	0
						5	3	60
						7	3	43

There are abundant pollen grains in a cluster of flowers. The pollen grains germinate in 5 to 30%, sugar solutions. The pollen remains viable from 2 to 9 days after leaving the anther. G. A.

823 **The Improvement of the Sugar-Cane by Selection, in the Philippines.**

MENDIOLA, N B. in *The Philippine Agriculturist* Vol X No 5 pp 211-215, 12 pl Los Baños, Laguna, December 1921

The sugar-canes at present grown in the Philippines mostly belong to low-yielding varieties that are very subject to disease. The author recognises that it is necessary to practise both crossing and selection in order to obtain better combinations of characters. He also reports on the promising work that has already been begun in this direction.

The process is very simple: the most vigorous and healthy plants in

the field are chosen; the ripe seeds (taken from the finest inflorescences), of one variety are sown separately in wooden boxes or frames, in which the soil should not be less than 10 cm. deep. These germination boxes must be covered with white-washed pieces of glass, or with glass with old jute sacks on the top. If weak or sickly seedlings appear, they are pulled up and burnt immediately. As the plants grow, they are transplanted to larger boxes, in which the soil is not less than 15 cm. deep, or to bamboo tubes cut into the shape of small pots. The boxes and tubes are not to be covered, but protected from direct sunlight. When the depth of the soil in the boxes is no longer sufficient for the proper development of the seedlings, the latter must be transplanted to the field or potted. During the first year of this work about 10 000 seedlings were obtained, but nearly one half died before reaching maturity.

When the sugar-cane plant is mature, it may be divided roughly into three types — the large, medium and slender. In each group there is great variability in colour.

The large canes are more or less similar in size to the Zambales, the Hambledon Seedling 1900, the Hawaiian Seedlings and other imported heavy canes.

The medium seedlings somewhat resemble the native canes in size, and the Japanese or "Uba" in habit and other characteristics. Most of the slender seedlings are in appearance and other characters like the Japanese or the "Uba" canes.

The second year of the test, 200 selected seedlings were sent to different places, in order to study their botanical and agricultural characters and especially their resistance to Fiji disease (observed for the first time in the Fiji Islands), of which the pathogenetic agent is still unknown.

The work of testing and isolating the best individuals and of obtaining new plants from seed is still being carried on. In 1920-1921 a second group of seedlings was raised.

824 - The Improvement by Crossing and Selection of the Raspberry (*Rubus idaeus* etc.) and the Blackberry (*Rubus fruticosus* etc.) in the United States. NEES, H. in *The Journal of Heredity*, Vol. XII No. 10 pp. 441-455 figs. 1. Washington December 1921

The author gives an account of the crossing and selection work carried out with *Rubus* at the Texas Agricultural Experiment Station since 1909. Two methods were adopted:

1) Very dissimilar forms were intercrossed in order to be able better to distinguish the elementary characters throughout the complicated processes of segregation and recombination.

2) A large number of seedlings of each variety were cultivated with the object of studying any variations that might occur and using them in the selection work.

COMMON THORNTLESS BRAMBLE - The ordinary Mac Donald bramble indigenous to Texas and which is thought to be a natural hybrid is provided with thorns and has a diffuse habit of growth.

The author cultivated 2000 of these plants from seed amongst them was a group of individuals of which the leaf blades were tough, glossy, smooth and almost coriaceous having three to five lanceolate leaflets with almost entire margins. In this group were found two entirely thornless individuals one spineless and diffuse and the other spineless and erect. Four generations of the former have already been observed and they show considerable fixity and constancy of character. The seedlings of this type can be distinguished as soon as the first leaf unfolds which is cordate or cordate lanceolate with entire or slightly dentate margins and much resembles the leaf of the violet for which it may be easily mistaken.

EARLY HARVEST (*Rubus floridus*) × AUSTIN MAYES (*R. Baileyanus floridus*) - Early Harvest has fruits of small size but they are very sweet and the seeds are very small, Austin Mayes bears large clusters containing several small berries with large seeds, an acid flavour and no ironia.

In the  $F_1$  individuals were obtained in which the characters of Mayes were clearly predominant though the clusters of fruit were very irregular and composed of small berries (Early Harvest) and of small and large berries mixed (Mayes). From one individual of intermediate character there were obtained in the  $I_2$  generation 367 seedlings of the Mayes type 37 intermediate and 21 of the Early Harvest type.

COMMON BRAMBLE × RASPBERRY - The experiments in crossing the common bramble with the raspberry were of special interest and proved successful. *Rubus rubricatus* (Rvdb) was chosen for the mother plant and fertilised with pollen from two kinds of red raspberry Brilliant and London (*Rubus strigosus*). After numberless difficulties due to the sterility of the  $F_1$  hybrids, a good crop of fruit of the  $F_1$  was finally obtained in 1915, and from the seeds a second generation ( $F_2$ ) of 280 individuals were grown, 125 of which reached maturity in 1917. Since, however, the mother plants of the  $F_1$  had not been isolated, the genetic composition of the  $F_2$  is a little uncertain. In any case, the above-mentioned

125 plants can be divided into 28 % in which the raspberry character is dominant, 41 % with the bramble characters; 22 % intermediate; 3 % indefinite

From the group in which the raspberry character was dominant, 5 plants characterised by their regular and high yield were selected

All these plants have the habit of the raspberry, their stems being strong and either erect or procumbent and covered with numerous, short, weak thorns. The leaves are large and similar in structure to those of the raspberry with three, or five, round leaflets, the flowers are intermediate in size between the flowers of the parent plants, and grow in clusters at the end of long peduncles, as in the case of the bramble. The fruit which is dark cherry-red in colour, turns a blackish-brown before ripening, it is larger than the berries of either parent and has a slightly acid flavour with a scent very similar to that of the raspberry.

From a large number of  $F_3$  hybrids, 4 individuals were chosen to propagate this new type of which the fixity and homogeneity had already been proved to the 3rd generation. The 4 selected plants bore fruit from the second half of May to the middle of August, being 3 months old at the date of fructification.

The fruit, even at the end of the season did not lose its aroma or decrease in size.

These experiments proved one notable fact viz., that normal fertility was only manifested by the most robust individuals of the  $F_2$  in which the raspberry character was predominant sterility being apparently a transitory phenomenon.

Not only did the plants of the  $F_2$  and  $F_3$  become perfectly self-fertile, but their pollen possessed extraordinary vitality even when applied to rather distantly related forms.

The  $F_2$  and  $F_3$  also distinguished themselves by resisting the drought and high temperatures of 1918.

Thus the objects of making these crosses between the Bramble and Raspberry have been successfully attained

#### AGRICULTURAL SEEDS

825 — Rapid Determination of the Germinating Power of Seed. — L. J. SAGE P. in *Compte Rendus de l'Académie des Sciences* Vol 171, No 11, pp 762-766 Paris, 13 March 1922.

In connection with a publication of M. M. NEMEL and DUCHON (1) the writer recalls a method which he brought to notice in 1911 and which he has recently completed. This method makes it possible to recognise whether seeds possess germination power without submitting them to germination tests. The writer placed seeds of *Lepidium sativum* in dilute solutions of caustic potash, if these seeds were capable of germinating, they coloured egg-yellow a dilute solution with a maximum concentration of 2.5 N (normal) in 4 hours at most, if on the other hand they had lost their vitality, they coloured also a very dilute solution, with a maximum

(1) See R. March 1922, No 253 (Ed.)

strength of  $\frac{3}{4}$  2-° N. In practice a solution between these two limits would be satisfactory. The coloration would indicate the incapacity to germinate. The author has ascertained that this method can also be used for seeds of 16 other plants experimented on. He considers that it offers a starting point for the physico-chemical study of seeds and that it has a practical value. L. V.

826 - "Trigu biancu", "Trigu arrubiu" and "Trigu moru", Varieties of Wheat grown in the Province of Cagliari, Sardinia (1). - BLANDINI, E. (R. Cattedra Ambulante di Agricoltura di Cagliari), in *L'Italia Agricola*, Year 59, No. 1, p. 16, 1 full page col. pl.; No. 2, p. 48, 1 full page col. pl.; No. 6, p. 179, 1 full page col. pl. Piacenza, 15 Jan., 15 Feb. and 15 June 1922.

CEREALS  
AND  
PULSE CROPS

"TRIGU BIANCU" (White wheat). — A hard wheat with normal vegetative cycle, cultivated mainly for making bread, in the plain of Sanluri. It tillers less than "trigu moru" (1); for this reason 1 quintal per hectare is sown.

It has little resistance to lodging and drought, but it is resistant to rust which, in the marshy lands of Sanluri causes much damage to other varieties of wheat.

Characteristics: — *ear* rectangular, light yellow, bearded, 20-23 loose fertile spikelets; *spikelets* with 2-3 fertile flowers *glumes*; oval lanceolate, with very marked sharp keel, terminated by a long pointed rostrum, and wax coloured edge; *glumules* oval bulging, with awns yellow wax colour; *grain* yellowish white, slightly gibbous, wrinkled, ventral profile slightly concave; *stalk* with semi-solid straw. It resembles very much the varieties called "Saragolletta" in Basilicata and "Farru" in Sicily.

"TRIGU ARRUBIU" (Red wheat). — A hard wheat with normal vegetative cycle, grown exclusively for making bread. Like "murrù" it tillers much but it is less resistant to lodging. It has the drawback of losing its ear at physiological maturity.

Characteristics: — *ear* golden-red, square, bearded, with 25-27 compact fertile spikelets; *spikelets* with 3-4 fertile flowers; *glumes* oval lanceolate, slightly keeled, terminated by a long pointed rostrum, edge red shaded with blue; *glumules* oval bulging, with golden yellow awns, deciduous at maturity; *grain* small 5-7 mm. long by 2 mm. broad; *stalk* hollow in the first three internodes, solid in the others. It resembles very much the varieties called "Rossia" in Basilicata and "Ruscia" in Sicily.

"TRIGU MORU" (Black wheat). — A hard wheat, with normal vegetative cycle, resistant to lodging, but loses its grain at advanced maturity. Owing to this defect it is grown in a zone of small extent (plain of Sanluri and Sulcio).

Characteristics: — *ear* rectangular, black with glaucous reflexion, bearded, with 23-35 compact fertile spikelets; *spikelets* with 3-4 fer-

(1) See R. March 1922, No. 254. (Ed.).

tile flowers, *glumes* oval lanceolate, with very marked sharp keel, terminated by a long pointed rostrum and with a bluish edge; *glumules* oval bulging, terminated by long awns dark black at the base and golden-red at the point, deciduous at maturity, *grain* golden-yellow, very gibbous, ventral profile concave, average length 8 mm, breadth 3 mm, *stalks* with solid straw in the 3 first internodes, semi-solid in the others, *ear* easily detached from the stalk at maturity. It resembles very much the varieties called "Zingarella" in Basilicata and "Scurzunera" in Sicily. F. D.

## STARCH CROPS

827 - Potatoes in the Islands of Chiloé (Chili). CARDINAS ANDRADE, O. in *Revista Universitaria*, Vol. VII, No. 1, p. 27-43. Santiago of Chili May 1922.

In the valleys of the Andes situated in the part of the Cordilleras opposite the island, as well as in the north part of Chili, indigenous growths of potatoes may still be seen at the present time. It is one of the most important crops in the island. Among the Provinces of Chili the crop grown in this island stands first as regards area planted under potatoes and fifth as regards yield per hectare, the average is 111 quintals, but with better tillage and manuring 300 quintals might be obtained.

MANURE - farmyard manure, sea-weed, house sweepings, "jibias" guano, folding of animals. Dung-heaps are not used, the pen where the animals pass the night is covered with the straw of cereals or vetches or with dry grass, every three or four days a fresh layer is added. The sea-weed is spread evenly on the ground to a depth of 10 to 20 cm. as soon as it is collected, or else if the quantity available is not sufficient, it is placed at intervals of 80 to 90 cm. or it is first placed in heaps or "hurones",  $\frac{1}{8}$  of a litre per plant is supplied.

The house sweepings are heaped up and allowed to ferment, sometimes straw is mixed with them, twice as much is used as in the case of farmyard manure. Their efficiency is mostly due to the ashes which they contain. The "jibias" or cuttle-fish are large marine cephalopods of an average weight of 25 kilogrammes and never less than 15 kilogrammes, very plentiful and easily caught from March to August, they are placed in alternate layers with earth between a compost is thus obtained which is spread later, it can also be used in another manner but less advantageously, fleshy portions, 12 to 15 per "jibia", are separated and buried in the between the potato plants, but never in contact with the plant which would be injured by it. Other manures have to be added to the "jibia", as it does not suffice, by itself to give a good crop.

The islands of the Deserterers furnish from 150 to 200 tons a year of "guano piedra caltus" which is composed of sand rich in the droppings of sea birds, it is scarcely used except in these islands, in addition there is a little walrus and bat guano on Talcán island. Regarding folding, a hundred sheep or more are kept for several consecutive nights in a square with 15 metre sides.

SORTING THE SETS - This is done with great care and twice over: in the field and in the house. When the crop is lifted a single heap is

made for each day's work; in the evening each labourer places the best tubers in sacks and carries them to the house, while he selects and places in separate heaps the very large tubers and all those which belong to other varieties; in the original heap only very small tubers, or those malformed or injured by the plough, or which in some way or other are not quite sound remain. After the harvest all the other heaps are also taken to the house, but care is taken to keep the different qualities separate.

The second sorting is more rigorous and takes place during the winter months, by separating the tubers for planting ("semillón") from the larger which are sold, and eliminating all those which are injured or which do not belong to the desired variety and have escaped the first sorting. If the sets have eyes, even small ones, they are removed.

PLANTING. — Two seasons; at the commencement of winter and in spring; the former is only for domestic consumption, for it produces early potatoes, too watery to be stored.

Lines from 80 to 90 cm. apart, and holes made with a peg at distances of 40 cm. are laid out by eye, and nevertheless the work is perfect. On sloping ground planting is done in the direction of the slope, one or two tubers being placed in each hole. About 17 quintals of sets are used per hectare. The manure is applied at the time of planting or on the following day. The spaces between the lines are ploughed, the clods of earth being turned over on to the line; by passing twice in opposite directions along the same space, open ridges are made on the lines. The ends of the lines, which the plough, drawn by oxen, has not properly ploughed are completed with a kind of 2-furrow plough worked by hand, called "lumas".

CULTIVATION. — This consists in breaking up the crust, weeding and keeping the ridges in order, this being done when the plants have sprung up, and in earthing up, which is done when the plants have reached a height of 15 cm. This operation is so important that when it cannot be done the crop is not dug up, it being considered *a priori* too scanty to be worth digging.

For the execution of this latter operation, which is called "quechatum" there is generally an exchange of labour ("mingo") between neighbouring farmers.

A few years ago, about 200 varieties of potatoes were grown in the island of Chiloé; but as the trade only wants the "corahila", this has taken the place of a great many other varieties, of which only some fifty remain at present. According to the writer the "mantequilla" is the best of all, with its fine yellow flesh and its very pleasant taste; but its yield is not very high. The "oro" is very highly thought of by the farmers of the island; for domestic or local consumption, the varieties "alerce", "toldena", "cabra" are grown. By far the most extensively cultivated variety is the "corahila".

The writer gives a list of 110 varieties which, for the most part, exist at present in the island in a wild state. Among these varieties the writer mentions:— the "emperor" of large size, good flavour, very suitable

for early planting, the "camote" whose tubers have a purple flesh, which imparts part of its colouring matter to other foods with which it is cooked, giving them a purple colour; its yield is fairly high; "michuñ", "mechoe", "picun negra" and other varieties show fine purple mottling which disappears in cooking.

If the soils are divided into 4 classes in decreasing order of fertility, the following average yields are obtained :—

1st Class soils	350 to 700	quintals per hectare
2nd " "	170 to 310	" " "
3rd " "	70 to 170	" " "
4th " "	70 to 100	" " "

The large yielding varieties are the following :— "camote" — "corahila" — "chapedes"; those of medium production :— "alerce" — "toltena" — "caballero"; small producers :— "mantequilla" — "michunes" — "cabras" — "rosas"

USES. — All these potatoes are used exclusively for food; they have no industrial use. Their flavour is much improved by placing them on gratings over the hearth, so that the smoke envelops them; slight longitudinal incisions 1 cm. long at intervals of 1 cm. are first made: after 8-10 days they are taken out of the smoke: the name "anquentos" is given to tubers so treated.

"Milcado" is a mixture of grated raw potatoes, cooked potatoes and wheat flour kneaded together; it is cooked in an oven or on a grid, or else boiled or fried and is better than bread.

"Chufño" is starch prepared in the following manner :— by grating, washing, filtration, decantation and drying the starch separated by decantation and finally grinding.

DISEASES AND PESTS. — The only disease which causes damage is "sarna" (*Oospora scabies*) which the local farmers attribute to the tubers being left too long in the ground and which they prevent by not delaying the harvest or by making it early. In this way, in 80 % of the cases, a satisfactory result is obtained. The variety which is most liable to this disease, especially in new moist soils, is the "corahila" to such an extent that in some places its growth has been abandoned.

In certain limited localities, the plants are attacked by insects ("bichos") called "cuncunilla"; they have been controlled, with satisfactory results, by the following mixture :— 16 kg. of bran + 2 kg. of molasses + 1 kg. of Paris green.

The general immunity of Chiloe potatoes with regard to diseases is all the more remarkable as the island has a damp, foggy climate. It must be attributed :— 1) to the congenital robustness of the varieties; 2) to the custom of smoking the tubers for planting by keeping them hung up in frames on the ceiling of the kitchen. This practice is worthy of notice as apparently it is not known outside the island.

F. D.

Cotton is incontestably one of the all important crops in world agriculture. Problems associated with production have therefore a high international importance and necessitate a unity and co-ordination of effort between every country concerned, from the standpoints both of production and consumption.

In 1905 an International Congress was held at Liverpool and Manchester, and as a consequence the International Federation of Master Cotton Spinners and Manufacturers' Association was established. This Federation calls meetings periodically and publishes the records and issues every six months the statistical data for the cotton stocks in the factories, February 1 and August 1 of each year as well as the cotton statistics for the half-year period, January 31 to July 31, and August 1 to the following January 31. This Association is limited, however, to the spinners and is not universal, as the American Association stands apart.

1ST INTERNATIONAL COTTON CONFERENCE (New Orleans, October 13-16, 1919) (I) -- The advantage of a World Cotton Conference was urged by the Americans with a view to supplying the gaps and making good the inevitable incompleteness arising from entire dependence on the International Federation of Master Cotton Spinners, which confines its attention to certain sides of the cotton question only.

The Conference was held in New Orleans, one of the chief cotton growing centres in the world on October 13-16, 1919. For the first time on record, the discussions of cotton growers, and merchants and manufacturers were united and the bases of agreements of fundamental importance were laid.

The programme of the Conference included 14 questions, which may however, be reduced to 10, as follows (II)

- 1) World cotton requirements, increase of the consumption entails increase of production, stability of prices
- 2) Production; selection of the seed; methods of cultivation and picking
- 3) Ginning; uniformity of baling and pressing in bales

- 4) Damage at time of shipment and in transit.
- 5) Transport and insurance.
- 6) Buying and selling; tare and net weight.
- 7) Markets; classification; public interest and speculation.
- 8) Capital, credit and exports.
- 9) International and national reports and statistical returns.
- 10) Permanent organisation of a world conference of cotton interests.

The results of the debates and discussions which took place at the Conference are summed up in the resolutions subjoined here :

1) The Conference desires such a system of cotton sales as to ensure a fair price for the best qualities and the best kinds of this product. Seed inspection must be instituted, and there should be furnished certificates of origin. An enquiry should be undertaken into the best means of combatting diseases of the cotton plant whether due to insects or to other causes: there should be quarantine of seed with the object of preventing the spread of disease. Seed selection must be improved and improvements should also be made in methods of cultivation. A task more difficult to achieve but equally essential is the fixing of the price in relation to the cost of labour. To do this an international agreement should be arrived at between producers, as it is on them that the burden falls of the higher wages that increase the cost of production. It will not be easy to lay down the principles governing such an agreement owing to the presence of a large number of factors, among others the extremely complex factor resulting from the fluctuations of the exchange.

2) American manufacturers have expressed the desire to see the southern planters devote themselves exclusively to the question of improving the quality and yield per hectare. It is absolutely essential to proceed so as to ensure an annual production corresponding to the needs of the industry and fulfilling the requirements of the consumer as regards quality.

3) It is essential to introduce generally the American grading of cotton both for the manufacture of, and the trade in cotton. It is also absolutely essential to adopt an *hora certa* for the publication of prices on all the American markets for spot sales. The unification of classification is a pressing necessity if an absolutely standard result is to be obtained, as serious difficulties are encountered when trade figures of different countries are compared.

4) The Conference recommends that the different countries continue, pending an enquiry into the best means of establishing a uniform system of organisation of statistics, to collect and publish statistics of exports and imports, of production and consumption, encouraging efforts of this kind from whatever quarter, and acting jointly for common ends.

5) The Conference congratulates the management of the United States Railways on their employment for up-country stations of freight-notes in respect of consignments intended for foreign destinations.

6) The Conference signifies its approval of the State aid given by the American Government to the transport of cotton by river navigation.

7) Bales, packages, or small bales containing cotton, silk fabrics

or silk and cotton fabric must be securely packed and well protected, so as to avoid mildew which causes serious loss to the dyers and printers.

8) The Conference states that it is incumbent on the Government to find the means to prevent losses caused by exposure to bad weather and it calls upon the competent authorities for effective action in this direction.

9) The Conference is strongly of opinion that warehouses should be erected at the quays and storage places so as to avoid losses caused by bad weather. Warehousing in suitable localities for keeping cotton will be encouraged. Working of these depots: storage charges, charges for weighing and grading to be kept low. Credit guarantees to the advantage of world trade; equally for producers and buyers.

10) The Conference recommends that a law be approved authorising the " War Finance Corporation " to issue bonds to enable purchases to be made under the best possible conditions in the United States of the raw materials necessary for the resumption of manufactures in the purchasing countries. These bonds will make possible the automatic regulation of foreign manufactures and organisations if they are accepted by the foreign banks and approved by the Governments of these countries. The law further declares that in order to assist the " War Finance Corporation " the banking and credit organisation already existing in the United States shall also be available for furnishing the funds necessary for the bank operations intended for the purchases of raw materials, and that about a thousand million bales of cotton or other main products should be put at the disposal of the European industries so as to enable them to recommence work.

11) A permanent Council or Committee of the Conference has been instituted and several sub-committees appointed: the principal task of these is the consideration of American production and manufacture. A general assembly of the members of the Committee and of its sub-committees will be held at Manchester in 1921.

One of the most important results of the Conference is the demonstration of the insufficiency of the world production of cotton, and an appeal it made for more intensive and improved methods of cultivation and for improvement in quality.

II. WORLD COTTON CONFERENCE (Liverpool and Manchester, June 13-22, 1921) (III). — The second great international conference was held in two sections. The first, June 13 to 15, at Liverpool, world famous as a cotton port and the seat of the leading cotton exchange in the world, dealing with the affairs of the 570 members of the Liverpool Cotton Association. Liverpool is also the Headquarters of the Tribunal whose decisions as regards the cotton trade are accepted throughout the world. At this Conference, questions of raw material were discussed and consequently also production, prices, sale methods and the best means of encouraging the importation of American cotton into the poorer European countries.

The following summary has been made of the addresses given :

D R COKER stated that at the existing prices viz. 15 cents per lb, neither land-owner, nor the cultivator finds it profitable to grow cotton. This was confirmed by TREVOR TROUGHT, Minister of Agriculture, Egypt.

W H HIMBURY, General Manager British Cotton Growing Association summarises the latest information as regards the development of new cotton fields within the British Empire, noting especially Nigeria, Uganda and the Sudan.

In Nigeria, the crop in 1920 was 16 100 bales (of 400 lb) for shipment, it is estimated, however, that 100 000 bales might be obtained, in Uganda, where 16 years ago cotton was unknown, the crop in 1920 is estimated to have reached 52 000 bales, it is expected that an increase of 20 % annually is possible, in Sudan, 22 000 bales were produced with a possible increase to 1 500 000 bales.

W R MEADOWS, representative of the U S Department of Agriculture brought forward a proposition to the effect that universal standards be adopted for American cotton.

Other addresses dealt with financial and commercial problems.

The second part of the Conference was held at Manchester on June 15-22. Manchester is the great manufacturing centre and employs 60 million spindles and 800 000 looms standing therefore as the chief world centre as regards fabrics and yarn. Questions relating to the cotton industry were discussed and the resolutions and decisions of the Conference as a whole were approved.

Among the most important addresses may be mentioned the following:

W HOWARTH on the 'Characteristics of cotton as required by the spinner', W DAVIS 'Quality and nature of cotton yarn used in the hosiery trade', S H HIGGINS and A HODGI, 'Preparation of cloth for finishing', A I HOLT, 'The cotton mill, its machinery and equipment', A WATSON, 'Transportation of cotton', A L SCOTT and BLANCHARD F S, 'Needed reforms in the ginning, baling and compressing of Cotton', J JACKSON, 'Factory accidents and their prevention', A THOMAS (Director of the International Labour Bureau), 'Hours of labour and the textile industry'. The disadvantage of the 8-hour system from the English spinners standpoint was discussed, with reference to the resulting decrease in production.

Dr A W CROSSLEY delivered an important address on the scope of the British Cotton Industry Research Association, which includes 1500 branches and has established a Scientific Research Institute with the following aims: a) study of the botanical and chemical and physical properties of cotton fibre, measurements, resistance, elasticity etc. of yarns, effect of climate and moisture on quality of lint, b) weaving and steaming problems, c) tendering of fabrics by acids, heat and light.

Resolutions were put forward in the various sub-Committees, 14 in number and dealt with the following subjects — 1) cotton growing, 2) ginning, 3) seed, 4) compressing and warehousing, 5) sales and purchase, 6) transportation, 7) banking and insurance, 8) spinning, 9) ma-

manufacture of fabrics, 10) sale of goods, 11) finishing, 12) research and statistics, 13) textile machinery, 14) cotton waste

The following important resolutions have been selected for quotation

1) Resolution of Committee I that growers should organise a Society of the Cotton growers of the world consisting of members directly interested in cultivation, and statistics etc to promote world wide improvements in the quality of the crop, the methods of preparation and handling and the establishment of equitable prices

2) The Resolution of the Compressing and Warehousing Committee, emphasising the need of reforms in the methods of handling cotton in the United States and recommending that closer and more frequent contact should take place between the representatives of the mills growers and merchants in order to improve the classification of cotton, its protection on the farms and at the ginneries etc and also that adequate warehouse accommodation be provided and high density encouraged without injury to the fibre and the bale contents

3) Resolution of the Sales and Purchases Committee approving the contract system and deprecating legislative interference as tending to impair its usefulness. This Committee recognises the importance of studying the various forms of contract with a view to assimilating any existing differences. It was resolved that a comparison be made between the American and Liverpool official standards

4) Resolution of the Research and Statistics Committee recognising the important functions of the International Institute of Agriculture and inviting the Governments to furnish to this Institute the requisite information at the earliest possible moment in order that it may be promptly made available for the benefit of all producing and consuming countries

COTTON IN BRAZIL (V VI) — Before passing on to the study of the programme of the International Conference which will be held at Rio de Janeiro in the month of October next it may be useful to make a rapid survey of conditions in Brazil as a cotton-producing country making use for the purpose of the material collected on the occasion of the first Cotton Conference organised in 1916 by the "Centro Industrial do Brasil" (in *Revista XXII* (1918) Numero Especial) and of the statistics published by the International Institute of Agriculture (*Les pays cotonniers Leur production et leur mouvement commercial* Rome 1922 provisional edition pp 1143)

Subjoined are the figures of Brazilian production

Years of picking	Area ha	Production q
1915-1916	203 966	611 900
1916-1917	202 775	608 327
1917-1918	294 051	747 154
1918-1919	244 820	714 161
1919-1920	277 356	842 071
1920-1921	325 947	977 842
1921-1922	574 600	1 326 000

The area suitable for cotton growing, according to PLARCF who has travelled throughout Brazil on behalf of the International Federation of Associations of Master Cotton Spinners, may exceed that of the United States

The northern or equatorial cotton-growing region extends from Maranhão to Bahia, both along the coast and inland, and consists of a strip about 240 kilometres wide. The southern region with its centre at San Paulo includes a number of fertile belts extending from 15 to 25 degrees of south latitude.

In the north sowing is from December to January for long-staple cotton (from 28 ½ mm and more), and from February to April for short-staple cotton (less than). In the south sowing is from September to November.

In the north picking is from August to December, in the south from March to May.

The best variety is the *Serido* or *Moce*, with a long staple of 35-45 mm and it is chiefly grown in Brazil at Parahyba and at Rio Grande do Norte.

The quantities of long and short staple cotton respectively grown in recent years, are (VII)

Years of picking	Long-stapled cotton (8 ½ mm and over)	Short-stapled cotton (under 28 ½ mm)
	l	qs
1915-1916	358 000	253 900
1916-1917	352 851	255 476
1917-1918	433 400	313 754
1918-1919	425 088	308 474
1919-1920	480 000	350 000
1920-1921	567 240	410 760

The enemies of the cotton plant are very numerous in Brazil. The pink boll-worm (*Platyedra gossypiella*) is the most formidable. Where the growth is very thick it is difficult to combat destructive insects. The officials and experts encourage the cultivators to sow new belts and to change the order of the crops. Good results have been obtained in localities where these methods have been adopted.

Subjoined is the quantity of cotton ginned and prepared in the Brazilian factories.

Years	Quintals	Years	Quintals
1911	457 380	1914	455 150
1912	483 630	1915	573 700
1913	465 720	1916	601 220

At the date of the Rio Cotton Conference, held in 1916, the average requirements of that year were more than 605 000 qs and they were fully met by the Brazilian cotton.

After the conference the increase in the home consumption was as follows :

Years	Quintals	Years	Quintals
1917 . . . . .	686 420	1919 . . . . .	700 000
1918 . . . . .	714 400	1920 . . . . .	705 000

The exports of ginned cotton reached the following figures in the last decade :

Years	Quintals	Years	Quintals
1911 . . . . .	146 469	1917 . . . . .	59 411
1912 . . . . .	167 739	1918 . . . . .	25 942
1913 . . . . .	374 236	1919 . . . . .	121 531
1914 . . . . .	304 342	1920 . . . . .	246 961
1915 . . . . .	52 276	1921 . . . . .	196 070
1916 . . . . .	10 709		

The yield per hectare of ginned cotton has been as follows :

Years	Quintals	Years	Quintals
1915-1916 . . . . .	3.0	1919-1920 . . . . .	3.0
1916-1917 . . . . .	3.0	1920-1921 . . . . .	3.0
1917-1918 . . . . .	2.5	1921-1922 . . . . .	2.3
1918-1919 . . . . .	3.0		

This yield has always been higher than that of the United States.

The imports of cotton into Brazil have been very small, except in 1916, as may be seen from the following table :

Years	Quintals	Years	Quintals
1909 . . . . .	169	1916 . . . . .	76 238
1910 . . . . .	1 219	1917 . . . . .	1 863
1911 . . . . .	2 590	1918 . . . . .	43
1912 . . . . .	2 108	1919 . . . . .	98
1913 . . . . .	589	1920 . . . . .	101
1914 . . . . .	1 416	1921 . . . . .	—
1915 . . . . .	1 267		

**THIRD INTERNATIONAL COTTON CONFERENCE (Rio de Janeiro, October 1922) (VIII-IX)** — The third International Cotton Conference arranged by the National Agricultural Society, and under the auspices of the Executive Committee of the National Exhibition and of the Department of Cotton of the Ministry of Agriculture, will be held in October 1922 at Rio de Janeiro.

It is clear from the preceding notes that cotton growing and the cotton industry hold a very important place in the economy of Brazil. The eyes of the English manufacturers have long been turned on this country, which is almost certain to become the largest cotton growing region in the world and one of the most important sources of supply of the raw material.

The programme of the International Conference (at which will be present undoubtedly all the growers and all the manufacturers of cotton in the world) includes ten enquiries or groups of leading questions:

*I) Cotton in Brazil. General enquiry into the cultivation of the cotton plant in the different States of Brazil and in other countries.*

- 1) Varieties of cotton in the different States of the Union. Characteristics of these varieties. Studies of the seeds and the quality of the fibre.
- 2) Advantages and disadvantages of annual and perennial varieties according to the topographical and climatic conditions and the nature of the soil. Disadvantages of mixing different varieties in the same plantation. Importance of establishing a system of cultivation with a single variety for each zone.
- 3) Proved yield for each variety.
- 4) Resistance of the different varieties to weather and to the diseases of the different regions.
- 5) Early maturity and productivity of the different varieties in each region.
- 6) Soils best suited to each variety. Topographical aspect, geological formation, chemical constitution of the soil and extent of each region. Examples of the best lands. Local climatic conditions.
- 7) Methods of production in each region, labour conditions, day labour with payment in kind or piece work, price of land, facilities for transport.
- 8) Retrospective study of the development of mechanical cultivation, with animals and tractors, all over the country.
- 9) Retrospective study of State and private action for the encouragement of the cultivation of the cotton plant in the country.
- 10) Statistics of cotton production in each State, if possible by municipal areas, exports to the different States and exports abroad.

*II) Improvement of the cultivation of the cotton plant in Brazil.*

- 1) Preparation of the soil, trenching, processes of tillage and raking, use of tractors and economic conditions of the operations.
- 2) The most economical systems of planting and the machinery to be used. Periods and methods of planting, according to the varieties and regions. Restocking, lopping, levelling.
- 3) Enriching or poor soils. Use of cotton refuse, of manure, and of chemical and other fertilisers.
- 4) Rotation of crops and need for regulating these so as to ensure both soil fertility and the control of plant diseases.

- 5) Picking, precautions to be taken to obtain the cotton pure. Storage so arranged as to avoid dirt and disease.
- 6) Selection of seed with reference to the variety of cotton and the quality of the fibre; methods employed in these operations
- 7) Acclimatisation of exotic varieties: advantages and disadvantages
- 8) Comparative study of the selection of Brazilian varieties and of the acclimatisation of exotic varieties: superiority of the first system over the second
- 9) Cutting: study of the different methods, their advantages and their economic results.

### III) *Diseases of the cotton plant. State Protection.*

- 1) Study of the diseases and insects which attack the cotton-plant, and particularly the "broca" (*Gasterocerodes Gossypii*), the pink boll-worm (*Platyedra gossypiella*), and the "curuqueré" (*Alabama argillacea*): studies of the material damage caused by each of the above mentioned diseases and pests as regards the quality of the cotton and the yield from the picking. Advantages obtained due to the measures taken by the States that have a department for protection of growers
- 2) Influence of bad weather at the time of planting and picking. influence of the surrounding vegetation, of the variety and of the methods of prophylaxis on the recurrence of diseases
- 3) Methods for combatting diseases. Insecticides, spraying materials and their application. Cutting of perennial cotton plants as a preventive method.
- 4) Cleaning of the seed and methods employed for this purpose, whether heat and exposure to the rays of the sun or carbon bisulphide or hydrocyanic gas. Study of apparatus employed on the large and on the small farms and for export trade. necessity of spreading the use of these. Arrangements for the importing of cotton seed from abroad and installation of apparatus for cleaning.
- 5) Plan of co-ordination of the federal legislation of the States and the Municipalities as regards the methods adopted for the protection of the cotton plant. The most important rules to be observed. Schemes including itinerant lectures and propaganda among cultivators, proprietors of ginning machinery and buyers of cotton
- 6) Measures to be taken to secure common action in the producing countries, with the object of avoiding the spread of the diseases that attack the cotton plant

### IV) *The cotton-plant in the North-East*

- 1) Operations in the North-East for developing and improving the cultivation of cotton and notes on the best methods of carrying them out
- 2) Lands under cultivation and a study of a plan of extension of the areas planted by the construction of large barrage works. Enquiry into methods of utilising and improving irrigated land, low lying land and elevated land by means of barrage constructions.
- 3) Distribution of water for irrigation purposes: rules to be adopted and methods recommended. Quantity of water required by the different crops and the relative charges. Method of procedure for speedy utilisation of irrigated land
- 4) Advisability of employing borrowed capital and utilisation of irrigated land: the best system of working to follow
- 5) Economic capacity of the great irrigation works of the North-East and plans for harbour improvements
- 6) Cultivation of land with large, small and medium barrage works. Enquiry into

the basins of irrigation, and the large canals. Economic possibilities of utilising the water in the great barrage works of the North East for irrigation purposes.

7) Value of the carriage roads in the whole cotton growing region and necessity for increasing their number.

### V) *Treatment and manipulation of cotton and its by-products*

1) Treatment of cotton. Preliminary grading in relation to the quality and kind of staple. Handling, ginning, pressing, baling, warehousing. Improvements to be introduced into the methods employed.

2) Ginning machines. Types of saws, rollers and cutters with notes on their use and on possible improvements. Inquiry into the application of these types of machine to the various kinds of Brazilian cotton, advantage and disadvantages.

3) Central stations for the manipulation of cotton according to kind, to length of staple and to the importance of the region. Conditions which should guide the choice of situation of these stations.

4) Types of cotton presses and their use in each case. High density presses at the ports of shipment and drying apparatus. Cotton warehouses at the ports of shipment. Kinds of bales for export and for home consumption.

5) Baling of cotton and treatment of by-products. Possibility of fraud in connection with these processes and means of prevention.

6) Cotton seed and its preparation. Conditions that must be fulfilled by the seed depots as regards collection, storage and consumption for local use as well as for export.

7) Oil factories. Study of machines intended for treatment of seeds so as to obtain maximum output. Oil, oil cake, residue, linter and husks. Position of the oil mills regarded from the point of view of the raw material, of transport conditions and of the best means of utilising the by-products, their industrial and economic value.

8) Refining of the oil from the chemical standpoint. Oil techniques for the manufacture of food products such as edible fat, table and cooking oils. Commercial importance of these by-products in national economy.

9) Utilisation of the cotton stalks and of the 'linter' in the paper making industry. Facilities to be given to factories established in the country.

### VI) *Development of cotton growing. Federal Cotton Department*

1) Encouragement of cotton growing by means of the primary schools, of co-operative cotton growing, of itinerant classes, experimental stations, stations for production of seed and the assistance given by public authorities to all that concerns the extension of the cultivation and its cost.

2) Encouragement of the extended use of agricultural machinery and facilities for purchase by importation free of duty and sale at cost of manufacture. Extension of similar privileges to machines intended for the manipulation of cotton products, to windmills, to apparatus used in making irrigation canals, to motor engines, to fertilisers and to insecticides used in cotton cultivation.

3) Grant of subsidies for the business of manufacturing cotton and its by-products.

4) Experimental plots attached to plants for the manipulation of cotton, their methods and aims, selection and cleaning of seeds intended for planting in accordance with the most approved methods.

5) Federal Cotton Department, the most suitable form of organisation or propaganda advocating scientific methods of work, protection of the plantations, distribution of selected seed, employment of agricultural machinery, and also the organisation of statistical returns of cotton production.

6) Grants made by public authorities mainly for propaganda, advocating scientific methods of working, and the control of plant diseases affecting cotton. Need for the Governments of the different States of Brazil and the Municipalities to make regulations for prophylactic measures and the protection of the cotton plant against infection. Fraudulent practices in the handling of cotton, in the manufacture and in the packing of the oil : measures directed against those guilty of such practices

7) Need for the establishment of a large number of small factories in inland districts of the States that are cotton producers. Facilities to be granted for the installation of these factories

8) Enquiry into the export of oil-cake : advantages of prohibiting this export. The place of oil-cake in the feeding of livestock

9) Premiums to cultivators employing oil cake as a fertiliser

### VII) *Classification of cotton and standardising of the commercial kinds of staple and of its by-products. The cotton trade.*

1) Need for a classification of cotton staple in order to facilitate buying and selling operations, and the creation of a type by which to check these operations

Methods to be followed in classification :

a) the degree of purity and the best conditions of the staple according to the American classification ; b) origin of cotton and the differentiation of varieties in respect of length of staple, its power of resistance and its fineness

2) Establishment of model types of Brazilian cotton, taking into account the characteristics of the variety, of the high standard degree of the manipulation and of the state of the fibre. Need for the Brazilian experts to work in collaboration with the specialists of other countries for the establishment of these model types and the trade importance of organising on these lines

3) Local exhibitions and markets ; way in which they should be instituted, directed and regulated in the interest of production, so that all concerned receive information as to cotton prices by means of the publication of a bulletin of market prices for all the principal centres in the country. The sale of cotton loose or in pool, testing of weights and balances

4) Co-operative societies for the production and sale of cotton. Credit banks

5) Cotton exchanges, need for their establishment in the principal ports of shipment and the conditions to be laid down for the organisation and regulation of the sale and purchase transactions in cotton and its by-products. State action in agreement with the Exchanges to obviate a classification prejudicial to the producer. The cotton trade and an enquiry into the class of agents and middlemen "Warrants" for cotton and its by products.

6) Establishment of types for the by products of cotton and of regulations in view of their utilisation both as food and commercially

7) International joint action for the improvement and increase of cotton production regulations relating to the settlement of trade disputes

### VIII) *Spinning and the textile manufactures. Home consumption of cotton. Export of material*

1) Enquiries into the Brazilian spinning and textile industries. The raw material used in them and their importance in the national economy. Practical methods of encouraging, by means of a keen foreign propaganda, the sale of Brazilian textile materials. Questions relating to the quality and condition of the cotton. Means of remedying defects observed. Statistics of spinning and textile manufactures. Means of getting these into line with international statistical returns

2) History of the development of spinning and weaving in Brazil, of the fluctuations

of stocks and of the prices of raw materials. Enquiry into the best methods of stabilising the conditions of industrial life : influence of export duties and of the exchange. Need for export of material for the attainment of commercial stability.

3) Joint action to be undertaken between the cotton industries and the Federal Government, together with the Governments of the different States of Brazil, for the development of production, for the control of plant diseases and for the improvement of the industrial processes. Report on the activity of the British industries especially in the Protectorates and in the colonies.

### IX) *Economic protection of cotton.*

1) Action taken by the Brazilian Union and by the cotton-producing States for the economic protection of cotton with a view to preventing too rapid fluctuations in price.

2) The fluctuations of the exchange and their influence on cotton prices and the prices of the by-products. Methods of ensuring regularity in home prices.

3) Fixing of the minimum price by special legislation. Advantages and necessity of such fixing for Brazil. Report on the British colonies where this procedure has been adopted.

4) International reserve of cotton. Stability of prices in the foreign markets.

### X) *Export of cotton and of its by-products. Duties and freight-charges.*

1) Desirability of reducing export-duties on cotton and its by-products and of making such duties uniform, with the object of improving the exchange and stimulating production. Differential duties in proportion to the amount of manipulation and the degree of the purity of the product. Enquiry into the substitution for export duties of other more equitable taxes likely to encourage the investment of capital in cotton growing and in its manipulation or manufacture. Suppression of customs and similar duties.

2) Reduction of the export duty for pure cottons, baled and graded into trade classes. Measures to be adopted in respect of impurities or fraud.

3) Municipal taxes on cotton. Ways of finding effective and convenient substitutes without hampering production.

4) Enquiry into the advantages direct and indirect of the intervention of the Union in favour of the development of cotton exports. Economic limits of the export of cotton and its by-products in view of international balance of trade.

5) Export of cotton and its by-products for world consumption and means of assuring a progressive development. Specialisation in the export of longstapled cotton as the best means of obtaining a stable high prices.

6) Establishment of new markets abroad for developing the trade in the Brazilian long-stapled varieties, with the support of the Chambers of Commerce and Cotton Exchanges. Need for basing this policy of development on improved and extended production and on the organisation of export in bulk, in accordance with the rules laid down for international trade.

7) Transport of cotton and its by-products by carriage, roads, railways, rivers and by sea. Enquiry into suitable methods of reducing and standardising freight charges, and the joint action necessary to this end. Differential tariffs according to the degree of compression of the cotton and the distances from export centres.

8) Safe methods of transport by land and sea for cotton and its by products, from the ginneries up to their arrival at the manufacturers.

Such is, in its complete form, the extensive programme of enquiries and discussions which will engage the attention of the Third International Cotton Conference to be held in October next, in Rio de Janeiro.

F. C.

829 — **Problems of Cotton Planting.** — See Article by Dr FR. CORTESI, p. of this *Review*.

830 — **Principal Vines Grown in Dalmatia.** — BULIC, S., in *Rivista di Ampelografia*, Vol. III, No. 5, pp. 73-74; No. 6, pp. 81-84. Alba-Leghorn, May and June 1922.

VINE GROWING.

Up to the middle of the 19th Century vine-growing in Dalmatia was almost entirely confined to the central part of the littoral and the neighbouring islands.

The two extreme coast districts, Zara and Cattaro, and the whole of the Mediterranean part did not even produce enough to satisfy the requirements of well-to-do people. Since that time, it may be said that there are in each vineyard many qualities of grapes, mostly red, producing wines differing little from those of Apulia and Sicily.

The development of vine growing and the selection of stock got their first impetus from the appearance of oidium in Lombardy-Venice in 1848-1850, which increased 9 or 10 fold the price of Dalmatian wine on the Venice market. This caused the almost total disappearance from the Dalmatian vineyards, of many of the most highly reputed stocks (Malvoise blanc de Raguse, Muscat rose d'Almuse) or else their growth was much reduced (Ungara blanc de Bruzza, Maraschina blanc de Sebenico), they were replaced by productive stocks of red grapes which were very resistant to oidium, which, however, never caused much damage on the dry rocky soils of Dalmatia.

From 1866 to 1878, the wines suffered a crisis owing to the annexation of Lombardy-Venice to Italy, the consequence of which was the loss of this market, and enormous duties imposed on Dalmatian wines for their importation into the other Austrian provinces.

The revival of the Dalmatian wine industry is largely due to LIEBENFROST. During the campaign 1870-71, he began to make high-grade wines at Castella, near Spalato, at Sebenico and at Zara for his important firm; the export which had been 6000 barrels (of 66 litres) in 1870, was 75 000 barrels in 1871. On the initiative of the same manufacturer, wine companies were immediately formed at Spalato, Zara, Civitavecchia de Lesina, and at once did good business.

For 12 years after 1878 there was a heavy export of Dalmatian wines to France (where the phylloxera was raging), to Germany and to Switzerland, and the prices increased considerably; consequently in about 10 years Dalmatia was "transformed into a vineyard" under red wine producing varieties. The growth of white stock was reduced to a minimum and of the former 200 kinds, only traces represented by a few vines remain. The present number in ordinary use is reduced to 4:— "Plavac mali" (small red Plavac), "Plavina" (red Plavina), "Nincusa" (red Nincusa) and "Kadarun" (red Cadarun); the writer gives for each of these vines:— extent of cultivation, synonyms, description of the plant, cultural data, value of the grape and wine.

There are, besides also about 10 secondary kinds.

F. D.

831 — **The Question of American Stock for the Vines of the Trentino** (1). — J. CACCIATORE, M. Sul comportamento dei portinnesti americani nel Trentino ed in particolare nei vigneti dell'Istituto agrario di San Michele all'Adige, in *Bollettino del Consiglio provinciale di Agricoltura etc del Trentino*, year XXV, Nos. 7 & 8, pp. 181-187. Trent, April 15-30, 1922. — II. GRAMMATICA. Sull'influenza del ceppo americano in rapporto alla qualità del vino. *Ibidem* pp. 101-117. — CATONI G. and GUSTOLINO A., I feligni predominanti nel Trentino in *Giornale vinicolo italiano*, year 18, No. 6 pp. 53-54. Casale Monferrato 1921, 5, 1.

The two former articles are complementary inasmuch as the first deals with the value of the different stocks from the vine grower's point of view and the second from the wine maker's standpoint.

I. — Review of the result given by American stocks in Trent and particularly in the vineyards of the Agricultural Institute of St. Michael, on rather calcareous soil (6.13% by BERNAKID'S calcimeter) partly compact clay and partly clayey sand fairly friable and subject to drought. From these results the writer draws the following conclusions: — 1) the hybrids Riparia × Rupestris 101/14, 3309 and Schwartzmann should be preferred, the first two because they do well in soils of various types such as those of the experimental vineyard, the third because it seems to adapt itself even to hilly ground too heavy and dry for Riparia, 2) the hybrid Riparia × Berlandieri Teleky which appears to adapt itself well to various soils, (3) the hybrid Rupestris × Berlandieri Teleky which appears to be worth propagating in dry poor hill soils, (4) the hybrid 420 A (Riparia × Berlandieri) which is well suited to stony dry calcareous hill soils, and the hybrid 3306 (Riparia × Rupestris) which should be tried in somewhat heavy, fairly moist, clayey calcareous soils.

It is only with great discretion that pure Riparia, pure Rupestris and the European American hybrid G. N. 1 can be recommended, there is also no reason to grow extensively the hybrids 1202 and 41 B, which might however, render good service if an opportunity should present itself of profiting by their peculiarities of adaptation without decreasing their vigour.

The Provincial Agricultural Institute of St. Michael and the Trent Provincial Council of Agriculture have been charged in recent years with the study of the selection of vines for the fresh planting rendered necessary by the destruction caused by the war and by phylloxera.

The problem cannot have a single solution, because in the valleys it is desirable to aim rather at abundant production and in the hills at superior quality. The results obtained by the Institute may serve as a guide to the vine grower after he has decided whether he should go in for quantity or quality.

The renewal with American stock was begun in 1906 in the vineyards of the Institute and ended in 1913. Numerous American stocks, especially for the vines most commonly grown, Schiave, Negrara, Teroldigo, Cabernet, were used for the purpose of studying the behaviour of different stocks in relationship to soil and varieties of local vines.

(1) See R. MARCHETTI, No. 52, R. JULY 1921, No. 28, R. OCT. 1921, No. 1012. (Ed.)

II. — The great majority of the new plantations are not inferior from a wine making point of view, to the old ungrafted vines. In the first place, the wines of Burgundy type made from red Pinot, Gamay, Molinaro, and San Lorenzo show a notable improvement, especially in aroma and fineness of bouquet.

The results of the new plantations of Cabernet are less satisfactory; the wines which have been obtained from them are much superior to those from the same ungrafted vines, but they lack bouquet. The fact that the method of ground growth had been replaced by pergolas, may perhaps have contributed to this result.

The quality of the wine has not deteriorated in the different varieties of Schiava, Teroldigo and Lagrein; but there is no doubt that in the case of Negrara it has suffered.

The white wines (white Pinot, Sanvignon, Traminer, Riesling), have maintained the high qualities of the old ungrafted vines. The writer advises a larger use of them in the renewal of vineyards at medium elevations; he also recommends the partial replacement of the white Vernaccia on the good soils of the Val d'Adige by red and white Veltliner, Sylvaner and Ruländer or grey Pinot, the must of which is very suitable for the manufacture of sparkling wines.

To prove the influence of the stock, the writer has made wine separately from grapes produced by the same vine on different stocks and has analysed the wines obtained.

A series of tabular statements show the results of these analyses. The highest quality was obtained from produce of *Riparia* × *Rupestris* 101/14 and *Rupestris*; followed, in decreasing order, by *Riparia*, *Riparia* × *Rupestris* 3309, Schwarzmann, Aramon × *Rupestris*, *Riparia* × *Berlandieri* Teleky.

III. — Among the numerous vines grown in Trent the following predominate: — *red grapes*. — Teroldigo, typical of the Atesina valley; Marzemino, especially in the Rovereto zone, late in ripening and yields fruit even on poor soils; Negrara, throughout Trent; Gropello, typical of the Non valley; red Schiava or Schiavone, almost throughout Trent, but especially in the Sarca and Cembra valleys; Rossara, throughout the Atesina valley; Pavana, native of Italy and grown only in Valsugana until a few years ago; as it resists oidium it was then brought into the territories of Trent, Rovereto and Civezzano;

*White grapes*: — Vernaccia, the most common of all; Nosiola, much better than the former; Trebbiana, the growth of which is only important in the Sarca valley; Riesling Italico, introduced some years ago into the Adige valley.

In consequence of the work of the Trent Council of Agriculture and district Agricultural associations and their affiliated societies and by the provincial Agricultural Institute of S. Michael, there is a tendency to limit the growth of Schiavone, Rossara and Pavana, which yield common wines, and to replace them by vines giving better wine, such as: — Veltliner, Bourgogne, Sylvaner, grey Pinot, Sauvignon, Muscat, Traminer, Riesling

of the Rhine, Bourgogne of the Rhine, Molat, Verdot, Cabernet-Sauvignon, etc. F. D.

## FORESTRY

832 - **The Renewal of Chestnut Woods in France.** — MANGIN, I., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. 8, No. 7, pp. 144-151. Paris, Feb. 15, 1922.

The chestnut woods, which formerly covered the Plateau Central and the Cévennes, and which were a source of wealth, disappeared as means of communication increased and made possible the growth of cereals; also because an export market is lacking on account of the poor quality of the fruit which has not been improved by selection. The profits of the chestnut woods have become so small that many proprietors do not hesitate to sell the trees to tanning extract factories and do not trouble to replant the cleared areas. To these causes must be added the damage caused by the "maladie de l'encre", which has denuded large extents of chestnut woods in many Departments.

In some twenty Departments, in which the chestnut woods have been replaced by more remunerative (sometimes four fold) crops, the question of renewing them does not exist. But in some ten Departments their disappearance is an actual loss, either because the soil is not suitable for more remunerative crops, or because want of labour does not permit of the cleared areas being brought under cultivation. Where clearing has been the work of man, indigenous chestnuts may be transplanted, the best varieties being chosen: they continue to fruit up to 50-60 years, and it is well to have them standing to that age, because it is then that the wood acquires its highest tannin content. On the other hand in the zones devastated by the "maladie de l'encre", the soil is infected and fresh plants are attacked by disease in their turn. The author has tried to disinfect the soil by watering the holes dug for the transplants and the earth dug from them with 20 % solution of ferrous sulphate and the results are encouraging. Another means consists in growing exotic chestnuts which resist the disease; such are the Japanese varieties of *Castanea dentata*, introduced about fifteen years ago by Prof. PRUNET of Toulouse University. But it is difficult to procure pure-bred plants of the best varieties; furthermore, the plants resist the disease but do not grow very large, nor do they possess the qualities required by the market. Another difficulty has arisen to complicate the problem of the renewal of the chestnut woods with exotic plants: for some years the woods in the United States have been devastated by a much more formidable disease than the "maladie de l'encre"; it is caused by the ascomycete *Endothia parasitica*, which develops on the trunk and branches and rapidly kills the tree. The American botanist C. L. SHEAT has proved that this mould exists also in China and Japan, but does not cause much damage, while introduced into the United States it has become virulent and has there caused the destruction of many chestnut woods. To prevent this new disease from being introduced into France with varieties of Japanese chestnuts, the Minister of Agriculture has prohibited the entry of Japanese

plants and fruit. This prohibition has been temporarily suspended only for the consignments of the MILVILLI mission, these consignments will be collected in the COUDRE nursery garden at Aubenas, and submitted to a serious examination. It is forbidden to distribute the plants without the approval of the Department of Plant Diseases. In America the Department for the protection of plants is searching for species or varieties resistant to *Endothia parasitica*. *Castanea mollissima* (C. Duclouxi), very common in China, has shown itself very resistant, and already in the United States nurseries have been arranged to fill with this species the blanks caused by *Endothia*. The improvement of the produce by grafting might be tried. Such is the programme which was submitted to the Commission of renewal of chestnut woods which is sitting at the Ministry of Agriculture. In the discussion (Messrs DE VIMORIN, GUIGNARD, HICKLI) which followed that communication the speakers called attention to the fact that grafting exotic chestnuts in France is of recent date and that fruit has not yet been obtained. There has therefore not yet been time to judge the results. It was also mentioned that it is difficult to obtain seed from China and Japan and especially plants in good condition. Packing is more difficult than was imagined. If the chestnuts are beginning to germinate they must be treated with great care. However M. HICKLI announced that he had received from China 7 or 8 years ago Chestnuts in excellent condition and which produced plants without any trace of disease. They were of large size similar in every respect to Lyon Chestnuts. M. HICKLI has also furnished proof of the introduction into France, many years ago, of the chestnut tree from China and Japan.

#### LIVESTOCK AND BREEDING

83, - **Poisoning by Green Carobs, in Italy.** — DI PAOLA P. in *Bollettino Ueterinario Italiano* Vol. XVIII No. 154 pp. 65-66; bibliography of 11 works. Turin May June 1922.

HYGIENE

In the district of Gieti (Italy) and in the neighbouring communes the carob tree (*Ceratonia siliqua*) is largely grown, its fruit constitutes with hay and grass the basis of the food of horses, and gives rise to a local trade of some importance. If the carobs are fed sound and quite ripe they form a rich (30-40% of sugar, 20-37% of starch) and digestible food, but if green they may cause poisoning as the author has noted in some cases. The following are the symptoms of the poisoning — diarrhoea, lowering of the body temperature, cynosis, trismus. The treatment is of doubtful efficacy: the writer tried hydropathy, rubbing with camphorated spirit, the administration of a tepid infusion of coffee or injections of caffeine.

The toxic effect of green carobs must be attributed to tannin which acts particularly on the circulatory system causing cerebral hyperhemia, and on the nervous system causing hypothermia.

Hungry animals should not be kept near carob trees laden with green fruit at a height which the animals can reach.

- 834 - **Colloidal Sulphur in the Treatment of Sarcoptic Mange in Horses** — SANI, I. and BELLUZZI, G. (Istituto de Patologia e Clinica medica veterinaria della R. università Bologna, in *Il Moderno Zootetto*, scientific section 1st Series, Year XI, No. 1, pp. 11-19, di bibliography of 33 works. Bologna, Jan. 1922.

The authors as a result of their experiments advise the use of colloidal sulphur in the treatment of sarcoptic mange of horses, which they especially recommend for intra-venous, sub-cutaneous and intra-muscular injection, in conjunction with some ointment or liquid acaricide. It exerts a beneficial influence on the general condition of the horse, and acts very energetically in the destruction and elimination of the acarides, and assists in healing the skin; the injections have no bad general effect and are easily carried out, and their cost is very low. By adopting this treatment animals are able to return to work from five to fifteen days sooner than is the case when other methods are employed. P. D.

- 835 - **Spirillae, Pathogenic Agents of Contagious Abortion in Germany** (1). — GUINDER, A. (aus dem Württembergischen tierärztlichen Landesuntersuchungsamt in Stuttgart), in *Berliner Tierärztliche Wochenschrift*, Year XXXVIII, No. 10, pp. 184-185, Berlin, April 20 1922.

In England, the United States and Denmark several writers (2) have drawn attention to the fact that in the case of contagious abortion, bacteriological examination does not always show the presence of BANG's bacillus and that the latter is sometimes replaced by spirillae which then appear to be the decisive agents of the disease. The author describes briefly the first two cases of this form of contagious abortion which have been observed up to the present time in Germany.

Two foetus were concerned one of 4 and the other of about 7 months, which showed few and non-characteristic anatomo-pathological injuries; the result of the microbiological examination was doubtful in the first case, while, in the second, preparations made by rubbing the gastric contents showed numerous short spirillae staining with Giemsa, as well as with LOEFFLER'S solution of methylene blue which was allowed to act for 2 or 3 minutes on the air-dried preparation, their shape and size differed little in the preparations taken direct from the foetus and in those obtained from cultures on agar with the addition of a few drops of defibrinated blood of rabbit or horse. In the former comma shaped (vibrions) and short spirillae with two or three cilia at most were found; in the latter long spirillae were seen having very often 5-10 cilia and more. The experiments of transmission by sub-cutaneous injection of the culture of the spirillae gave positive results, by causing artificial abortion in guinea-pigs with young. It is well to draw attention to the practical importance which spirillary infection, in the absence of infection by BANG's bacillus, may have in the pathogenesis of contagious abortion. E. F.

- 836 - **Cases of Contagious Abortion in Cows without Demonstrable Cause.** — TRAUM, J., and HART, G. H., in *Journal of the American Veterinary Medical Association*, Vol. LXI, No. 1, pp. 15-30. Washington, April 1922.

The authors believe that most cases of contagious abortion in cows are due to the presence of *Bac. abortus* Bang, though in the five instances described in their paper they were unable to find *Bac. abortus*, or any other micro-organisms of pathological significance.

In a herd of some 50 head (which in 1920 had given negative results when subjected to the agglutinating test for *Bac. abortus*), five cows aborted between September 1920 and September 1921.

An examination of the foetus was possible in three cases only, the organic fluids and solutions from the tissues were sprinkled on special cultural media, but the authors were unable to isolate any definite micro-organism. Transmission experiments were made on numerous guinea-pigs but these, as well as the microbiological investigation of the milk from the diseased cows, only yielded negative results.

It should be mentioned that in two cases out of five, the abortion took place 10 and 20 days respectively after a bimanual manipulation of the reproductive organs made with the object of determining pregnancy. There is thus good reason to believe that this operation together with other unknown factors may have been instrumental in producing abortion. Hence every precaution should be taken when this method of diagnosis is adopted.

- 837 - **The Treatment of Sterility of Non-Pathological Origin in Cows.** — DAUBLER, E. C., and BARNES, M. F., in *Journal of the American Veterinary Medical Association*, Vol. LXI, No. 3, pp. 251-258. Washington, June 1922.

The authors have treated cows which, although apparently normal in every other respect, showed no signs of heat, and succeeded in inducing the normal cycle of heat periods and in rendering the animals fertile by giving them the ovaries or extracts from the ovaries of sows. Small pieces of the ovaries of healthy sows were administered, two at a time in a capsule which the cow easily swallowed, or a sterilised extract of sows' ovaries was prepared and injected, each cow receiving a subcutaneous injection of the extract of 1 or 2 ovaries. The latter method proved the more satisfactory. The ovarian extracts of commerce failed to produce the desired effect.

F. D.

- 838 - **Diseases of Zebu in Madagascar.** -- See No. 853 of this Review.

- 839 - ***Necator suillus* n. sp., a New Swine Parasite.** — ACKERT, J. E., and PAYNE, F. K. (Agricultural Experiment Station, Kansas State Agricultural College, Manhattan, Kansas), in *Journal of the American Veterinary Medical Association*, Vol. LXI, n. s., Vol. 14, No. 2, pp. 186-188, bibliography of 4 works. Washington, May 1922.

The authors found at Trinidad (British West Indies), a swine parasite very similar to the hookworm (*Necator americanus*), that attacks man, but forming a distinct species to which they have given the name *N. suillus*. This parasite is usually met with in the ileon or the jejunum and a single

individual may harbour several hundred of these worms. The host become greatly emaciated and therefore *N. suillus* is of considerable economic importance (1).

840 - **A Disease of Young Pigs consequent on Dry Years.** — MOUSSU, G., in *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VIII, No. 18, pp. 534-541. Paris, 17 May, 1922.

Study of osseous cachexy of young pigs aged 2 to 5 months. Clinically, the disease is characterised by the following stages:—

- (1) Stopping of growth and difficulty in walking (period of the disease called the squalor period);
- (2) articular deformation and walking on the knees (gout period);
- (3) deformations of the skeleton and of the head;
- (4) final decay, the sick animals die of starvation.

The first stage only lends itself to therapeutic intervention, in any case of doubtful value.

This disease may break out any year and occurs chiefly in certain regions (Aube, Marne, Yonne, etc.), but consequent on dry years, it spreads a little everywhere, except where the pigs are regularly run on pasture. A ration given at too early a stage, composed of a large proportion of farinaceous matter, without dairy refuse, vegetables, roots and green fodder, favours the disease. Up to date, no micro-organism capable of reproducing the disease has been isolated, but the writer has shown, a long time ago, that it may be reproduced experimentally by direct contagion and by starting with emulsions of the diseased osseous marrow.

Treatment recommended by the writer:— 1 gramme of chloral per day per 10 kg. of live weight, in the rations, as anodyne to the painful condition and as general antiseptic; sometimes hydrochlorate of ammonia as a stimulant to nutrition; salts of lime (phosphates, bi-phosphates, carbonates, chloride of calcium, etc.) to facilitate the osseous recalcification.

#### FEEDS AND FEEDING

841 - **Calculation of the Money Value of the Nutritive Unit.** — DECHAMBRE, P., in *Revue de Zootechnie*, No. 5, pp. 410-417. Paris, 15 Feb. 1922.

An attempt is made to strike a balance between the requirements of the animal and the provision of food with the least expense. To do this, the cost price of food stuffs must be compared one with another. The market price of a food should be proportional to its nutritive value. We should therefore take as basis the price of the nutritive unit fixing the quotient of the price of the unit of weight by the number of nutritive units therein contained. If  $P$  represents the price of a kg. of the food,  $N$  the number of nutritive units which it contains, the money value of the nutritive unit,  $V$  would be equal to  $\frac{P}{N}$ .

(1) In 1920 O'CONNOR discovered in pigs at Fumafuti in the Ellice Islands, an *Ankylostoma* resembling the human parasite (*A. duodenale*), but smaller. In 1921 LEGO and REUBEN found *A. duodenale* in swine in North Queensland (Australia). (Author's note).

$N = [\text{Protein} + (\text{Fats} \times 2.2) + \text{non-nitrogenous extracts and cellulose}] \times \text{Productivity.}$

**ENGLISH METHOD.** — The *English Journal of the Ministry of Agriculture* gives opposite the market price of food stuffs used for animals, the price of the nutritive unit. This method may exercise an influence on the market rates by preventing an unfair rise on products whose nutritive value is not in proportion to the current price. In the calculation of units nitrogenous principles are given the coefficient 2.5, as it is generally the protein content which determines the market price of a product. Amount of nutritive units =  $(\text{Protein} \times 2.5 + \text{Fats} \times 2.5) + \text{Carbohydrates}$ . Having obtained this result, the price per nutritive unit is determined and the foods classified in increasing order of value. This information is completed by equally useful tables, giving the distribution of foods in the 4 following categories: —

- (1) Products rich in protein and fats.
- (2) Products fairly rich in protein and rich in fats.
- (3) Products rich in protein, poor in fats
- (4) Products rich in starch, not rich in protein and fats.

More recently the *Journal of the Ministry of Agriculture* presents its information in quite a different manner: the price of the different foods is diminished by the manurial value of the nitrogen contained. The difference between these 2 values is the food value

Price — Manurial value = Food value.

If this price is taken, together with the starch value, it is easy to deduce the value of a pound or kilo of the food under consideration. However, the author remarks that the more our knowledge extends, the less is the value which should be attributed to proteins, as such; quantity becomes less important than quality. These ideas of quality are applicable not only to albuminoids, but also to fats and carbohydrates.

To avoid useless discussion regarding the choice of the coefficient to be attributed to albuminoids, the writer calculates the number of nutritive units by simply adding to the figure representing the percentage of digestible albuminoids and carbo-hydrates, that relating to fats multiplied by 2.2 to take into account their greater calorific value. The figures obtained according to this very simple method, make it possible to estimate the cost price of the nutritive unit in each food, and the nitrogen content which will also be given will enable the value of these foods to be judged according to the object in view.

F. S.

#### 842 — The Insufficiency of Lime and Phosphoric Acid in the Feeding of Animals. —

GOUIN, R., in *Revue de Zootechnie*, No. 6, pp. 526-531. Paris, 15 March 1922 (1)

It has been remarked that dry years are followed by an outbreak of more or less similar affections: — osseous cachexy, osteomalacy, osteoclasty, rickets, gout, rheumatism, etc., having always a common cause: — the insufficiency of mineral matter in the bones. Now, as the year 1921 had this

(1) See B. Oct. 1914, No. 921. (Ed.)

dry character, the author thinks that it is not unprofitable to remind breeders of the affections to which their animals, especially young ones, are liable, and the precautions to be taken to avoid them. From the observations of GRANDEAU, BOUGARTZ, KEILNER, SEEL HORST, it is apparently proved that want of water for vegetation hinders the mineralisation of plants. When a deficiency is caused in a diet, the organism draws on its reserves. These being exhausted, it consumes its own substance and reduces its expenditure to a minimum. This faculty of saving and the importance of the reserves explain the irregularity in the periods of resistance. It is therefore not surprising that it should be in the spring and summer following the dry period that affections show themselves. To compound a ration we must know the useful substances, the foods which do not contain them sufficiently, the requirements of the organism for each and the form in which it is most suitable. The author proposes to take an inventory of the present knowledge on these questions.

**MINERAL ELEMENTS OF THE ANIMAL ORGANISM.** — Up to the present, the substances found in the organism are fairly numerous. We may suppose that, generally, the organism is well provided except with four of them: — Chlorine, sodium, calcium and phosphorus. It is easy to remedy the insufficiency of the first two. There remain the last two substances: — lime and phosphoric acid. KELLNER's experiments have shown that their assimilation attains the maximum when they exist nearly in the proportion suitable for the formation of a neutral salt. On the other hand WEISKE's researches have taught that compounds of phosphorus with an acid reaction can cause decalcification of the skeleton; apart from the addition of common salt, we have only to consider it in relation to animal nutrition. Very few foods have been studied regarding their mineral composition. It is therefore rather difficult to make an approximate account of the quantities of phosphoric acid and lime afforded by a ration. As a rule herbaceous fodder gives the lime. Grain and its derivatives provide more of the phosphoric acid.

**THE REQUIREMENTS OF THE ORGANISM.** — Researches to ascertain the daily requirements of the organism in mineral principles are very few and the results lack precision. To determine the requirements of an animal in lime and phosphoric acid it is not sufficient to establish the difference between the amounts consumed and those excreted. In the faeces are found materials which have played a part in vital processes. For herbivorous animals that is the principal exit of phosphoric acid and in all species, of lime, magnesia and iron. The urine, on the other hand, only contains phosphates which have been utilised by the organism. A certain proportion may have been assimilated during digestion and finding itself in excess in the blood, may be eliminated by the kidneys without having ever had to perform any function whatever. It is the over-supply which flows away. To determine the requirements of the organism, we cannot therefore have recourse to this method of balances. This opinion is confirmed by skilful experimentors such as LAVALARD, JOULIE, GRANDEAU, LEClerc and REGNARD. An exact determination, is not necessary and an

excess of tricalcic phosphate in feeding can do no harm. We may be guided regarding the requirements of growth by the figures obtained by LAWES and GILBERT and which were confirmed by the classic experiment of SOXHLET. However, deviations should occur in the proportion between the skeleton on one side and the fat, muscular masses and moisture on the other side, and according to age, feeding, race and the individual. To the elements determined by growth must be added those utilised for daily maintenance. We may obtain an indication of these in the quantities eliminated in the urine and foeces during a complete fast. But the fact that, in this case, the organism restricts its expenditure should be taken into account. Another factor which must be taken into account is the digestibility, and the influence exercised by the proportion one to another in which the various mineral elements are found in the ration and the predominance of acids over bases or vice-versa.

The author quotes some figures obtained with full grown oxen to ascertain their daily requirements in mineral elements. From their examination he concludes that it is not enough to consider the deficient element, but that the proportions between the various mineral substances should also be considered.

IN WHAT FORM SHOULD MINERAL SUPPLEMENT BE FURNISHED. — The direct assimilation of mineral phosphates was proved by FILLORY. From researches made by KOHLER, we may conclude that :— (1) the mineral phosphates have been assimilated ; (2) the assimilation of tricalcic phosphate has been greater than that of bicalcic phosphate ; (3) the phosphates of degelatined or calcined bones are shown to be decidedly less.

The author adds that bone meal may cause injury.

PRACTICAL CONCLUSIONS. — As a general rule, for herbivorous animals receiving in their rations a sufficient quantity of good herbaceous forage, there is no need to trouble to supply a mineral supplement. With hay of the dry period, or obtained from acid meadows, or when straw largely predominates in the ration, phosphate of lime may suitably be added. It should also be added to the ration of cows in milk or in calf when they get less than 5 kg. of good forage per day. With calves it will always be wise to give phosphate of lime from the time they are weaned, or even earlier if they are brought up on skim milk. Pigs are given foods poorest in mineral salts. The good effects noticed when they feed on clover, lucerne and green forage, are largely due to better mineral nutrition and also to the vitamines furnished by growing plants.

The requirements for maintenance in phosphoric acid and lime are approximately proportional to the live weight, and are the same for all domestic species.

Growth in the pig requires from 1 to 2 gm. of phosphates of lime per 100 gm. of acquired weight. Taking digestibility into account, a pig weighing 50 kg., gaining daily 600 gm. should get from 40 to 50 gm. of precipitated phosphate ; if this supplement is given in the form of bone meal the quantity should be doubled.

R. S.

843 - **The Stock Breeding Establishment at Sidi-Tabet, Tunis.** — GINTEIS, (Director of the breeding Establishment of Sidi-Tabet) in *Bulletin Mensuel de l'Office du Protectorat Français, Tunisie*, Year XIV, No 127, pp 161-164; No. 128, pp. 177-179; year XV, No 129, pp 1-4; No. 130, pp 17-19 Paris, Nov 1921-Feb 1922

The author recommends selection from the best Tunisian cattle and the improvement of these by crossing (1).

(a) *Continuous crossing* tends to substitution of the introduced breed and success depends on the quality of the imported breed. From the standpoint of the improvement of "mixed aptitudes", that is to say for the simultaneous development of meat and milk and draught animals, the Taranto breed is the first to deserve a trial. In case of non success, the Aubrac breed would perhaps be easily acclimatised

To obtain an animal specialised for the production of milk, two breeds possess notable qualities — the Breton and the Montbéliard breeds. Unfortunately their unpigmented parts predispose them to "amra". To avoid this the Bordeaux breed, whose black skin resists the harmful action of the sun, might be tried. At the same time the establishment will try to overcome the obstacles which paralyse the dairy industry in Tunis: — the unsatisfactory character of native labour, want of suitable buildings, severity of the climate, lack of transport

Crossing is of doubtful value for improvement of draught qualities. The Arab ox is such a good draught animal that selection would be sufficient. Crossing should be tried all the same, if only as a comparative method to give greater scope to the experiments and greater certainty to their conclusions. Only the Gascon breed of Ariège or of the Haute-Garonne, owing to its habitat in a warm climate, could be acclimatised in Tunis.

In the case of cattle intended for the slaughter house, improvement in beef qualities will come with other improvements

(b) *The industrial cross* produces cattle of high market value, but unsuitable for breeding purposes. It exercises no influence on the improvement of the breed. The Norman, and also the Dutch breed could be used for the production of milk, the Charolais, the Limousin or the Hereford breeds for the production of meat. The industrial crossing of the Arab cow with the zebu of India should alone be tried for the improvement of draught animals.

The selection and crossing of the indigenous breed will be supplemented by the maintenance of pure bred foreign stock. The results will be compared among themselves, and then with those obtained with the indigenous pure breed and with the various crosses.

Finally, alternative regular or irregular crossing followed by cross-breeding will not be neglected. Several questions suggest themselves — should animals with mixed or with special qualities be sought after? — if dairy farming appears to be the most remunerative, how will the milk be disposed of? — what is the yield of the different methods of fattening applied to various types of cattle? — for fattening calves, can

(1) See R. Jan. 1922, No 81. (Ed)

milk be replaced by substitutes? — in rearing, what is the cost price of the products of different ages? — when should they be sold?

All these questions can only be solved by experiment.

**EXECUTION OF THE PROGRAMME AND RESULTS OBTAINED.** — Such a large programme requires a number of years to accomplished. It has, however, been started and some animals of indigenous breed, some pure-bred zebus and some zebu-arab crosses have been studied and bred. Seven pure bred Arab cows have been bought. Their calves, by good feeding have developed remarkably and are better shaped than their parents. Varying between 10 and 15 kg. at birth, they weighed from 250 to 260 kg. when 18 months old. The bullocks bought from the dealers or in the country districts only weighed 220 to 250 kg. when 28 to 30 months old. This difference already proves how the native cattle can be improved by regular and abundant feeding. For want of a suitable Arab bull, the native cows were put to one of the zebu bulls and produced fine bull and heifer calves. The zebu-Arab cross would be an excellent animal for work were it not unmanageable and vicious. At the age of 24 or 30 months it is already a powerful worker, whereas the country ox does not become strong enough for draught purposes until about  $3\frac{1}{2}$  or 4 years.

The Establishment imported a bull and 2 Zebu cows from Ceylon and now possesses a herd of pure Zebu breed which includes 9 cows. With the object of avoiding too close inbreeding, another bull imported from India, has been used for breeding during the past two years. Most of the heifer calves have remained at Sidi-Tabet. In its new habitat the herd has not suffered any degeneration. In spite of his good shape the first bull gave defective calves. These defects were attributed to the bad influence of the climate, but as the second bull produced better calves, that cannot be the cause. The shape has been kept unaltered and the weight has not diminished, also the health of the herd is perfect, but the cows seem predisposed to abortion. The bulls rarely serve the cows under the age of 20 months or 2 years. Even when full grown and trained for service they will only serve cows which are well disposed to receive them.

**FUTURE PROGRAMME.** -- The purchase of one bull and 20 Arab cows will enable the selection of the race of the country to be undertaken. The purchase of bulls and cows of foreign breeds will render possible continuous crossing and the industrial crossing of the indigenous breed, as well as acclimatising experiments with imported animals.

**SHEEP.** - The sheep supplies 3 products: — meat, wool and milk. Meat is the dominant production; the wool at present has only a secondary importance. Nevertheless it will not be neglected, for its sale considerably increases the revenue of the Establishment.

In Tunis, sheep's milk forms a large part of the food of a considerable section of the population. Attention should be given to improving the milk yield of native cattle. To sum up, while giving the production of meat the chief place, the other products of the sheep should not be over-

looked. It is necessary to decide whether it is better to utilise special milch breeds or dual-purpose animals.

As in the case of cattle, the programme requires the examination of the two following problems: — 1) selection of the best animal, 2) study of the various requirements. To get the best animal two methods are suggested:— (a) the improvement of the native sheep; (b) the importation in mass of foreign flocks.

Whenever the race is worthy of it, the improvement of the native animal is the best method. It will influence every aspect of the case, and might then be followed up by selection and crossing.

In spite of its defects, the sheep of the country does not deserve to be condemned *a priori*. By judicious breeding with the best animals and sound methods of rearing of the lambs, better shaped sheep, heavier, producing more wool and more milk will be obtained.

But selection cannot be the exclusive method of improvement. It is incapable of transforming the thick tail into a thin tail. Innumerable observations have shown that by crossing a thick tailed sheep with a thin tailed sheep the thick tail disappears in the first generation. Owing to the short life of sheep, improvement should be obtained rapidly; this is impossible with selection, the results of which are very slow. Besides, crossing has not such serious drawbacks with sheep as with horses and cattle. Inbreeding will therefore be used for the ultimate improvement of the breed and industrial crossing for the rapid increase in profits. The experiments will bear, simultaneously, on both meat and milk producing races. For improvement of meat production Gran merinos, Berichon, Solognot, will be excellent improvers in extensive breeding. To suit the requirements of intensive breeding the Establishment will try:— Merinos of Soissons and of Châtillon, Southdowns, and Oxforddowns and Dishley Merinos. As regards milk-production three races deserve to be tried:— the Larzac, the Sardinian and the Bergamasque breeds.

The industrial crossing will be practised first of all with the breeds mentioned above and afterwards with still heavier races.

Although importation in mass of a foreign breed should only be an exceptional measure, a few breeds will be maintained under selection at Sidi-Tabet with several objects:— to compare first of all the whole of the indigenous selected animals, the half-breeds produced by the various crosses and the pure animals of the imported breeds; next, to ascertain the breeds which accomodate themselves best to the Tunisia and thus to determine the crosses to be recommended; lastly to provide the colony with rams.

**STUDY OF THE FACTORS.** — Regarding the production of meat, the fattening and sale of sucking lambs, of lambs of 7 to 10 months, of yearlings and of full grown sheep, from the standpoint of milk production, the descendants of the various races and of their cross-breeds will be compared, also the returns from the milk and its products. Is it better to produce the sucking lamb, sold when 3 or 4 weeks old, and then make use of the milk or to fatten the lamb up to the age of 3 to 4 months and not milk the

ewes until after weaning? Lastly in making use of the milk, what kind of cheese will be most profitable to produce? All these questions the Establishment will try to solve.

EXECUTION OF THE PROGRAMME. — Three breeds of sheep are at present being experimented with at Sidi-Tabet: —

- 1) Chatillon Merino,
- 2) Gran Morino improved by TRUELLE;
- 3) Barbary Solognot, established by Madame LAGRENÉE.

In 1917, 12 yearlings of from 16 to 18 months, and 5 yearlings belonging to the Chatillon Merino breed, were bought. Most of these sheep were well shaped and fulfilled the required conditions for an experiment of acclimatisation. Topping, gestation, lambing and weaning took place normally in 1918, 1919 and 1920. Topping commenced in June, lambing in November, weaning in March or April. While suckling, the ewes were fed with hay and grain; from weaning to lambing, they were run in the fields and on the stubble and in the evenings some green food or hay was given to them. The young animals always had hay and a ration of grain and with such a diet the animals were always in excellent condition. Up to the present they do not appear to suffer from the climate. The ewes imported from France have increased in weight and the lambs born in Tunis are as well shaped as their parents.

M. TRUELLE, a noted breeder in Tunis, has formed a fine flock of Gran Merinos and the Establishment bought a lot comprising 6 ewes and 1 ram from him. Since its introduction at Sidi-Tabet the Truelle Merino has prospered. All the animals bought are still in excellent health.

Madame LAGRENÉE had established a fine breed by crossing red legged Algerian ewes with a Solognot ram. Owing to its qualities the Solognot-Barbary cross is one of the most successful. From this flock, Sidi-Tabet purchased 6 yearlings and 1 ram, selected among the sheep which most resembled the Solognot. From all these experiments the following conclusions may be drawn: —

- 1) the possibility of acclimatising the 3 races tried;
- 2) the superiority of the Châtillon over the Truelle, and of the Truelle over the Solognot-Barbary, for good shape, development of the ribs and hind quarters, and richness of fleece;
- 3) the greater facility of lambing and more marked vitality of the lambs of the Solognot-Barbary than of the Gran Merino and specially than of the Châtillon, which seems most sensitive to inbreeding. In short, the Solognot-Barbary appears most likely to prosper on farms where the flock is sent to graze on distant land infested with amra; the Gran Merino is indicated rather in regions free from amra; the Châtillons will do well especially on farms where sheep are bred for the butcher. Lastly, if Tunis wishes to export frozen mutton to the French markets, the Châtillon breed is one which will obtain the greatest success in France.

Other domestic animals are not yet represented at Sidi-Tabet but

the programme of their improvement is worked out. It is the same as that which has been prepared for the horse, the ass, the ox and the sheep.

814 - **Methods of Castration of Domestic Animals.** -- I. TREFFEL, Unblutige Kastration von Bullen, Schaf und Ziegenböcken mit der Burdizzozange, in *Berliner tierärztliche Wochenschrift*, Year XXXVIII, No. 11, pp. 121-123, figs. 3, bibliography of 14 publications. Berlin, March, 16 1922 -- II. SCHIEL, Ueber die Kastration der Haustiere, *Ibidem*, Year XXXVIII, No. 12, pp. 133-135, Berlin, March 23, 1922. -- III. BECKER, Fünfundzwanzig Jahre Kastration mit Sand'scher Zange und Emasculator, *Ibidem* year XXXVIII, No. 20, pp. 231-232. Berlin May 10, 1922.

I. NON-BLEEDING CASTRATION OF BULLS, GOATS AND RAMS WITH PINCERS OF THE BURDIZZO TYPE. -- The use of Burdizzo pincers (so called from the name of the Italian veterinary surgeon who patented them in 1910) is already, very wide spread in practice. The author, who began in 1920 to replace instruments of less recent date by these pincers, details the results obtained and the surgical technique which he has practised in the castration of numerous bulls, goats and rams.

II REGARDING THE CASTRATION OF DOMESTIC ANIMALS. This is a lecture which the writer gave before the Meeting of the Oldenburg Veterinary Association and the Meeting of the Association of Veterinaries of Eastern Prussia. The writer deals in an elementary manner with the different methods of castration of domestic animals, summing up the data of the experience which he has obtained from his long and extensive professional practice.

III. TWENTY FIVE YEARS USE OF THE SAND PINNERS AND THE EMASCULATOR IN THE CASTRATION OF DOMESTIC ANIMALS. The author has used the instruments indicated in the title of the article for 25 years and he has obtained excellent and constant results with them; he sets forth in detail the surgical technique adopted respectively for stallions, bulls, boars, goats, and rams, and makes some remarks on the preceding article by SCHIEL.

#### HORSES

845 - **Survey of Horse-Breeding in Roumania.** -- STAVRILESCU, P. (Chief of the Veterinary Service of the Roumanian Army, Inspector General of the State breeding studs), in *Revue de Zootechnie*, No. 7, pp. 619-629. Paris, April 18, 1922.

Old chronicles, as well as accounts by travellers and representatives of the Great European Powers in the Danubian principalities, are agreed in recognising the superior qualities of Roumanian horses of the 16th and 19th centuries. Even in the pedigrees of the present famous Anglo-Norman horses of the *Nonius* family, there is found at the source in the tenth generation a *Moldavian mare*. The reputation of the Moldavian breed lasted up to the middle of the 19th century. The writer then gives the characteristics of Moldavian and Wallachian horses and of the horses of Dobrudja. The decay of the Roumanian horses dates from 1775, when the Treaty of Adrianople opened the Roumanian ports, and so enabled the wheat of the Danubian principalities to be exported. England offered good prices for Roumanian cereals, the vast grass plains were transformed

into granaries and breeding was neglected. With the introduction of agricultural machinery in 1840 the horses lost their last important work, that of threshing wheat. At the same time after 1785 Austria and Germany became self-sufficing as regards their requirements in horses and Hungary became the chief breeding ground for Europe and supplied horses even to France. Roumanian horses were no longer valued and a complete decay of the race set in. In reality the horses of the ancient Roumanian Kingdom were, and are still today, a mixed breed of ponies varying in height between 1.45 m. and 1.25 m. mostly with short and straight lines. In Moldavia, the Syrian type dominates, next the Persian, the Barb, and the Tartar; in Wallachia, the preceding and the ancient Magyar; in Dobrudja, the Turkish and Barb types and with these the Danish, Percheron and Russian Ardennes types are bred. Owing to lack of care and selection and being in worse conditions than in a wild state, the Roumanian horses have perpetuated themselves during the whole of the 19th century with a tendency to reversion to the wild type, the more so as the best of them were sold while the poorer specimens of the race were kept for breeding. This decay in the breeds of horse was produced as a consequence of the international economic fluctuations leading to all kinds of change. The double agricultural and social evolution of modern Roumania was coincident with rapid progress in animal production in neighbouring countries. Roumania had not the means of correlating her various productive activities, and devoted all her attention to the growth of cereals and learnt too late that Hungary was importing Roumanian wheat, milling and selling it to foreign countries under the Hungarian label and in exchange, in concert with Russia, was sending Roumania her cheap modernised horses. To remedy the bad conditions with regard to horsebreeding a national stock of mares was established in 1864, in 1908, it passed to the charge of the Ministry of Agriculture by whom it was entrusted to veterinary surgeons, who boycotted the English thoroughbred race. However some Arabs and Anglo-Arabs were bought in the south of France, as well as some stout half-bred horses. Of these there were about 350 when the war broke out.

During the war Roumania placed her stallions in Podolia, and not one of them returned. The mares of the country were, during the German occupation evacuated into Germany and to the French front. Thus Roumania found herself practically without horses in 1918. But Bessarabia still possessed a fairly good number of mares, and Transylvania and the Banat had kept during the war several thousand mares of half-bred Arab, half-bred English, Anglo-Norman, Naric, English thoroughbred and American trotter types and as stallions, 200-300 half-bred English and Anglo-Norman. Such was the situation of horsebreeding in *New Roumania* at the Treaty of Versailles.

The offensive of the Hungarian army against Roumania, in 1919, gave Roumania facilities for improving its position for horse breeding as the mounts and teams of the Hungarian prisoner army became Roumanian and mares were bought in occupied Hungarian territory. The number was increased by 800 Hungarian national stallions from depôts in Transylvania

and the Banat or from those captured. Almost all the stallions of the Royal Hungarian Stud of Mezo Hegyes became war booty and were added to the total. With all these elements it has been possible to create the following national horse breeding institutions:— *Military studs* — at Comischani, Ciolan, Zilistea, Jigalia, Hamanzi; *Civil Studs* at Valassont-Boutzida, Fagaras, Partza and Radaoutzi; *Stallion depots* at Constanza, Slobozia, Grasci, Radaoutzi, Homorod and Tournou-Severn.

As large estates have ceased to exist in Roumania since 1917, and the 5 hectares sold to each peasant not being suitable for horse breeding, measures have been taken to establish a national horsebreeding estate of 12 500 hectares to be handed over in lots of 250 hectares to breeders able to produce stallions intended for the improvement of the horses of the peasants.

846 - **Observations on Twin Gestation in Mares.** - REISEL, A. in *Berliner Tierärztliche Wochenschrift*, Year XXXVIII, No. 3, pp. 28-29. Berlin Jan. 19, 1922.

The author states that mares do not generally reach the end of the period of gestation when carrying twins, but that they abort or that the foals which they bear do not live. In confirmation of his statement he quotes three very convincing cases which he observed in 1921. In the light of these cases it may be considered probable that mares carrying twins, if they abort one, can complete the gestation process to the end and give normal birth to the second.

The practical importance of these observations is very considerable for the numerous class of breeders which makes a practice of insuring their mares in foal and their foals: in a case of twin gestation, it may well happen that either abortion is limited to one of the twins and then the breeder, who will have the other twin healthy and normal, has no right to the whole of the insurance benefit, or else that the insurance company considers itself free of risk when an abortion takes place, whereas in reality the breeder must still take the risks of the birth of the other twin. The veterinary surgeon should refrain from ordering or even recommending the washing of the uterus after an abortion, as in such a case this treatment may cause the abortion of the second foetus.

It is possible in the absence of other symptoms to recognise the death of one or of both the unborn twins, when it is known that the teats of the mare in foal swell and begin to function, as is the case physiologically at the end of the period of gestation.

847 - **Limits of the Breeding Age in Thoroughbred Mares.** - WOOD, in *Annales de Médecine Vétérinaire*, Year 67, No. 6, pp. 269-270. Ixelles-Brussels, June 1922.

In order to ascertain the age at which a thoroughbred mare ceases to reproduce, the author who is a member of the Cambridge School of Agriculture consulted the first volume of the General Stud Book, which covers a period of about one hundred years.

Out of 1216 mares for which the dates of birth and of last foaling are exactly recorded, 709 (58.3 %) reproduced at the age of 18 years; 648 (53.05 %) at 19 years; 548 (45.07 %) at 20 years; 457 (37.58 %)

at 21 years; 333 (27.38 %) at 22 years; 248 (19.01 %) at 23 years; 146 (12.01 %) at 24 years; 85 (7 %) at 25 years; 37 (3.06 %) at 26 years; 17 (1.42 %) at 27 years; 7 (0.61 %) at 28 years; 4 (0.27 %) at 29 years; 2 (0.11 %) at 30 years. One mare is recorded as having given birth to a foal at the age of 33 years.

From the above figures it would appear that the reproductive capacity of the mare lasts all her life. The fact that life does not last longer than the period of fertility is undoubtedly due to the state of the teeth, the wearing out of which generally precedes the functional rest of the ovary. For this reason it is practically impossible to fix the epoch of the menopause for the mare.

The author has been able also to ascertain that in a total of 80 stallions death has taken place at the average age of 22.7 years. F. D.

848 - **The Stock of Cattle in Morocco.** LERAY, A. M. in *Revue de Zootechnie*, No. 6, pp. 512-523. Paris, March 15, 1922 (1).

CATTLE

The strength of the Moroccan herds has doubled in the space of 6 years. This remarkable development is largely due to the prohibition of the slaughter of females of less than 8 years old and of bull-calves with less than 4 second teeth.

It is to the relative humidity of its winter climate and to its numerous streams, which do not dry up in summer as do the Algerian and Tunisian "oueds", rather than to the physical and chemical properties of its soils, that Morocco appears to owe its special adaptation for the production of cattle. It has been ascertained that there is in Morocco 1 head of cattle per 15  $\frac{1}{2}$  hectare. In Algeria the proportion is 1 for 50 hectares; in Tunis it is 1 for 26  $\frac{1}{2}$  hectares.

The stock of cattle in Morocco is not homogeneous. In the herds belonging to the native are constantly found individuals which, by their external characters, appear to have resulted from the union of three fundamental types, which the author describes. Generally, it is very difficult to succeed in isolating in the herds an individual which possesses exclusively all the characters of one of these types. However, it would be easy by patient selection to constitute in Morocco three distinct races of cattle. This work is partially realised at Meknès. The author describes this animal and concludes that it resembles all country bred cattle which have not yet benefited from the improving effect of the procedure employed by large breeders. The European colonists, who replace the rough native methods by more scientific agricultural working, obtain better animals, but the data collected are still too few to allow the determination by means of precise figures of the degree of advance in development.

**APTITUDE FOR THE PRODUCTION OF MEAT.** — The cattle of Morocco are subjected, according to the season, to alternate abundance and scarcity of food. The yield of dressed meat of the animals slaughtered, reaches a maximum from May to July and a minimum from November to January.

(1) See *R.* June 1914, No. 544. *R. Sept.* 1917, No. 1253 — *R.* Feb. 1919, No. 226 — *R.* April 1919, No. 413. (Ed.)

and the quality of the meat varies also during the same periods. In spring Moroccan butchers meat compares favourably with that of French feeding, whereas, from September it tends to become tough and stringy. On the average the weight of the 4 quarters is as much as 40 to 55 % of the live weight in Moroccan cattle. The hide of a full grown animal weighs about 30 kg.

**DRAUGHT QUALITIES.** — The natives employ draught oxen almost exclusively for ploughing and require at least 100 000 oxen for agricultural work. With the object of determining the capacity for work of these animals, dynamometric tests have been made according to RINGELMANN'S method. According to the results obtained at Casablanca, the average effort of a Moroccan ox appears to be about 35 kg. This fact requires to be taken into consideration, for it is connected with the problem of the improvement of native methods of cultivation.

**MILK-PRODUCTION (I).** — The author notes the importance of milk production for supplying the towns, the success of milk and butter competitions at Meknès, and the results of comparing the milk record, of cows belonging to a native dairyman of Salé on one hand with those of 31 cows bought in the country and rationally fed on the other hand. These results lead one to conclude that it would be possible to constitute in Morocco herds of indigenous cows giving per head, on an average, in a period of lactation of 10 months, from 1800 to 2000 litres of milk. To effect this it would be sufficient at the outset to form a herd by careful selection, preferably from the black-piebald Meknès breed.

#### 849 - The Importation of Tropical Cattle into the Northern Territory of Australia.

I. Brahmin Cattle for the Tropics, *The Pastoral Review*, Vol XXXI, No. 9, pp. 687, Melbourne, September 1921 — II. W. DAVISON, (Live Stock Expert, Department of Agriculture, Mysore State, India), (Tropical Cattle for the Northern Territory), Notes on Indian Breeds, *Ibid*, Vol. XXXI, No. 12, p. 603, Fig. 1, Melbourne, December 1921.

I. — It is considered advisable that the *Brahmin* breed of cattle should be imported into the Northern Territory of Australia. This breed has been introduced into the South-eastern districts of the United States and has given excellent results; the animals are resistant to parasitic insects and their quality is transmitted to the descendants even when the blood-relationship is only  $\frac{1}{16}$ . The hump, which is characteristic of the breed disappears almost entirely in the half-breeds, in general appearance the animals give the impression of possessing great vitality. They develop well and mature at an early age.

The bulls exceed 17 cwt. in weight.

II. — DAVISON denies the accuracy of some of the above statements; in the first place the name *Brahmin* is misleading and is used in Texas to include all cattle of the species *Bos indicus*. Actually, the term *Brahmin* is applied to bulls of any breed which have been dedicated to a temple or deity. Moreover, these cattle are not immune from ticks which are found in thousands on every animal. There is certainly a marked resistance to

(1) See R. Sept. 1920, No. 893. (*Ibid*)

piroplasmosis, but this resistance is very much weakened in the first cross with European breeds.

DAVIDSON does not agree that the stock mature at an early age; bulls are not fit for service until they are more than two years old, and heifers rarely have their first calf before the fourth year.

As a matter of fact, this slow maturity adds to the cost of production and hinders cattle-breeding in India. Experiments which were recently carried out by the Mysore Department of Agriculture to compare the food value of different rations for half-bred calves, the results of crossing a pure-bred Ayrshire bull with Sindi cows, and pure bred Sindi calves give very convincing results.

The total body-weight increase for the experimental period was 75.5 % in the case of the half-breds, and 43 % for the Sindi calves. It is worthy of note also that the half-breds matured much earlier than the native breed.

The author agrees that some Indian breeds, but not all, are much more resistant to certain epidemic diseases than are cattle from temperate zones. Their export has been chiefly to Texas and the States bordering on the Gulf of Mexico, and also to Jamaica, South America and Java. E. F.

- 850 **Studies on Beef Production.** -- I. HAECKER, T. I., *Investigations in Beef Production, The University of Minnesota Agricultural Experiment Station, Bulletin 103*, 110 p., figs. 11, University Farm, St. Paul, 1921. -- II. POTTER E. L. and WILHYCOMBE, R., *Raising Steers, One on Agricultural College Experiment Station, Station Bulletin No. 182*, 15 pp. Corvallis, Oregon, Sept. 1921. -- III. BLACK, W. G. and SALMON, W. D., *Influence of the Plane of Nutrition on the Maintenance Requirement of Cattle, Journal of Agricultural Research*, Vol. XXII, No. 3, pp. 115-121, Washington, Oct. 15, 1921. -- VI. LEROY, A. M., *Signification physiologique de l'etat des dépenses de la croissance chez les bovidés, formulée par MM. Goutin et Andouard Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI II, No. 10, pp. 501-507, Paris, May 11, 1922.

I. -- STUDIES ON BEEF PRODUCTION. -- T. L. HAECKER'S work is divided into 3 parts: 1) the composition of steers during the different periods of growth and fattening; 2) the relation between the consumption of nutritive units and the accumulation of substances in the organism during the different periods of growth and fattening; 3) the need of digestible nutritive substances for the production of beef.

He makes a study of the composition of steers from their birth until they are slaughtered, dividing the time into successive periods of 100 lb. increase of live weight. The study is based on the chemical analyses of the different parts of the body of 63 animals, and on the record of the food consumed by 189 animals. The analytic data are given in 54 Tables, and the methods of analysis employed are described in an appendix.

Table I gives some of the most important results recorded in the two first parts of the work. The term "total tissue" at the top of the 2nd

column signifies the body weight minus the weight of the digestive organs.

TABLE I. — *Body constituents of steer at different weights, and composition of increases in weight of tissues.*

Live weight in pounds	Body constituents of steer in pounds					Percentage composition of increase in weight of tissues			
	Total tissues	Water	Protein	Fat	Ash	Water	Protein	Fat	Ash
						%	%	%	%
100	84.85	60.94	18.88	3.41	3.62	71.84	19.89	4.00	4.26
200	157.91	111.23	30.24	9.45	6.99	68.83	18.29	8.27	4.61
400	326.60	214.83	63.08	34.63	14.16	61.42	19.46	14.87	4.25
600	487.05	298.05	94.51	73.30	21.19	51.87	19.58	24.17	4.38
800	679.12	398.78	127.72	125.82	28.80	51.40	17.30	27.34	3.96
1000	873.57	454.30	140.29	235.40	34.58	29.58	11.10	56.35	2.97
1200	1085.84	530.55	173.91	351.26	40.12	31.21	11.61	54.58	2.60
1500	1344.90	534.74	211.45	505.60	43.11	24.78	14.49	59.58	1.15

A gradual increase of the capacity of the animals' gastro-intestinal capacity kept pace with the increase in the live-weight.

In the case of steers slaughtered when they had attained the same live-weight, there were greater dressing losses in the animals kept at grass, than in the stall fed animals.

In passing from 45 to 545 kg. of live weight, the increased live-weight of the total tissues was 91 kg.; this was made up of 41.78 kg. of water and 49.22 kg. of dry matter containing 14.28 kg. of protein, 31.62 kg. of fat and 3.32 kg. of ash. The dry matter in the total tissues rose gradually from 28.16 % (live-weight of 45 kg.) to 52.23 % (live weight of 500 kg.). Between 500 and 600 kg. the organism undergoes no essential change in its composition.

It contains 19 %, or more, protein up to a live weight of 318 kg. The protein subsequently diminishes gradually until it amounts to 16.02 % (live weight of 545 kg.) and to 15.72 % (live weight of 681 kg.).

The fat increases from 10.5 to 18.5 % between 182 and 363 kg. of live weight, and from 18.5 to 32.0 % between 363 and 500 kg. Later, the percentage only varies slightly. The amount of ash is very constant viz., 4 % or more between 45 and 409 kg. and 3 %, or more subsequently.

The bones contain a considerable amount of protein and fat. When boiled 4.5 % of the protein, 28.5 % of the fat and 1.07 % of the ash pass into the broth.

The edible part of the quarters is 50 % of the weight in the case of animals weighing 45 kg. and 59 % and 72 % respectively for those of 272 kg. and 545 kg. respectively of the total organic substances (fat  $\times$  2.25 + protein), the eatable percentages are : 50.6 at 45 kg. of live weight ; 66.4 % in animals 2 years of age and 86.6 % when the weight live is 545 kg.

These data show how important it is from the point of view of economic production not to slaughter any but mature animals.

As regards the constituents fixed during the increase in live weight, the following may be noticed among the many mentioned by the author:

There was little change in the amount of water fixed in the tissues for every successive increase of 45 kg.

The animals slaughtered after reaching the weight of 227 kg. or less, had fixed in their tissues 28% of the crude digestible protein ingested; those slaughtered when they weighed between 272 and 363 kg. had assimilated 24.4 % of this protein, and animals sent to the abattoir when they weighed from 408 to 680 kg. had assimilated 20.4 %.

The amount of food (digestible fat  $\times$  2.25 + digestible protein + digestible carbohydrates), consumed to produce 1 kg. increase in live weight was 8.2 kg. for weights from 45 to 363 kg., 6.6 kg. for those between 45 and 681 kg. which confirms the advantage of slaughtering mature animals. The percentage of protein fixed in the tissues was 13.35 of the digestible ingested protein in the case of steers slaughtered when weighing 45 kg., 14.58 in that of steers weighing 136 when slaughtered, and 15.53 — 14.7 — 14.20 respectively when the animals weighed 363 — 454 — 617 kg.

There was a gradual increase in the fixing of fatty substances, 6.06 % between 45 and 901 kg.; 17.34% when the animals weighed 363, 24.35 — 31.28 % when they weighed between 409 and 545 kg., and 36.21 % when their weight was 681 kg.

The amount of ash fixed rose from 3.36 to 3.73 % between 90 and 318 kg., and fell slowly afterwards to 2.8 % at 681 kg.

The total organic products fixed increased slowly from 26.99 % (at 90 kg.) to 85.22 % (at 545 kg.).

It is possible to distinguish a growth period up to 363 kg. and a fattening period after 363 kg. During the first period, more protein is assimilated than fat, during the second, the opposite is the case.

In the third part of his work, the author gives the feeding plans for beef cattle. He bases his remarks on the results of eight years' research and fixes the maintenance ration at 0.4 kg. of crude digestible protein per 100 kg. of protein contained in the organism and allows 1.75 kg. of crude protein to be fixed by the organism. The total necessary food is determined from the protein requirements assuming that the nutritive ratio should be gradually extended, until the animals weigh 409 kg., and from that time should remain 1 : 10.

Assuming grains to mean not only grain, but its by-products (bran, shorts, cakes), and bulky forage to include hay and silage, and increasing by 10 % the amounts actually used in the experiments, in order to better agree with the conditions of practical stock-feeding which cannot be so systematically regulated as in an experiment, the author advises feeding the following quantities in kg. for every 100 kg. of live weight: at 60 kg. 0.7 grains + 0.7 bulky forage; at 91 kg.: 0.9 + 1.3; at 136 kg. 1.1 + 1.7; at 182 kg.: 1.1 + 1.8; at 227 kg.: 1.1 + 1.7 at 250-318 kg.: 1.0 + 1.6; at 363 kg.: 1.0 + 1.7; at 409 kg.

1.0 + 1.6; at 454 kg. 1.0 + 1.4; at 500 kg. : 1.0 + 1.3; at 545 kg. : 1.0 + 1.1 per head and per day.

II. — WINTERING OF STEERS. — Report of 3 different experiments lasting two years in which bulky forage was fed to wintering cattle.

The calves were bought in the autumn and kept when they were given no concentrates, until the end of the second grazing summer.

As a basis for the comparison of other foods a whole ration of lucerne hay was taken (on an average 9 kg. for calves, and 11.8 kg. for steers above one year of age). Straw with the addition of a little silaged forage (4.5 kg. the first winter and 6.8 kg. the second), or a little cottonseed cake (0.9 kg.) produced slow, but satisfactory increases in live weight.

In the first experiment, a lot fed straw and cake attained the same live weight by the time they were sold for the abattoir as the lot fed inferior lucerne hay the first winter and good lucerne hay the second. In the third experiment, one group fed exclusively a full ration of silaged forages (14.5 kg. given to the calves and 21.3 kg. to the steers) increased considerably in live weight during the winter, but their final live weight per head was only 539 kg. as against 594 kg. for the group fed the same ration of silage + 0.9 kg. cottonseed cake. In the same experiment animals that had wintered on lucerne hay alone only attained an average live weight of 563 kg., whereas the others fed a little silage in addition weighed 577 kg.

In all these experiments, one or two groups received during the winter some barley with the lucerne hay, or else barley + lucerne hay + silaged forages, and were sold at the end of the second winter. The live weights attained were not always satisfactory.

The thinnest animals at the end of the winter increased most in weight during the summer grazing, thus regaining 55 % of the difference between their weight and that of the cattle that had been well fed throughout the winter.

From these results the following conclusions may be drawn.

The way in which cattle are wintered does not merely determine the increase in live weight during the winter, but has a great influence also upon the live weight attained during the grazing season, as well as upon the age at which they are ready for the butcher and their final weight and quality. Cattle kept on scanty rations during their first and second winters were not as heavy when slaughtered as the animals that had been liberally fed during that time. On the other hand, the cattle that had grown least during the winter rapidly increased in size during the summer grazing season, while those that had developed most during the winter, lost about half this advantage by increasing little in size when turned out to grass in the summer.

Steers should be kept in good condition during the winter, but large increases in live weight at that season are not necessary or even desirable, unless they can be attained at small cost.

The increase of live weight obtained at grass is always cheaper than that produced by winter feeding, thus the steers should be kept at grass

as long as possible. If early maturing calves are reared, it is well to feed concentrates during the winter, they should not, however, be given to cattle that are to remain at grass during the summer. Where abundant pasturage is available, the rearing of young, early steers fit for the butcher before they are 2 years old pays much better than breeding animals to be slaughtered at the age of 2 or 3 years.

III. — BREEDING BEEF CATTLE IN THE MAIZE ZONE OF THE UNITED STATES (1). — This Bulletin which has been enlarged and brought up to date has been substituted for the Farmers' Bulletin 588 "Economical Cattle Feeding in the Corn Belt" and gives rules for rearing, buying and fattening beef cattle in the maize zone of the United States where the pastures are gradually disappearing and being ploughed up. A summary is given of the results of experiments made at the Experiment Stations of North America, the rations based in this work are recommended, and some of the numerous data collected as a result of an enquiry as to the fattening methods adopted in Indiana, Illinois, Nebraska and Missouri are set out in Tables II and III.

In the general average calculated for the whole maize belt, the average amounts of food consumed by one cow during the winter (5½ months) are as follows: grains 55 kg. + hay 86½ kg. + silaged forage 318 + straw 300 kg. + maize fodder 4.8 ares + maize stalks 65 ares + maize stover 9.7 ares + 4 days winter grazing

*Rations advised for wintering a herd of breeding cattle*

Rations with silaged forages.

1) Silaged forages 13.6 kg. + straw 4.5 kg. + cottonseed cake or linseed cake, 0.5 kg.

2) Silaged forages 11.4 kg. + clover hay, or lucerne hay, 4.5 kg.

3) Silaged forages 16 kg. + mixed hay 4.5 kg. + cotton, or linseed, cake 0.2½ kg.

Rations without silaged forages:

4) Maize-fodder 6.8 kg. + oat straw 4.5 kg. + cottonseed, or linseed cake 0.5 kg.

5) Clover, or lucerne, hay 9 kg. + straw or maize stalks 2.3 kg.

6) Mixed hay 4.5 kg. + mixture of equal parts of maize, bran and oats 2.3 kg. + straw, or maize stalks 4.5 kg.

Wintering rations for thin cattle:

1) Silaged forages 6.7 kg. + clover, or lucerne, hay 1.8 kg.

2) Silaged forages 6.8 kg. + cottonseed, or linseed, cake 0.23 kg. + straw, or maize stalks, 2.3 kg.

3) Clover, or lucerne, hay 4.5 kg. + straw, or maize stalks 2.3 kg.

4) Mixed hay + straw, or maize stalks + cottonseed, or linseed, cake 0.5 kg.

These rations are suitable for one-year-old animals; and must be increased by about one half when the cattle enter upon their second year.

(1) See R. March 1919, No. 33. (Ed.)

*Rations for fattening two-year-old steers (in kg. per 1000 kg. of live weight).*

- 1) Silaged forages 40 + maize 6 + cottonseed, or linseed, cake 3 + straw, or maize stalks, 5; nutritive ratio 1:7.5.
- 2) Silaged forages 40 + maize 10 + cottonseed, or linseed, cake 2 + lucerne, or clover, hay 2; nutritive ratio 1:7.3.
- 3) Silaged forages 30 + maize 15 + cottonseed, or linseed, cake 2 + straw or maize stalks, 4; nutritive ratio 1:9.
- 4) Silaged forages 20 + maize 18 + lucerne, or clover 6; nutritive ratio 1:8.7.
- 5) Silaged forages 40 + maize 15 + linseed, or cottonseed, cake 2.5 + straw, or maize stalks, 4; nutritive ratio 1:8.1.
- 6) Silaged forages 30 + maize 10 + cottonseed, or linseed, cake 3 + molasses 2 + straw, or maize stalks 5; nutritive ratio 1:8.
- 7) Maize 10 + cottonseed, or linseed, cake 4 + mixed hay 10 + straw, or maize stalks, 5; nutritive ratio 1:5.8.
- 8) Maize 10 + cottonseed cake 2 + lucerne or clover hay 5 + straw, or maize stalks, 10; nutritive ratio 1:7.
- 9) Maize 16 + cottonseed, or linseed cake, 2.5 + clover, or timothy, hay 10; nutritive ratio 1:6.8.
- 10) Maize 20 + lucerne, or clover, hay 10; nutritive ratio 1:7.2.
- 11) Maize 15 + cottonseed, or linseed, cake 3 + straw 5 + maize stalks 10; nutritive ratio 1:7.8.
- 12) Maize 15 + cottonseed, or linseed, cake 2 + molasses 2 + legume hay 4, nutritive ratio 1:7.3.

TABLE II. — *Food consumed per head and per 100 kg. Increase in live weight in the maize belt, United States.*

Initial weight per head . . . . .	357 kg
Average final weight per head . . . . .	486 "
Increase per head . . . . .	129 "
Length of fattening period. . . . .	174 days

*Total food consumed per head:*

Grains . . . . .	877 kg
Commercial concentrates . . . . .	79 "
Dry bulky forage . . . . .	504 "
Silaged forage . . . . .	1113 "
Grazing . . . . .	55 days

*Total food consumed per 100 kg. increase in live weight:*

Grains . . . . .	680 kg
Commercial concentrates. . . . .	62 "
Dry bulky forage. . . . .	391 "
Silaged forage . . . . .	863 "
Grazing . . . . .	20 days

TABLE III. — *Method advised for fattening two-year-old steers at grass with supplementary rations.*

Methods	Length of grazing period days	Supplementary food per head and per day
Grass only . . . . .	150	
Grass + maize . . . . .	210	Maize 4.5 kg. to 5.4 kg.
Grass + cotton seed cake . . . . .	210	Cake 1.1 kg. to 1.8 kg.
Grass + maize + cotton seed, or linseed, cake . . . . .	210	Maize 3.6 kg. to 4.5 kg. + cottonseed, or linseed cake 0.5 kg. to 0.9 kg.
Grass for 210 days followed by maize for the last 90 days. . . . .	210	Maize 5.4 kg. to 6.8 kg.
Grass for 210 days followed by maize + cottonseed, or linseed, cake for the last 90 days . . . . .	210	Maize 4.5 kg. to 5.4 kg. + cottonseed, or linseed, cake 0.7 kg. to 1.1 kg.

IV. — CATTLE FEEDING INVESTIGATIONS. — This Circular gives a very good account of the results obtained by 5 different experiments.

During the first experiment of which the object was the maximum economical utilisation of silage in fattening baby beef, lasted 207 days. Two different rations were fed, one containing much silaged forage and a small quantity of grains, and the other little silaged forage and a large amount of grains. Lots 3 — 4 — 5 — 6 (each of 10 head) consumed respectively an average daily ration per head of 3.4 — 9.3 — 5.3 — 6.2 kg. of cane silage; the 5th lot received in addition 0.8 kg. molasses per head and per day. Lots 3 and 4 were fed no maize during the first 120 days of the experiment. The addition of 0.9 kg. of lucerne hay per head daily increased the gains of lots 3 and 5 132 gms. a day, reduced the cost of live weight gain 55 cents per 100 and added 50 cents per 100 to the selling price of the steers in lot 3. The addition of molasses increased the daily gain in live weight and improved the general appearance of the calves in lot 5, but also increased the cost of the gains and apparently reduced the selling price compared to lot 4.

In the second experiment, ordinary mature steers were fattened versus good quality mature steers for 178 days; both lots were given the same ration, cane silage + lucerne hay + cottonseed meal + shelled maize.

The ordinary cattle were big, rough, coarse, plain-headed animals uneven in size and conformation. The good quality cattle were smooth, well made steers with good heads, even in size and conformation. The daily gains were practically the same in both lots, but the quality steers required slightly less feed to produce 50 kg. gain and showed a slightly higher dressing percentage.

The results of this experiment do not indicate that scrub cattle should

be produced, but show that the big, heavy-boned, broad-backed individual makes the greatest and most economical gains, whereas the small fine-boned, tidy animal makes a good-looking fat steer but is expensive and does not fetch a sufficiently high price to compensate for the extra cost.

In the third experiment, the rival merits of silage versus lucerne hay for the development of stock cattle were compared. It was found that steers over 2 years of age if wintered on silage made very satisfactory gains when placed on pasture the following summer.

The fourth experiment deals with the relative feeding value of different kinds of maize silage viz., 1) maize harvested and silaged when in dent stage of maturity; 2) maize cut and silaged 6 weeks later when quite ripe; 3) maize stover cut at the same time as 2.

The maize cut in the dent stage produced 9.47 tons of silage per acre, of which 2.89 tons were dry matter, whereas the maize cut when fully mature, only produced 4.47 tons of silage of which 1.88 tons were dry matter.

These results show that silage made from maize cut in the dent stage has considerably more feed value per acre than maize cut when fully mature, one acre in the dent stage producing 330 kg. gain compared to 200 kg. gain per acre from silage made of maize cut in the fully mature stage.

The fifth experiment was made to determine the relative feeding value of the grain of fully mature maize in silage and the grain of maize that has been husked, shelled, and fed dry. The test indicates that silage from mature maize has a greater feeding value (12% higher), as shown by gains in live weight than shelled maize grain.

V. -- CONNECTION BETWEEN THE AMOUNT OF THE RATION AND THE MAINTENANCE REQUIREMENTS OF CATTLE (1) MESSRS. MUMFORD, HOGAN and SALMON have determined the amount of net energy required for maintenance, basing their estimate on the food consumed and gains made by 10 steers used in the experiments carried out at the Missouri Agricultural Experiment Station.

The animals used in the experiment were divided, while still calves, into three lots, each being kept on a different plane of nutrition. Lot 1 was able to grow rapidly, but did not fatten; lot 2 fed less than lot 1 gained about 225 gm. per head and per day, while lot 3 which received still less food, only gained about 150 gm. per head and per day.

The concentrates fed were whole maize meal, wheat bran and linseed cake (6 : 3 : 1); the bulky forage being usually lucerne hay and straw (3 : 3); a little milk was also given to the calves.

The maintenance requirements were determined during the summer in successive periods usually lasting 180 days. The energy gain and loss due to alterations in weight were reckoned from the data summarised in Table IV.

(1) See R. Mar. 1922, No. 280. (Ed.)

TABLE IV. — *Net energy required for maintenance by the cattle and transformed into live weight.*

Lot	Increase in weight	Energy required for 1 kg. increase in live weight at different ages (in thousandths of calories)						Energy consumed daily for mainte- nance per 1000 kg. of live weight (in thousandths of Calories *)	
		at 6 months	at 18 months	at 36 months	at 54 months	at 66 months	at 78 months	Determined by dry matter method	Determined by Armsby-Fries method
1	Rapid without fatten- ing . . . . .	2.112	2.413	3.879	4.860	5.525	6.63	12.206	12.709
2	About 225 gm. per day	2.112	2.338	2.566	3.116	3.392	3.89	9.912	10.760
3	About 150 gm. per day	1.843	2.086	2.333	2.433	3.269	3.65	8.464	9.742

The maintenance energy required was calculated in two ways: 1) from the consumption of dry matter; 2) from the consumption of digestible organic matter (ARMSBY-FRIES) method (1); the authors consider the latter slightly the more exact.

The digestion coefficients used were taken from the results of the digestion experiments carried out at the Missouri Experiment Station, and the amount of energy necessary for the maintenance of each 1000 kg. of live-weight was calculated on the assumption of its being  $\frac{5}{8}$  of the live weight, according to the results obtained by MOULTON (2).

The data summarised in Table IV show the strict connection between the amount of net energy consumed and the maintenance requirements. Taking at 100 the amount of energy consumed by lot 1 per 1000 kg. of live weight, the net energy consumed is 84.4 % in lot 2, and 76.3 % in lot 3, if calculated according to the ARMSBY-FRIES method, and 81 and 69.3 % if estimated from the quantity of dry matter ingested.

There appears to be no connection between the age of the animal and the amount of energy required for its maintenance.

VI. — THE PHYSIOLOGICAL SIGNIFICANCE OF THE LAW OF GROWTH COST AS FORMULATED FOR CATTLE BY MESSRS. GOUIN AND ANDOUARD. GOUIN and ANDOUARD's law is based on the hypothetical existence of a connection between the growth cost on the one hand, and the daily increase

(1) ARMSBY, H. P. and FRIES, J. A. Net Energy Values for Ruminants, *Pennsylvania Agricultural Experiment Station Bulletin*, 141, 1916; summarised in *R.* March 1917, No. 258.

(2) MOULTON, C. R., The Availability of the Energy of Food for Growth, *Journal of Biological Chemistry*, Vol. 31, No. 2, pp. 389-394; summarised in *R.* April 1918, No. 441. (Ed.)

in live weight of the animal on the other; this correlation is supposed to be independent of the age of the animal.

Of the two portions making up the ration of an animal which is not yet adult, the *maintenance ration* is clearly proportionate to the surface  $S$  of the individual (being connected with the weight  $P$  by a relation in the form of  $S = K \times P^{2/3}$ ); the *production or growth ration* depends on the daily gain  $g$  and the weight  $P$  according to the formule  $C = K^1 \times g \times P$ .

If the values of  $P$  and  $g$  are estimated in kilogrammes it is enough, in order to obtain the growth ration in terms of starch units, to multiply their product by the constant factor 0.005.

LEROY, the Head of the Stock-breeding work of the National Agricultural Institute of Paris, compared the findings by this law with the results of the most recent researches on the growth of animal organisms and states that the two series of results were very nearly the same.

In order to carry out this comparison he adopted the following procedure.

The value of the growth ration is probably in close relation to the daily fixation of energy in the animal's body and this amount of energy corresponds to the heat produced by the combustion of the nitrogenous and fatty substances accumulated every day by the organism. In order to obtain a preliminary approximation it therefore seems permissible to take together the energy value of the growth ration and the energy represented by the growth constituents.

The heat generated by the combustion of the substances fixed in the bodies of animals as a result of growth varies considerably with the age of the individual. The tissues of adult animals are much richer in dry substances and fat than the tissues of young animals.

As equal weights of fat contain 2.2 times more energy than is contained in the other growth materials, equal weights of the tissues formed during the first months of life represent a lower energy gain than the tissues formed later.

A curve could be drawn representing, in function of time, the variations in the energy fixed per kg. of increase in weight in the case of ruminants. As the data for constructing it are too scanty it seems logical to merge the curve, at all events for ages between five months and two years, into a straight line and to assume that the increase in energy per kg. of growth during the corresponding period is a linear function of the time.

The equation of the straight line has the form  $\frac{a}{\alpha} + bt$ ,  $a$  and  $b$  being the coefficient constants.

If  $C$  represents the energy gain per kg. expressed as starch units and  $t$  is the age of the animal in days, the equation of the straight line is as follows:

$$C = 0.9 + 0.0028 t.$$

According to this equation, a two-year-old calf which daily gains 0.800 kg. increases its energy supply by

$$(0.9 + 0.0028 \times 360) \times 0.8 = 1.54 \text{ starch units.}$$

It must therefore be able to obtain this amount of energy from its daily ration in addition to satisfying its maintenance needs.

On the other hand, when young cattle are systematically fed, their daily live-weight gain may be regarded as practically constant and somewhere between 0.5 and 1 kg. according to the early or late maturity of the breed to which the animal belongs. The constancy of this gain makes it possible to calculate the live weight  $P$  of the animal at any age  $t$  by means of the formula  $P = p + gt$ , in which  $p$  is the weight of the calf at birth.

The relation  $\frac{C}{g + P}$  or  $\frac{\text{energy value of growth ration}}{\text{live weight} + \text{daily gain}}$

can therefore be expressed by the equation :

$$\frac{C}{g \times P} = \frac{(0.9 + 0.0028t) \times g}{(p + gt) \times g} = \frac{0.9 + 0.0028t}{p + gt}$$

In animals of rapid growth, this relation can be considered as independent of the time  $t$ , and equal to the constant 0.005.

If in the expression  $\frac{0.9 + 0.0028t}{p + gt}$  the successive values 1 kg. ; 0.9 kg. ; 0.8 kg. ; 0.7 kg. are given to  $g$ , and on the other hand, the values 200 ; 300 ; 400 ; 500 ; 600 days are subtracted from the time  $t$ ; and if we further suppose that the weight of the calf at birth was 40 kg. the values of the relation  $\frac{C}{g \times p}$  given in Table V. are obtained.

It is to be expected that there will be large deviations between the calculated and the real figures. Early maturity, for instance, may alter the results.

TABLE V. — Values of the Relation  $\frac{C}{g \times p}$

Values of $t$ days	Values of $g$ .			
	1 kg.	0,9 kg.	0,8 kg.	0,7 kg.
200	0.0061	0.0066	0.0073	0.0081
300	0.0051	0.0056	0.0062	0.0069
400	0.0046	0.0050	0.0056	0.0063
500	0.0043	0.0047	0.0052	0.0059
600	0.0040	0.0044	0.0049	0.0056

The author compares the data of GOVIN and ANDOUARD with those obtained by KELLNER and by T. L. HAECKER (*University of Minnesota Agricultural Experiment Station Bulletin* 156, 1916) (see Table VI), and

expresses his opinion that the forecasts made according to KELLNERS' rules are manifestly too high, at all events during the first year of growth.

TABLE VI. — *Comparison of the values obtained respectively by GOUIN and ANDOUARD, KELLNER, HAECKER.*

Age of animal in days	Weight in kg.	Daily gain in kg.	Expected value of growth ration			Growth ration actually fed
			According to GOUIN and ANDOUARD $C = K^1 \times g \times P$	According to the formula $C = (0.9 + 0.0028 t) g$	According to KELLNER	
			Starch-units	Starch-units	Starch-units	
218	204	0.750	0.77	1.13	1.68	1.29
280	249	0.750	0.94	1.26	1.87	1.22
238	294	0.750	1.10	1.39	1.87	1.40
400	340	0.750	1.28	1.51	1.88	1.99

851 — **Butter-Fat Percentage of Cow's Milk Increased for Two Days by Partial Milking.** — REGAN, W. M. and MEAD, S. W. (Dairy Department, New Jersey Agricultural Experiment Station, New Brunswick), in *Journal of Dairy Science*, Vol. IV, No. 6, pp. 495-509. Baltimore, November, 1921

In the supervision of advanced registry tests, it is required that cows be milked dry at the milking preceding the test period. This entails considerable loss of time and expense and the question has arisen as to the necessity for the operation.

The author carried out some experiments with Holstein, Jersey and Ayrshire cows. The animals were milked dry twice daily for 6 days; on the 7th day only half the milk was drawn, and during the 4 subsequent milkings, the cows were again milked dry.

Samples were taken at each milking and tested, for butter-fat. It was found possible to increase the percentage of butter-fat in milk during a period of 2 days by leaving half the milk in the udder during the milking prior to the two-day period. Although the average increase in butter-fat was only 0.27 % the data collected seem to show that it is possible to obtain an increase of over 0.5 per cent by leaving a certain amount of milk in the udder, but if too much is left, the contrary effect is produced. The highest fat percentage was not always reached at the milking following the partial milking; it was only attained in 12 out of the 27 trials. As there was an average increase of only 0.766 lb. of milk for the two days following the partial milking, the practice of leaving part of the milk in the udder could not be detected by a study of the cow's milk record.

The data collected in this experiment show that a preliminary milking is necessary as a measure for safe-guarding the accuracy of advanced registry testing.

F. D.

- 852 - **Effect of Temperature on the Fat Percentage of Milk.** — RAGSDALE, Q. C., and BRODY, S. (University of Missouri, Columbia), in *Journal of Dairy Science*, Vol. V, No. 2, pp. 212-215. Baltimore, March 1922.

It is well-known that a correlation exists between the season of the year and the fat content of milk, which is lowest in summer and highest in winter. HECKLES states that this variation is found in the case of cows fed the same rations and in the same period of lactation; it therefore appears to depend directly on differences in temperature.

The authors carried out an experimental test which proved the correctness of this hypothesis. All other factors being equal, and within the limits of the experiment (from  $-3^{\circ}\text{C}$  to  $+21^{\circ}\text{C}$ ), the fat content of milk is highest when the temperature is lowest. F. D.

- 853 - **The Zebu of Madagascar regarded as a Meat Producer.** — CHRÉTIEN, M. (Vétérinaire aide-major de 1<sup>re</sup> Classe, Charge de la surveillance de l'usine de la Montagne d'Ambre [1917-1919]), in *Revue de Zootechnie*, No. 5, pp. 395-409, Paris, Feb. 15 1922.

The author begins with a description of the shape and the method of rearing the Zebu cattle of Madagascar, and the enumeration of the diseases which he has observed during the lifetime of the animal and of its external parasites (1). Although this animal is generally good-tempered, it is not wise to handle it, hence it must be judged exclusively by sight. The author indicates the shape which should be looked for in a good meat-producing animal.

Examining after slaughter the characters of the meat of "herbivorous animals", the first thing that strikes one is the almost entire absence of covering fat. The hump is formed of fatty tissue in the middle of which are buried scanty muscular fibres. The fat of the splanchnic cavities is much less abundant than that in cattle of French races, even of poor quality. In the thoracic cavity the amount of the fatty masses of the mediastine and of the apex of the heart is insignificant. That fat is generally of a very faintly yellowish white. When cut up the various muscular sections appear of a plain shining red. But the muscular juice seems scanty; the grain of the muscle lacks fineness and the "mottled" appearance so much prized in French races is never found. The fat seems to be almost exclusively accumulated in the hump.

**DETERIORATIONS OF THE MUSCULAR TISSUE.** — The author has never noticed meat of the "feverish" or "fever of fatigue" type, nor of "hydrohemia". The muscle was always quite red. On the other hand, local injuries were common and often necessitated large "picking out".

**DISEASES NOTICED AFTER SLAUGHTER.** — These are very few. A few cases of local pleurisy in the thoracic cavity and localised abscesses; some in the region of the scrotum and consequent on castration, others in shoulder parts or on the withers. The other diseases noted and having

(1) See R. Jan. 1919, pp. 1-12. Article by M. George CARLÉ, Stock Breeding in Madagascar, and R. Dec. 1921, No. 1252. (Ed.)

no appreciable effect on the general state of the animals were due to the following parasites.

*Echinococcus*:— in the liver, very rare.

*Filaria of the peritoneum*:— fairly frequent.

*Periligamentous and peritendineous onchoceres (sucking-worms) of the conjunctiva*:— in all the animals.

Out of 108 037 animals examined the author only noticed two cases of tuberculosis. But this disease is much more frequent in the breeding places in the centre and south.

**YIELD.** — It varies little and may be estimated at from 48 to 52 %. The proportion between the weight of the fore and hind quarters is always greater than unity, inversely to that which is the case with improved races. From the 2nd August 1914 to the 31st December 1916 the average net weight calculated on 48 072 animals was 159 kg. From January 1917 to August 1919, the monthly variations in the average net weight varied between 135 and 155 kg.

**UTILISATION OF THE ZEBU OX OF MADAGASCAR FOR MAKING CANNED-MEAT.** — The yield for making the French preserve called "spiced beef" varies from 212 to 236. This figure indicates the quantity of dressed meat necessary for making one kilogramme of preserve including fat and broth. This yield is practically the same as that of French oxen. The author adds that the native staff use all necessary cleanliness in the making of the preserves.

**CONCLUSIONS.** — Although of small size and weight, the zebu ox of Madagascar was valuable during the war, and supplied a satisfactory canned meat. The zebu ox may therefore be recommended for breeding purposes with a view to improvement of the race. The author indicates the measures to be taken and concludes that the native should not be relied on, but that the grant to colonists of large concessions in the regions where there are water holes would enable good results to be obtained.

F. S.

#### SHEEP

854 — **Notes for a History of the French Breed of Sheep of La Charmoise.** — LAPLAND, M. and GARNIER, A., in *Revue de Zootechnie*, No. 5, pp. 447-462 Paris, Feb 15, 1922.

MALINGIÉ bought in 1835 the farm of La Charmoise, at Pontlevoy (Loir-et-Cher), and a flock of Kent sheep of pure breed and particularly well shaped. He then decided to found a race by making the following crossing: *Kent* or *New Kent* × ewe of mixed blood having in approximately equal proportions Solognot, Berrichon, Laurangeau and Merino blood. He obtained a well shaped offspring which presented within a very short time an absolute fixity of characters.

Such is the history of the Charmoise breed.

The question of the real existence of the Charmoise breed arises. SANSON has definitely proved that the Charmoise was not a separate breed while BARON has substantiated a contrary opinion. The authors think that the differences of opinion depend mainly on the understanding of what a breed is. As proof they mention the question of pigmentation. There

is a tendency at the present time to suppress pigmentation, but it is hereditary, and when MALINGIÉ established the Charmoise breed the constituent races were all slightly pigmented. Nor is it either useful or important that the Charmoise breed should be depigmented, for this question does not affect the meat. However, if the pure breed is to be at all times what it ought to be, it is certain that it changes continually; and, for the sheep of the Charmoise race, the causes of variation from type are:— 1) a natural geological cause; 2) artificial causes:— selection and crossing.

In 1919, the estate of Vaulx-de-Cernay in the neighbourhood of Paris bought a lot of about 120 sheep (ewes, tegs, lambs and rams).

In 1920, more than 65 % were eliminated and only 41 ewes were retained. On January 26, 1921, the estate acquired from M. TH. VAILLANT of Guélis his flock of pure Charmoise race. This flock had been purchased in 1859 from M. Ch. MALINGIÉ, and was one of two lots which constituted, on the death of M. MALINGIÉ senior, the founders of the Charmoise breed. It is on these two flocks, one bought in 1919 and the other in 1921, that the authors have made their observations. They first of all made an ocular examination of the type of Charmoise sheep in the group at Vaulx-de-Cernay and in the group coming from M. VAILLANT of Guélis, and afterwards a detailed examination in the course of which they passed successively in review the cephalic type, the pigmentation, the weights and the measurements. They concluded that it is quite remarkable to see how much the characters have remained alike after 70 years, in groups having the same origin; that the Charmoise breed is as homogeneous and as pure as any other; and that some evolution of the types is a necessity and is of general occurrence. F. S.

**855 - Sheep of Catalonia, Spain.** -- CASABOSCH, D., in *El Cultivador Moderno*, Vol. XII, No. 3, pp. 3-4, figs. 2. Barcelona, March 1922.

According to the writer there remain now in Spain very few flocks in which crossing with some foreign ram (Leicester, Cheviot, etc.) has not been tried, which is unfortunate, as the country possesses the founders of the renowned Merino race, which has been used for improving breeds in so many countries and has given rise to the fine and numerous sheep of South America. In Catalonia the sheep are of three principal races:— "Valle de Ribas", "Sagarrenca", and "Pallars" or Catalonian properly so called. This latter has its centre in the country of Pallars; it is hornless (with the exception of a few horned individuals); the head is straight in profile; the fleece white marked with black on the head, especially round the eyes; the head, legs and belly are not covered with wool, which is fairly open, heavy, excellent for making mattresses, very much in request for cloth, its staple being fine, long, undulating, soft, without coarse hairs, and of regular diameter; this race is a good milk producer, as for 2 months after weaning half a litre of milk per day is obtained. The second show of rams of the Catalonian race took place recently at Valle di Aneo. The prize winners (all of the Pallars race)

gave the following measurements:— average height 77 cm. length 116 cm. thoracic girth 98 cm. breadth between the haunches 24 cm. The purchase of the wool is made by monopolists, by weight without any classification; the author urges that at the Shows the classification of wool should be taught to breeders, and that they should arrange to have it applied.

F. D.

**856 - Romney Marsh Sheep in New Zealand.** — MATTHEWS, A., in the *Pastoral Review*, Vol. XXX\*, No. 12, pp. 963-965. Melbourne, December 1921.

The typical Romney Marsh sheep is hornless, well-covered with wool, broad and flat between the ears, which are large and thick and covered with fine hair or down. The muzzle is full and not too white in the ewes, and broad and masculine in the rams; the eyes are large, bright and prominent; the nose is coal-black; the neck strong and thick and well-planted on the shoulders, which are broad and level with the back. Relatively high shoulders are characteristic of bad travellers. The chest is large and deep; the back straight; the loins wide and flat; the ribs well-sprung and giving a round appearance to the body; the rump is wide, long and well-rounded; the thighs well set down and developed. The tail ought to be set almost level with the chin, as ewes with low set tails are often bad breeders; legs should be short with big bones and the trotters large and black. The fleece should be close, not tangled and as uniform as possible in quality from head to tail; the wool long and crimped, lustrous and soft and easily combed; it should be free from patches of white hair which are hard and brittle and cause difficulties in woollen manufactures. A clean, pink coloured skin is an indication of good health and constitution.

The sheep of this breed are very prolific and are able to thrive from sea-level up to an altitude of 5 000 to 6 000 feet. They were introduced into New Zealand in 1853 from Kent and the purity of the breed has been maintained by fresh importations from the Home Country.

The first flock book for New Zealand was published in 1895 and recorded 51 Romney Marsh Flocks. Since then there has been a steady increase in numbers and in 1920 the Flock Book records a total of 139 470 head of this breed out of a total of 287 000 for all breeds (1). There has also been a great improvement in quality and New Zealand Romney Marsh sheep compare very favourably with those raised in England. The local breeders have always been careful in selection until they have in course of time produced some of the finest examples of the breed, carrying wool wherever it is possible to grow. Moreover the wool is so comparatively soft that Romney Marsh sheep are used for crossing with Lincolns to tone down the harshness of the Lincoln wool.

Before the Great War the export of Romney Marsh sheep was on a fairly large scale, mostly to North and South America; this was interrupted by the outbreak of hostilities but has been resumed and

(1) The predominance of this breed is especially noticeable in the North Island; — 88 967 Romney marsh sheep out of 133 846.

must grow considerably, not only on account of the intrinsic value of the breed but also because the number of sheep raised in New Zealand so far exceeds local requirements.

E. F.

- 857 - **The Present Condition of Merino Sheep Breeding in Australia.** — I. The World's Live Stock, *The Pastoral Review*, Vol. XXXI, No. 10, p. 784. Melbourne, October 1921. — II. ABBOTT, W. E., The World's Supply of Merino Sheep, *Ibidem*, Vol. XXXI, No. 12, pp. 964-965. Melbourne, December 1921.

In 1891, Australia possessed 106 million sheep, of which over 100 million belonged to the Merino breed; before the War, the number had fallen to 83 046 000, and in 1920, there were but 73 002 000 sheep including only 50 million Merinoes. Thus, within the short period of about 30 years, the stock had decreased 50 %, in spite of the fact that from 1891 to the present day, many million acres have been laid down to pasture, while enormous sums have been expended on the improvement of already-existing pastures. This great reduction in the flocks has been concealed to a certain extent by the rapid rise in the price of wool which has kept up the export returns.

In the author's opinion, the diminution in the number of sheep is due to two main causes: 1) the serious increase in rabbits; 2) the attacks of the blue fly (*Calliphora* spp.) (1), an insect to which Merino Sheep are more susceptible than any other breed.

The author severely criticises the Rabbit Control laws passed by the Australian Government and asserts that on a property where the poisons have been continually spread for 10 to 15 years, all the small carnivora and insectivorous birds have been destroyed, thus leaving the field clear for the invasion of rabbits and the blue fly.

F. F.

- 858 - **The Effect of Food upon the Fat Content of Goat's Milk.** — SHEELY, F. J., in *The Scientific Proceedings of the Royal Dublin Society*, Vol. XVI, Nos. 35-39, pp. 478-488, diagrams 3, bibliography of 11 works. Dublin, 1922.

GOATS

The author attributes the contradictory results obtained by his various predecessors who have experimentally studied the effect of food upon the fat content of milk to the fact that most of the animals were in good condition and liberally fed, so that any changes due to alteration in diet were difficult to detect. Moreover, as one food was substituted for another, the part played by the different constituents of the ration had also to be taken into account.

For these reasons, he decided to devote his attention to the question, but instead of choosing a cow for his experiments, he took a goat of the old Irish breed. After determining the amount of food required to maintain the live weight and normal milk yield of the animal, the author added various quantities of simple foods such as roots, farinaceous substances and soy bean oil and observed their effect upon the fat content of the milk.

(1) See: *R. Dec.* 1918, No. 1374 (*Ed.*)

The rations fed per head and per day were :

- A) 37 days : hay *ad. lib.* + mangels 6.4 kg. + crushed oats, bran and brewers' grains 0.68 kg.
- B) 21 days : hay *ad. lib.* + mangels 4.5 kg. + skim milk powder 0.58 kg.
- C) 24 days : Ration B + 0.21 kg. soy-bean oil.
- D) 11 days : ration C, without the mangels.
- E) 21 days : hay 0.45 kg., turnips 4.5 kg. + oats 0.38 kg.
- F) 20 days : Ration E + 0.23 kg. of soy-bean oil.
- G) 23 days : Ration F + 0.23 kg. of soy-bean oil.
- H) 17 days : hay 0.45 kg. + turnips 4.5 kg. + oats 0.38 kg.

The passage from ration A to ration B produced no change in the quantity of milk, but decreased its fat content.

The passage from ration C to ration D caused a considerable decrease both in the amount of milk and in its fat content.

The passage from ration E to ration F caused no change in the amount of milk, but the fat content was increased.

The passage from ration F to ration G did not alter the milk yield, but increased the fat content.

The passage from ration G to ration H produced no change in the amount of milk, but reduced the fat content.

The same results were obtained with all three goats used in the experiment.

It might be assumed therefore that in the case of the goat, a considerable reduction of the ration may cause a lowering of the fat content of the milk.

In order to obtain an increase in the percentage, and total amount of fat in milk, starch, fatty substances and protein can be substituted for one another ; when the minimum of protein is to be given, equal quantities of starch and of casein can be interchanged.

Foods added to the ration gradually lose their effect in increasing the fat percentage of the milk as the fat content approaches its maximum, but there is a progressive rise in the live-weight, or milk yield, or even of both together.

#### PIGS

859 — “ **Large Black** ” Pigs in Italy. — I. La razza Large Black, *L'Industria lattiera e zootecnica*, Vol. XX, No. 5, pp. 57-59, fig. 1 Reggio-Emilia, May 1922. — II. FRACANZANI, G. A., Il maiale Large Black, in *Allevamenti*, Vol. III, 5th part, pp. 163-164, fig. 1. Palermo, 10 May 1922. — III. BONDON, C., La suinicultura I Stanga di Grotta d'Adda, in *Il Coltivatore*, Vol. LXVIII, No. 11, pp. 342-345, figs. 4 ; No. 12, pp. 374-376, figs. 2 Casale Monferrato, 20 and 30 Apr. 1922.

I. — Two new races of pigs are at present recommended in Italy for mixed rearing “ *semibrado* ” (for keeping in styes alternating with free pasture) : — the English “ *Large Black* ” and the American “ *Po-land China* ”. The former which is obtained in the South of England by crossing the local breed with the Chinese pig and with the Caserta breed, has shown, on the whole, greater hardiness and precocity than the Yorkshire ; it is better suited to pasturage and more resistant to heat. Its offspring, however, does not always reach the weight of the Yorkshire

The most important breeding centre of this race in Italy is in the zone of Reggio Emilia, where conditions are very favourable, and it is possible to utilise the by-products of the cheese industry, which is so important in the district; the pigs which are slaughtered attain the enormous weight of 2 qx. to 2 ½ qx. In the provinces of Bologna and Forlì, pigs are killed over 2 and even 3 qx in weight. Often these heavy weights, are given by crosses of Yorkshire with the Romagno or with the Tuscan. If the production of great weight is aimed at, the Berkshire does not meet with much favour as it produced smaller pigs.

But the Large Black can give the same weights as the Yorkshire, and has also the advantages mentioned above; it therefore seems perfectly justifiable to recommend its diffusion. Meanwhile, in the Royal Dépôt of animal improvers at Reggio Emilia, Large Black boars have been introduced and it has been noted that they are very suitable for giving fresh blood to the descendants of degenerated Yorkshire sows, several breeders have made use of them for industrial crossing in the first generation with the Yorkshire.

At the Royal Dépôt at Reggio Emilia, the following facts have been ascertained. — a Large Black sow of 2 ½ years gave birth to a litter of 6; she suckled 5 of them; they had at birth a weight of 2.5 kg; 30 days later, 8.18 kg.; in 60 days, 15.7 kg.; in 90 days, 28.7 kg.; the same sow, at the age of 2 years, gave birth to a litter of 8; she suckled 7, the weights of which were: — at birth, at 30, at 60, at 90 days, respectively 2.7 kg.; 8.0 kg.; 26.5 kg.; a Large White sow of 1 ½ years gave birth to a litter of 6, she suckled 5 of them; the weights — at their birth — at 30, 60, 90 days, were respectively, 2.3 kg.; 9.0 kg.; 19.0 kg.; 29.0 kg.; the same sow at the age of 2 years produced a litter of 8, all of which she suckled; their weights — at birth, at 30, at 60 days were, respectively, 2.03 kg.; 7.7 kg.; 16.1 kg.; a Large Black × Large White sow of 2 ½ years produced a litter of 12; she suckled 11 of them; their weights — at birth, at 30, 60, 90 days were respectively, 2.1 kg.; 7.3 kg.; 14.0 kg.; 24.0 kg.

The data relating to the weights of the breeding animals of both sexes and of the two races at the age of 3 to 11 months show that on the whole they are about equal.

II. — Dr. FRACANZANI, in rearing the Large Black, has noted that it stands heat and is fairly resistant to humidity, provided it is not too prolonged, and as compared with the Yorkshire, it is less exacting as to food and housing; it is hardier and the flesh has more flavour. One of his boars, purchased from the STANGA breeding establishment, weighed 418 kg and had the following measurements: — length 1.92 m.; height of the forequarters 0.94 m.; of the hindquarters 0.96 m.; thoracic girth 1.68 m.

The sow gives plenty of milk, is very docile and gives good results even when reared in preference on pasture; she can be fed on good lucerne hay chopped, or still better on clover; and benefits very much from a certain amount of oil-cake in the clover months.

In a breeding station at Porto Recanati (Province of Pesaro), for animals kept at pasture supplemented by concentrates, the weights of 145 to 185 kg. — 233 — 286 — 329 — 319 to 351 kg. were obtained respectively at the age of 9 — 13 — 16 — 19 — 23 months.

III. — Description of a large Establishment for breeding pigs established at Grotta d'Adda (province of Cremona) by Marquis Idelfonso STANGA (1) and specialised for the production of breeding animals of pure race.

During the fine weather, the animals are often kept on pasture; the basic ration consists of maize meal, chopped lucerne (obtained with the SMALLEY chopping machine, "tankage" (meal of meat, blood or fish) to which a mixture of mineral substances is added. When in winter the pigs cannot enjoy pasture, they are given marcita.

At present three races. — Large Black, Poland China, Chester White are mainly being bred.

The Large Black race is gradually replacing the Large White, especially in Central and Southern Italy, for it is more vigorous, more suited to "semibrado" rearing, and responds better to the requirements of the market for the qualities of its flesh. The Poland China was imported for the first time directly from the United States into Italy by the Marquis STANGA in the autumn of 1920, and the Chester White in the summer of 1921. These two races are also very vigorous and with suitable treatment, can give a high yield.

The crosses Large White  $\times$  Large Black have been very successful with customers.

The Establishment also breeds on a smaller scale the Large White, Berkshire and Gloucester Old Spot races.

**860 - Remarkable Specimens of Pigs of the Iberian Breed, in Spain.** — *La Industria pecuaria*, Vol. XXIII, No. 724, pp. 101-103, figs. 4. Madrid, March 1922.

The heavy weight reached by pigs of the Iberian breed, raised on pasture and fattened by feeding with acorns in the district of Jaburgo, Sierra Morena (Spain), is reported.

Pigs of 2 years old, and even less, gave an average live weight of 230 kg. and animals of about 3 years old gave an average live weight of 368 kg.

One specimen in the latter group had the following measurements:— length 1.85 m.; thoracic girth 2.22 m.; height at withers 1.10 m.; width of the quarter 0.57 m.

These results show to what degree the Iberian breed can be perfected: it is a race remarkable for its hardiness and the choiceness of the meat and lard which it produces.

- 861 - **The Effect of Breeding on Immature Sows.** — I. MUMFORD, F. B., *The Effect on Growth of Breeding Immature Animals*, in *University of Missouri, College of Agriculture, Agricultural Experiment Station, Research Bulletin* 45, 37 pp., diagrams 12, bibliography of 8 works. — II. *IDEM*, *The Effect of Lactation on Young Sows*, in *The Breeder's Gazette*, Vol. LXXXI, No. 7, p. 217. Chicago, February 16, 1922.

I and II. — The following facts have been observed by the author during the course of a long series of experimental researches :

Although gestation does not retard growth in sows, lactation hinders development, for however liberal the food supply, it is all used in the production of milk, and at the end of the lactation period, the sow is found to have lost considerably in weight and to some extent in height and length of body. A young sow of the same age, but not suckling pigs increases in weight and size during the same period of time.

This arrest and therefore retardation of development is not, however, permanent, for the rate of growth between two successive lactation periods is greater than in the case of young unfertilised sows. The compensation is only partial, for it has been found by careful measurement that if a sow is fertilised at the first heat period and produces two litters a year while she is growing, she will be actually smaller at full maturity than an animal that is not fertilised so early. Further she will not reach full maturity till one year later.

It should, however, be remarked that the difference in size is never sufficient to have any real commercial significance. E. F.

- 862 - **The Bresse breed.** — VOITELLIER, CH., in *Revue de Zootechnie*, No 7, pp. 703-709, Paris, 15 Apl. 1922.

POULTRY

The high price of eggs and poultry since the war has certainly been the predominant factor in the extension of practical poultry keeping which is to be noticed in every part of France. For some reason or other, the people who proposed to start or to improve a poultry farm, gave their preference to the Bresse breed, and it is a question whether the choice is justified. A very marked current of opinion had already set in, in the last ten years before the war, in favour of poultry without any superfluous attributes, such as tufts, over-developed combs, throats or peculiarities of plumage which are regarded as unfavourable to good maintenance or to the good health of the poultry. Everywhere, on farms, any other kind of country residence, where a fixed space is allotted to poultry, whether relatively large or small for the number of birds, where specialisation is required and intensive production of eggs indicated, the only points to be considered are the real aptitude of the fowls to transform their food into eggs, the weight and colour of the eggs, and the conditions of the laying. The larger breeds, obliged to consume more up to the time when their growth is almost complete and the first egg is laid, have for that reason been eliminated as soon as their productivity was proved not to be exceptional. Everywhere where there was no local breed answering to the conception of the ideal hen from a practical standpoint, people were led by one inference after another to adopt the Bresse breed, and especially the typical black variety. It was blamed for its

small size, but it was also known that its flesh is very delicate. It was also noticed that the search for a big fowl was generally a mistake, because on the market the fowl of medium or small size, found more purchasers and was finally bought at a higher rate per kilogramme. However, there was no certainty as to its laying capacity. In adopting it, one had only a relatively good chance of finding individuals that were very good layers. If unsuccessful, one was at any rate in possession of a good breed for table purposes. This was, to sum up, the reasoning generally adopted.

As a matter of fact, the forecast of its laying qualities have been partly realised. The large number of fowls of this breed shown at the last Grand Palais Show enabled the judges to lay down precisely their views regarding external characters. They gave prizes only for fowls with combs and gills of fine texture and medium size, with well marked pure white ears, with long bodies, wide and deep behind, with well set tails making a decided obtuse angle with the line of the back.

Grey or white varieties, rather larger in size, possess the original qualities of the black and it is quite possible that, if submitted to methodical selection, they would quickly give similar results. F. S.

863 - **A little known South American species of Fowl: - the "Colloncas de Aretes" of Chili (*Gallus inauris*).** — CASTELLO, D (Director of the Royal School of Poultry Rearing at Arcnys del Mar), in *Bassa Corte*, Vol III, No. 54, pp 1161-1164. Mola-sana (Genoa), June 1922.

The writer found in Chili a species of fowl which, although very old, is unknown to poultry rearers in Europe and North America, and to most of those in South America; according to the description given in his report "Avicultura en las Américas latinas" presented to the Universal Congress of Aviculture at the Hague (1921), this species received the name of *Gallus inauris*, that is to say ear-ring or (more accurately) tufted fowl. The birds are characterised by a small crest which has a spheroidal tuft of feathers, on both sides, over the ears, and by the complete absence of tail, due to the non-existence of the vertebrae of the coccyx.

The dimensions are normal or slightly less than normal, the plumage is very varied (the finest fowls are white or white with red wings); the eggs have a greenish blue shell, sometime spotted with brown.

In South America these fowls are called "colloncas", that is to say tail-less, or "de aretes" that is to say with tuft, or (combining both features), "colloncas de aretes.

The author and Dr. Bustos exhibited a selected group of these fowls at the Santiago de Chili Show in 1914.

This species is found not only in Chili, but also in Bolivia, Peru, Colombia and Ecuador; it is largely kept by Indians.

Crossed with European breeds, it lays bluish eggs. From several historical, philological and zoological sources the author concludes that it is a case of a native species derived from a wild race which has now disappeared, and differing from the *Gallus Bankiva*, the original source

of the fowls of the American continent, and from breeds imported from Europe into America.

F. D.

864 - **Egg Laying Characteristics of the Hen.** — DRYDEN, J. in *Oregon Agricultural College Experiment Station, Bulletin 180*, pp 1-96, Tables 74, figs 26. Corvallis, Oregon, Aug. 1921.

Results of breeding experiments begun in 1908 with Barred Plymouth Rock and Single Comb White Leghorn pullets. The cross-breeds known as the Oregon breed gave 201 eggs the first year, Plymouth Rock, 164 and White Leghorn 183.

During certain years selection was based on trap-nest records, but as a rule laying hens were chosen according pedigree. The annual production was increased by removal of unsatisfactory layers but individual variation was still evident, ranging from 0 to more than 300 eggs in a year.

This variation does not appear to be a breed characteristic. The highest individual record among the Barred Plymouth Rocks was 308 and the lowest 3; for White Leghorns, 302 and 1 respectively; for Ore-gons, 309 and 14. Breeding has apparently no definite effect on decrease in variation; the range between high and low remains almost the same.

The highest egg record for one year was 218 for the foundation stock; this was increased to 308 for the pedigreed stock. In one case with 17 super-quality hens (laying 300 eggs or more), a record of 330 eggs was secured.

The hens of high record stock gave a marked increase in production over the unselected, poor-laying foundation stock; high fecundity is therefore hereditary. Regardless of any question of prepotency, the selection of breeding stock on the basis of high production record is a certain method of increasing production.

Certain individual cases showed greater power of transmitting high fecundity than others. More satisfactory progress will be made, therefore, if only hens and cocks are selected for breeding which are already noted for transmitting this characteristic. The average egg production the first laying year was less when the parents were selected from the highest produces than in subsequent years, but in certain individual cases the production was exceptionally high the first year.

The best layers continue to maintain the increased egg production; selection gives in reality a higher rate at the end than at the beginning of the year.

The number of eggs laid during the two most active months, March and April, is a fairly accurate basis on which to select good laying hens. Late laying in the summer and autumn does not always indicate a good layer.

The highest egg production is obtained in the first year; the following years there is a decrease. The greatest decrease was with hens with highest first year records; when the production was very low the first

year, there was on an average an increased production in the second year.

There appears to be a correlation between rate of laying and the fat content of the eggs. F. D.

## BEE-KEEPING

865 - **Studies on Bee-Keeping in the United States.** — I. DEMUTH, G. S., Swarm Control, in *Farmers' Bulletin* 1198, *United States Department of Agriculture*, pp. 47. Washington, June 1921. — II. MILNER, R. D. and DEMUTH, G. S., Heat Production of Honey bees in Winter, in *U. S. Department of Agriculture, Bulletin* 988, 18 pp., diag. 4, December 5, 1921. — III. PHILLIPS, E. F., The Occurrence of Diseases in Adult Bees, in *U. S. Department of Agriculture, Department Circular*, 218, 16 pp. bibliography of 23 works, March 1922.

I. — **THE CONTROL OF SWARMING.** — The author discusses the factors contributing to the tendency to swarm and to natural swarming and the best means of prevention. He then gives a detailed account of the most important measures of swarm prevention viz:

1) Careful selection of stock in breeding as some strains of bees have a stronger tendency to swarm than others.

2) The use in the spring of brood-chambers and hives large enough to hold the maximum amount of brood without crowding.

3) The use of good worker combs in the brood chamber to obviate a reduction in the available brood-rearing space.

4) The arrangement of the brood combs so as to avoid placing barriers in the way of a free expansion of the brood nest during the spring.

5) Providing extra space for the bees within the brood chamber by wider spacing of combs and a deep space below the frames.

6) The use of large entrances during the swarming season, especially when the weather is hot, and in some cases, additional openings for ventilation.

7) Protection of the hives from the direct rays of the sun by the use of shade-boards or double covers, or by painting the hives white, especially the cover.

8) Preventing the building of barriers of sealed honey around the brood-nest, or breaking down such barriers if they exist.

9) Inducing the bees to occupy supers as soon as the honey-flow permits during the first half of the season, or when the colony is rapidly increasing.

10) Providing extra combs for the ripening of the nectar, so that the field bees can dispose of it as soon as they reach the hive, to prevent any stagnation of the activities of the colony.

11) Removing some of the emerging brood to reduce the number of emerging bees within the brood-chamber, thus producing a better distribution of the bees throughout the hive.

12) The destruction of the queen-cells, provided they have been but recently started. Frequently however when they have been destroyed, other cells are immediately formed.

Finally, as a remedy for swarming, the bee-keeper relieves the con-

gestion of bees within the brood-nest by creating conditions comparable either to the swarm, or to the parent colony in nature.

II. — HEAT PRODUCTION OF BEES IN WINTER. — Continuation of the researches published in *U. S. Department of Agriculture Bulletin*, 93, 1914 (1).

A small colony on 4 combs having natural honey stores was placed in the chamber of a respiration calorimeter and their carbon-dioxide production and oxygen consumption were measured for 10 days while the temperature of the air surrounding the bees was kept just low enough for them to remain clustered. There were 14 thermo-couples distributed in the hive in the calorimeter so as to register the temperature of different points inside and outside the cluster. The temperatures were read every half hour day and night for about 12 days. The readings were plotted on charts, and the results thus obtained led to the following conclusions.

In the colony of bees under observation in the respiration chamber, the expenditure of energy was reduced to the lowest limit by the maintenance of a favourable temperature and the avoidance of all disturbing factors.

In these circumstances, which are rarely found in the apiary, the energy developed by the bees as measured by the carbon dioxide and water produced and the oxygen consumed was greater according to body-weight than that developed by a man engaged in hard manual labour when it is realised that the work was done by only a few of the bees in the cluster. Even assuming that the work of the period was equally distributed among the bees, their energy output per unit of body weight is higher than that of the average labourer. Since bees do not usually have such favourable conditions in winter, it is clear that the energy output is enormous in the average apiary.

III. — DISEASES OF ADULT BEES. — The diseases so far known and of which the causes have been revealed by laboratory research are the following. 1) Isle of Wight disease, 2) Nosema disease due to *Nosema apis*; 3) indirect toxic effects of spraying with insecticides containing arsenic salts.

The Isle of Wight disease, caused by *Acarapis (Tarsonemus woodi)* (2), does not exist in the United States, according to specimens sent from the most different parts of the Union for examination by the author. In order to ascertain whether it could be introduced from Great Britain, where it appears to be widely spread the author had two infected hives sent out from England. When the first arrived all the bees, as well as the parasites, were dead; the second arrived with both bees and mites alive. Thus it is proved that the disease can easily be introduced by the importation of infected colonies.

(1) See: *R.* Oct.-Dec 1919, No. 1211; *R.* July 1921, No 748. (Ed.)

(2) See: *R.* Feb. 1920, No. 243. (Ed.)

The *Nosema* parasite already exists in the United States, and is even common there, but it seldom produces serious disease in adult bees in that country.

866 - **The Winter Care of Bees.** — WILSON, H F, in *Agricultural Experiment Station, University of Wisconsin, Bulletin* 338, 26 pp figs 7 Madison, Wis., January 1922  
Practical rules for intensive bee-keeping.

The death of the bees during the winter entails great losses to bee-keepers in Wisconsin (the average winter losses for the entire State are from 15 to 20 %, and sometimes run as high as 30 %), and throughout the northern part of the United States

Successful wintering is, however, possible if the hive is well supplied with good honey and the colony has a queen not more than two years old whose maximum egg-laying period has not been reached. All artificial feeding should be done before November 1. The place where the bees are wintered is of little importance provided other conditions are suitable. The temperature of the bee-cellar must be about 45° to 50° F. Too much ventilation in the cellar may cause serious losses among the bees in winter. The insects must be well protected and sheltered from the prevailing winds in spring, they should be put into their winter quarters early and removed at the beginning of spring, when, however, they still require protection. Bees ought not to be disturbed from November 20 to March 21 and should be kept in absolute darkness

The fundamentals of spring care are: protection during April and May, a large amount of stores, not less than two hive-bodies. Every colony must be provided with more stores than it seems likely to be able to use (40 to 50 lb). A strong colony will need throughout the spring season from 75 to 100 lb of honey or sugar syrup, and if the bees cannot get it in the field, the bee-keeper must supply it

## FARM ENGINEERING.

### AGRICULTURAL MACHINERY AND IMPLEMENTS

867 - **Electricity and Agriculture** (1). — MATTHEWS, R B (Institution of Electrical Engineers), in *Journal of the Royal Society of Arts*, Vol LXX, No 3620, pp 367-368, London, April 7, 1922

The problem of increasing the yield from the numerous small holdings in England and Wales has directed attention to the possibilities of use of electricity on the farm in districts where it is difficult to use gas and coal for machinery etc

The author points out the economic advantages to be derived from electric lighting for cow sheds, the improvement in cleanliness, reduction in waste of milk, cattle food etc. by providing adequate light in habitually darkened buildings. In addition the electric motor can be readily utilised for machine work, for chopping cattle food, working churns, milk separators etc. Such motors are easily handled and require a minimum of la-

(1) See R. Feb. 1920, No 243 (Ed.)

bour. The fact that hay can be dried artificially by means of electrically driven fans gives the farmer more control over his crops and makes him more independent of the weather. Successful results with electric heating for the prevention of frost amongst stores of roots and vegetables have been reported and also for drying fruit in bottling factories etc. The use of electric heat has also already proved its value for incubation purposes, and has given an increased yield of eggs at a time of year when they are of the highest market value. There are undoubtedly great possibilities in its application to milk sterilisation, and ensilage purposes.

Recent experiments on a practical scale have demonstrated that an extremely small amount of electrical power converted in a suitable apparatus to a very high tension and discharged from overhead wires strung across the fields has a remarkable effect upon most forms of vegetable life, increasing yield and in many cases advancing the period of harvest. Although it is at least possible that this effect may be rather in the nature of a stimulant than a food, and due to some effect upon the plant which improves its power of absorbing and assimilating nutriment from suitable soil, there is already sufficient evidence to justify careful and continued research in this direction (1).

M. L. Y.

868 - **Posts supporting Agricultural Electric Wires.** — SOURISSEAU, J. H. (Director of Agricultural Mechanics at Toulouse), in *Journal d'Agriculture pratique*, v 37, No 18, p 365-368, 5 fig Paris, 6 May 1922

In the consideration of any scheme for the distribution of electricity to farms the question of the durability of the supports of the electric wires should receive attention. Experience has shown that any large-scale undertaking for the distribution of electric power is impossible, if it is liable to frequent replacement of the supports. It is necessary therefore to know what kind of post should be adopted for the transmission of electric power to farms. Iron posts are costly to install and to maintain, in spite of of paint many are attacked by rust, chiefly near the ground, and their resistance rapidly weakens in the critical section where the post enters the ground. Posts of re-inforced concrete are difficult to make on the spot and still more costly than iron posts; moreover, their average durability is not yet sufficiently proved by experience. For agricultural lines the wooden post is most suitable but it rots very quickly. Untreated pine posts have an average life of 4 to 5 years, and from 9 to 10 years if they have been treated; fir posts untreated last on the average 7 to 8 years and 12 to 14 years if treated. Their « life » is often less, so that most specifications limit replacement by the contractor at his own expense to posts which become rotten during the second, third and fourth years.

The causes of decay in the wooden posts are in the ground and in the air. The foot of the post rots in the ground chiefly in the 30 cm below the surface of the ground, owing to the attacks of parasitic fungi, which

(1) See R. Nov. 1910, pp 20, 38, 40; R. 1911 Nos. 81, 543, 1175, 1709, 1788, 2684; R. 1912. Nos. 70, 641, 1076, 1282; R. 1913 Nos. 167, 266, 727; R. 1914 Nos 263, 604, 775, 89; R. 1915. No. 17; R. 1916. No 1260; R. 1917. Nos 753, 1202, 1206; R. 1918 Nos. 10, 255, 383, 453, 891, 1085, 1272; R. 1919. Nos. 99, 166, 686, 720; R. 1920. Nos. 273, 245. (Ed.)

grow in the soil and gradually penetrate into the wood ; in very moist soil, in addition to the rotting, decay is also caused by the small mollusks, known as teredos. Above ground the untreated posts are destroyed by termites and borers, followed by alternations of dryness and humidity, the cracks allowing the germs of decomposition to pass inside the wood.

The most effective protection of wood is given by creosote.

The treatment is as follows: the posts, after drying in the air, are further dried to cracking point in a stove by a current of hot dry air, the cracking of the posts does not weaken their resistance under the strain of the wires or under the pressure of the wind, but on the contrary insures that no new crack will open later when the post is in use, the post dried and cracked artificially often loses as much as 20 % of its weight. After drying the posts are placed in a large cylinder in which a vacuum is created by pumping, and the cylinder is then filled with creosote under a pressure of 10 atmospheres, this pressure enables the creosote to penetrate by the cracks to the heart of the posts. The posts thus treated with creosote turn black, and hence are known as "black posts."

Black posts, put up in 1905 and examined by the writer in July 1921 remained in a perfect state of preservation. The author further ascertained that the parts not cracked by the drying before treatment did not crack under atmospheric influences in the course of 17 years service, and that as creosote is insoluble in water, the body of the wood was nowhere affected by rain water. The author also made experiments, in July and August 1921, on the conductivity of the posts. To establish the amount of current conveyed in the two systems, untreated and treated fir posts were set up alongside each other. A thin wired line was attached to the top of the posts by turrets without insulators, the wires of the line were 0.50 apart. An ampèremeter placed on one of the wires indicated the intensity of the current passing along the posts in the test, a voltmeter gave the tension between two of the wires. The values found are given in the following Table.

Posts tested	State of the surface of the posts	Tension in volts	Intensity in ampères
5 black posts of fir 8 m. treated with creosote in 1920 and 1921	dry	536	0.064
	after spraying with water by means of a vine dresser's spray	540	0.070
5 fir posts 9 m. untreated	dry	540	0.250
	after spraying with water by means of a vine dresser's spray	540	5.250

Experiments made on posts treated and set up in 1905 have given currents of intensity sometimes equal to those of the posts treated in 1920 and 1921 and sometimes weaker. To sum up it may be stated that the untreated

ed posts should be provided with insulators. With the black posts, the loss of energy between the wires due to conductivity is small, hence the wires can be fixed directly on to the posts, provided that the current is not utilised when it rains and in the intervals between working. F. P.

### AGRICULTURAL INDUSTRIES.

869 - **New Type of Copal Oil from the Belgian Congo.** — PIERAFRITS, J., in *Cono*, year 3, Vol I No 4, pp. 550-555 Brussels, April 1922

Report of tests and chemical analyses of specimens of copal seed oil from plants growing near Kinda (District of Lulua) in the Belgian Congo, known locally as "huile de m'Pafu".

The question whether the seeds which provide this oil, come from the *Copaifera Demensei* or from distinct species is still unsettled.

The data obtained for the fatty acid content and general characteristics of the oil indicate that it is of distinct commercial value. It may be classed with the non-drying oils, and although attention should be paid to the possible, though improbable, existence of a toxic element, the oil is a homogeneous product, with an agreeable taste, while its somewhat unattractive greenish colour can easily be remedied by the addition of animal charcoal and washed infusorial earth and subsequent filtration.

It is considered that this oil can be utilised advantageously in the manufacture of margarine and the remaining stearin in the soap factories, pharmacies, and in the fabrication of nutritive fats, for which its high fatty acid content makes it very suitable.

The residuary oil could be used for scent-making and as a table oil.

M. L. Y.

870 - **Apparatus and Methods of Analysis for Dairy Industries.** — I FASCIETTI, G., *Apparecchio commerciale per la rapida determinazione del latticello e del grasso nei burri naturali ed artificiali*, in *Annali dell'Istituto sperimentale di Casale in Lodi*, Vol 1, No 2, pp 71-74 Lodi, April 1922 — II DELLA TORRE, G., *Un nuovo termoregolatore elettrico a mercurio*, *Ibidem*, pp 75-77, fig 1 — III VARACOS, G., *Metodo rapido, per la determinazione del grasso nei formaggi*, *Ibidem*, pp 79-81

I. — The apparatus suggested by Prof FASCIETTI for the rapid determination of whey and fats in natural and artificial butters is composed: — of a butyrometer, consisting of two glass tubes of which the lower, with the narrower diameter, contains a scale graduated in fifths of a cubic centimetre, of a centrifuge giving 300-400 revolutions a minute; of a colouring matter (hydroalcoholic solution of methylene blue); of a fluidising liquid (pure amyllic alcohol) and of a water bath; 25 gni. of the sample to be examined is placed in the butyrometer, it is immediately raised to a temperature of 80°-90° in the bath, it is then taken out and one drop of the colouring matter and 5 cubic cm. of the fluidising liquid are added; it is next corked; shaken up; replaced in the bath and after heating for 5 minutes it is centrifuged and with another 5 minutes interval centrifuged for a second time, it is lastly allowed to cool to body temperature, and the volume of the blue column is read; this reading multiplied by 4 gives the percentage of non-fatty matter.

INDUSTRIES  
DEPENDING  
ON ANIMAL  
PRODUCTS

II. — The thermoregulator invented by Dr. DELLA TORRE has been used, with success, for 5 years at the Laboratory of Bacteriology at the "Istituto sperimentale di Caseificio in Lodi". It consists of a glass tube with a bulb at the base, almost completely filled with mercury on which floats a T shaped pin, one of the horizontal arms of which is in contact with mercury fixed on an insulating substance, while the other is in contact with a small platinum plate fixed in the same insulating substance. If the temperature exceeds the desired limit, the mercury expands, the pin rises and moves the other arm from the small platinum plate, thus breaking the circuit. The apparatus is regulated by raising or lowering the part which carries the mercury tube and the plate.

III. — A rapid method for determining the fats in cheeses, invented by Prof. FASCETTI and tested by VARACOS has given, when compared with the SCHMIDT-BONDZYNSKI method, very slightly different results and therefore merits consideration. The process is as follows: — weigh into an Erlenmeyer tube 2.3 gm. of grated cheese; add 10 cubic cm. of sulphuric acid diluted in the same volume of water; place in a bath at a temperature of 80°-85° shaking constantly, after complete solution, decant the liquid into the butyrometer, wash the tube with 5 cubic cm. of dilute sulphuric acid, which is poured into the butyrometer; repeat the washing; add 1 cubic cm. of amyl alcohol; cork; shake; keep for 5 minutes at 65-70°; rotate in the centrifuge for 5 minutes, replace in the bath and read bath at the height of the layer of fatty matter. F. D.

871 — **Correlation between the Quality of Cream and Butter and the Yeasts and Oidia they Contain.** — REDFIELD, H. W. (U. S. Bureau of Chemistry New York City), in *The Journal of Dairy Science*, Vol. V, No. 1, pp. 14-21, bibliography of 11 works, Baltimore, January 1922

This paper gives a description of the technique to be adopted for the determination of yeasts and oidia in cream and butter, and an account of the method used in estimating the correlation between the quality of these products and the number of micro-organisms they contain.

The actual number of bacteria present in freshly made butter is of little importance. The addition of the starter introduces so large a factor of the purely acid type of organism as to dominate the bacterial flora at this stage. The other groups which were only occasionally represented showed a significant number of organisms. Many individuals of the peptonising group occurred only in butter of very poor quality. The number of yeasts and oidia found, however, suggested the possibility of attaching some significance to this determination.

As a rule, low-grade samples show high counts of these micro-organisms, but discrepancies occur frequently enough to indicate that other agents are also capable of causing deterioration in dairy produce.

## PLANT DISEASES

### GENERAL INFORMATION

872 — Various measures adopted in France for the Control of the Potato Colorado Beetle (*Leptinotarsa decemlineata*) (1).

I. — Act of the 13th July 1922, supplementing the provisions of the Act of 15th July 1878, regarding measures to be taken for arresting the progress of *Doryphora decemlineata*. — *Journal Officiel de la République française*, Year LIV, No. 189, p. 7371. Paris, July 14 1922.

Art. 1. — The provisions of the Act of July 15, 1878 as to the measures to be taken to arrest the progress of *Doryphora decemlineata* are applicable to cultivated plants other than the potato, when such plants have been, by decree of the Minister of Agriculture, made on the advice of the Comité des Epiphyties, declared liable to attack by *Doryphora*.

Art. 2. — A credit of 500 000 fr. for expenses of all kinds in view of the application of the Act of July 15, 1878 and of the present Act, is opened for the Ministry of Agriculture under the general budget for the year 1922, in addition to the credits granted by the Act of 31 December 1921 and by special Acts.

Art. 3. — When a farmer has made regularly the declaration provided for in Art. 9 of the Act of July 15, 1878, an indemnity may be granted to him in proportion to the portion of the crop attacked which it has been possible to save.

Art. 4. — The Act of 15 July 1878 is modified so far as it contravenes to the present Act.

2. — Decree of July 13, 1922 prohibiting the entry into France and the transit of potatoes and their leaves and refuse coming from the United States and Canada. — *Ibidem*, p. 7418.

Art. 1. — The entry and transit in France of potatoes, and their leaves and refuse coming directly or indirectly from the United States and Canada, countries where the existence of *Doryphora decemlineata* of Colorado has been ascertained, are prohibited. This prohibition also applies to boxes, barrels, sacks and other packing in use or having been used in the transport of the above mentioned produce.

Art. 2. — The prohibition contained in Art. 1. above will be applic-

LEGISLATION  
AND  
ADMINISTRATION  
FOR  
PLANT  
PROTECTION

(1) See also No. 897 of this Review.

able also to consignments of fresh fruit and vegetables other than potatoes and their leaves and refuse, as well as to material used in their transport and packing, when the presence of *Dor decemlineata*, has been ascertained on such consignments

To give effect to this measure, the said consignments will be specifically examined for the purpose on arrival in France

3 — Decree of July 13, 1922 declaring that crops of tomatoes and egg-plants are liable to attack by *Doryphora* — *Ibidem*, p 7418

4 — Decree of July 13 1922 as to measures to be taken to check the progress of *Doryphora*. — *Ibidem*, p 7418

Art 1 — As soon as the appearance of *Doryphora* has been reported in a Department, the Prefet shall immediately appoint with himself as Chairman, a Committee of control composed of the Director of the Agricultural Department, the Director of the Entomological Station for the Department, the Inspector of the Plant Disease Service, the President of the Agricultural Department Office, and 4 leading agriculturists. This Committee will be charged with the duty of giving advice on all measures to be taken in the Department to check the propagation of *Doryphora* and to insure its destruction

Art 2 — An order of the Ministry of Agriculture will fix the limits of the areas attacked and infected by *Doryphora*. Over the whole extent of the Departments in which the areas so defined are situated and of the neighbouring Departments it is incumbent on farmers to burn on the spot immediately, after the harvest, the dead leaves and bad potatoes or the refuse left on the ground

Art 3 — A decree of the Ministry of Agriculture will fix the limits of the control zones to be established around the said attacked or infected areas and the measures to be taken to prevent the propagation of *Doryphora* therein

Art 4 — Preventive treatment with arsenite of lead should be prescribed on crops attacked or infected by *Doryphora* as often as may be necessary during the growth of the plants. When these treatments are considered insufficient, the Prefet, on the motion of the Committee of Control, shall request the Ministry of Agriculture for authority to prescribe the destruction of the crops of potatoes, tomatoes and egg-plants under the conditions fixed by the Acts of July 15, 1878 and July 13, 1922. Trap crops may be prescribed when this procedure is considered likely to prevent the dispersion of the insects and the creation of fresh centres of infection

Art 5 — In the Departments in which are situated the areas attacked or infected by *Doryphora*, the Ministry of Agriculture may place at the disposal of the Director of the Agricultural Department, as a temporary measure, agricultural experts taken from the Service in other

Departments, and in sufficient number to assist him in his duties and to direct on the spot, in accordance with his instructions, the work of control or destruction, to watch for the appearance of the insect in the zones where it is likely to be encountered and to assist the supervision service charged with determining during the winter the centres where the work of control should be started at the beginning of spring

Art 6 — The potatoes, tomatoes and egg plants and their leaves and refuse harvested in the regions declared, by decree of the Minister of Agriculture, to be attacked or infected by *Doryphora*, or in the control zones provided by Art 3 of the present decree, may not be consigned and transported in any manner whatsoever, to places in the uninfected regions

The products above enumerated and harvested in regions other than those indicated in the preceding paragraph may not, if they have been introduced into the said regions, be re-consigned or re-transported, in any manner whatsoever, to places in the uninfected regions

The same prohibitions apply equally to boxes, barrels, sacks and other packings used for the transport of the products indicated above and also to manures, composts, soils or earths

The packing material used in the regions indicated in the first paragraph of the present article for the transport of potatoes, tomatoes and egg-plants from the place of harvesting to the estate of the grower or to market shall be cleansed and disinfected by washing or steeping in boiling water

873 — Ministerial Order of May 27, 1922 announcing the Precautions to be taken against the Propagation of the "Argentine ant" (*Iridomyrmex humilis*), in Italy. — *Gazzetta Ufficiale del Regno d'Italia* (Extraordinary), No 173, p 1752 Rome July 24 1922

In virtue of Articles 2 and 22 of the regulation of March 12 1916 No 723 (1), the "Argentine ant" (*Iridomyrmex humilis* Mayr) (2) has been included in the list — inserted in Art 4 of the Ministerial order of September 28, 1919 (3) — of plant pests of which the Ministry of Agriculture is empowered to decree compulsory destruction

The control of the "Argentine ant" is therefore obligatory in the localities where it has been found and it should be undertaken upon the responsibility and at the charges of the interested parties

The rules and methods of control will be fixed by the Royal Regional Observatories of Plant Diseases

The superintendence of the operations and the execution of the official measures of control will be carried out by the staff of the Observatories, at the cost of offenders or defaulters

(1) Cf — INTERN INST OF AGRIC *Annuaire international de législation agricole*, Vith Year (1916) pp 875-887 Rome 1917 (Ed)

(2) See R June 1920 No 102 (Ed)

(3) See R Oct Dec 1919, No 1260 (Ed)

The Provincial Prefects in whose districts invasion by the "Argentine ant" is notified, shall proceed to the formation of compulsory control Groups in the manner prescribed in Art. 38 of the above mentioned Order.

G. T.

### DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN

874 - "Gummosis" in Chestnut Wood. — DUFRENOY, J in *Comptes rendus des séances de la Société de Biologie*, Vol LXXXVI, No. 7, pp. 371-374, figs. 4 Paris, 1922

Gum is deposited in the wood of various plants as the result, for example, of parasitic infection. In the vessels, this gum may come from the degeneration of the thyllae. Woods, like that of the chestnut, which normally form thyllae, exaggerate their formation under parasitic stimulation: some old chestnut trees, suddenly killed by the "maladie de l'encre" have the transparency of their vessels completely obscured by the more or less marked gummosis of the thyllae.

Gum may be deposited in the woody vessels in the absence of thyllae, as in the ligneous cells. A pronounced "gummy" condition may be observed in the wood of the radicles formed by Chestnut trees affected by the "maladie de l'encre" even when these radicles are terminated by luxuriant mycorrhizae.

Gum specially invades the wood laid bare by cauline or radical cankers. This histological gummosis, which produces the gum of wounds, is mainly superficial and local. The gummosis caused by the thyllae is deep and extensive. These two forms of gummosis should be distinguished from that which comes from the gelatination of the middle layer of the membranes.

G. T.

### DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

#### GENERAL

875 - Bacterial Plant Diseases in the Isle of Luzon in the Philippines. — WELLES, C. G., in *Science*, New Series, Vol LVI, No 1436, p 18 Utica, N Y, July 7, 1922.

It is well known that fungus diseases are numerous and destructive in the Philippines, though up to the present time very few bacterial diseases have been reported so far at any rate as concerns Central and Southern Luzon where scientific investigations have been carried out

Tobacco and other Solanaceous as well as some non-solanaceous plants are attacked by *Bacterium Solanacearum* E. F. S., a micro-organism that has undoubtedly been introduced with certain host plants from temperate regions.

Citrus trees are attacked by *Pseudomonas Citri* Hasse; cabbages by *Ps. campestris* (Pamm.) E. F. S.; beans by *Ps. Phaseoli* E. F. S.; cotton by *Ps. Malvacearum* E. F. S., and parsley by a micro-organism

not hitherto described. These are the only bacterial diseases affecting economic hosts in Luzon so far as present information goes (1).

With the possible exceptions of the bacterial diseases caused by *Ps. Citri* and the hitherto undefined disease of parsley, none of the other diseases and none of their respective hosts are native to the Philippines. There is no doubt that these diseases were imported, and generally with their hosts, from temperate regions. G. T.

MEANS  
OF  
CONTROL

883 - *Helminthosporium* sp. on Rice in Madras. — SUNDARARAMAN, S., in Agricultural Research Institute, Pusa, Bulletin No. 128, pp. 1-7, pl. 4. Calcutta, 1922.

DISEASES  
OF  
VARIOUS CROPS

During the year 1918-19 great damage was done to the rice crop in the delta tracts of Godaveri and Kistria, and a fungoid disease was observed particularly in fields where growth was somewhat poor.

After microscopic examination this disease was traced to a new species of *Helminthosporium* seen on the leaves, the leaf sheaths and the glumes. On the leaves small spots were noticed with a brownish central portion in which smoky black spots appeared visible on both the upper and lower leaf surfaces. These increased in size and frequently united so that the whole area turned brown. Sometimes the entire leaf withered, dried up and turned yellow. Weather conditions play an important rôle in the spread of this disease; heavy and continued rains and cloudy muggy weather favour development. In advanced stages when panicles appeared on plants which showed a severe form of disease, the grains also were effected. Sometimes also the nodes are attacked and

(1) According to ERWIN F. SMITH (*An Introduction to Bacterial Diseases of Plants*, Philadelphia and London, W. B. Saunders Co. 1920, p. 54) some other diseases may be found to occur in the Island. (Ed.)

blackened when the plants approach maturity. Black spots appear on the surface of the glumes and the enclosed grains are found shrivelled up and discoloured.

The fungus was isolated from diseased spots on the leaves and a pure culture obtained. The spores germinate readily in water. A long series of inoculation tests were made with leaves, leaf sheaths and panicles of rice from July 1920 to February 1921. The larger proportion of inoculated plants contracted the disease: spots were formed but these did not develop far. The plants used for control purposes were healthy throughout. The results of the inoculations confirm the field observations made, namely that the fungus in question is, under normal conditions, a weak parasite, and that the disease should not cause serious damage to the crop. G. T.

884 - *Sarna (Oospora Scabies)* on Potatoes on Island of Chiloe (Chili). — See No. 827 of this Review.

885 - Diseases of Cotton. — See Part I and No. 828 of this Review.

886 - *Thielaviopsis paradoxa*, a Hyphomycete injurious to the Coconut Palm in the Presidency of Madras. — SUNDARARAMAN, S., in *Agricultural Research Institute, Pusa, Bulletin* No. 127, pp. 8, pl. 6. Calcutta, 1922.

Many of the coconut palms in the Presidency of Madras are attacked by a malady known under the name of the coconut stem-bleeding disease, of which the first symptom is the oozing of a dark reddish brown fluid from any crack that may be present on the surface of the stem. This exudation turns black as it dries. Below the bleeding portion the tissues decay and turn yellow. In the early stages of the disease, the discoloration or decay of the tissues is localised. In advanced stages, when more than one bleeding patch is seen, a general decay of the internal tissue takes place.

When this point is reached, the palm ceases to bear nuts, the crown dwindles and the tree dies. The effect produced on young trees is worse, especially if the base is attacked. In these cases the outer patches give no indication of the internal decay. The inner soft tissue rots, and a cavity is formed in the central portion of the stem in which a thin yellowish fluid accumulates that gushes out when an incision is made in the cavity. If the decay extends downwards, the tree becomes hollowed out, though there is no external sign of disease. The only thing to be done is to take up the whole tree, carefully removing every bit of the root and burn all on the spot.

The cause of the stem-bleeding disease is the *Dematia Thielaviopsis paradoxa* (de Seynes) von Höhnelt.

Inoculation experiments made in the laboratory at Coimbatore on palms grown in large pots have shown that the fungus can only infect the plants when the stem is injured, or cracks formed on its surface.

The progress of the disease seems to depend upon the age of the host plant. If the infection is localised, the easiest and most effective remedy is the removal of the diseased parts. These should be cut out and

also for greater security some of the healthy tissue, which is easily distinguishable being flesh-coloured, while the diseased tissue is yellowish-brown.

Tar should then be applied to the wound after the wet surface has been dried by scorching either with a lighted torch made of coconut leaves or with a cloth dipped in oil and tied to the end of a stick, in order to insure the proper adherence of the antiseptic. The pieces cut out of the tree should be carefully collected and burnt.

The treatment above described was applied to 100 coconut palms at Sholavandan in the Madura district which were found to be attacked by the disease in September 1918. Two years after treatment the trees were found to be free from disease, quite healthy, in full leaf and bearing heavy bunches of nuts.

G T

887 - *Sclerotinia carunculoides*, n. sp. Discomycete on Mulberry in South Carolina. — SUGLER F. A. and JINKINS A. I. in *Science*, new series, Vol LX, No 1512 pp 353-354. Utica N. Y. G. March 31 1922.

A disease of the cultivated mulberry (*Morus alba*) characterised by the misshapen fruits, has been observed by ORTON and recently by TAUBINHAUS.

The authors have traced the cause of this disease to a new species of *Sclerotinia* known as *Scl. carunculoides*. The fungus was collected in March 1921, at Scianton (S. Carolina).

G T

888 The Mucedin *Monilia cinerea*, found on the Leaves of the Peach Tree in Piedmont, Italy. — CIFERRI R. in *Il Coltratore*, year LXVIII, No 16, pp 501-502. Casale Monferrato. June 10 1921.

In the spring of 1921, drooping leaves of a young peach tree were collected in the Province of Cuneo. The author noticed on them, in addition to small galls due to an unknown agent, the Aphid *Anuraphis persicae* Boyer the Mucedin *Oidium leucoconium* Desm. and the Dematia *Helminthosporium macrocarpum* Grev = *Monilia cinerea* Bon., which in Europe, does not normally live, on the leaves of the host-plant.

## WEEDS AND PARASITIC FLOWERING PLANTS

889 - *Biological Studies on Cuscuta Epithymum* var. *Trifolii*. — CAMPANILI, G., in *Rivista di Biologia*, Vol IV Part 2 pp 175-202 pl 2. Rome, 1922.

Preliminary contribution to the study of the biology of *Cuscuta Epithymum* Murr. var. *Trifolii* Bab.

For his numerous experiments the author used seeds of the parasitic Phanerogam taken from a single lot of Abruzzi lucerne.

The presence of the host-plant (lucerne), in any stage of growth, has no influence on the germination of the parasite which develops even with scanty and intermittent moisture and lives and grows just as well as in a constantly moist environment.

There is a connection between the permanence of the seminal tegument and the comparatively rapid drying of the radical swelling while

the swelling disappears immediately owing to bad hygroscopic conditions the tegument remains longer, protects the extremity of the stalk during the dry period and insures to the plantule a longer life than the unfavourable conditions of the environment would have given.

Shoots of *Cuscuta* detached from the mother plant, apart from their host and under dry conditions, have lived for about a month behaving self destructively and while they dried up at one end, they grew at the other.

Severe attacks by *Cuscuta* were noticed on vigorous hosts as well as on plants whose growth was poor

The behaviour of *C. Epithymum* var. *Trifolii* does not appear to be clearly parasitic except at the time of the formation of its flowering branches; up to this stage, the parasite contents itself with surrounding the host-plant near the base; when the flowering branches have grown they reach the top of the lucerne plants, which they envelop closely and the host rapidly perishes. Disturbing the parasite during the flowering period would therefore prevent the lucerne from exhausting itself and giving poor yield on the resumption of vegetation.

Spring sowing, mixed cropping and generally all factors which help to delay the first cutting of the lucerne until the parasite has already grown its floral branches, are unfavourable to the host-plant, and if the first mowing of the lucerne field is made in the second year, the parasite is quite free to flower, fructify and heavily infect the ground. On the other hand, the factors which shorten the growth period of the lucerne, such as irrigation, influence unfavourably the propagation of the parasite

Tricalcic phosphate and sulphate of potash seem to cause a certain immunity in the host-plant. Organic manuring would have an indifferent action, but as it gives a greater succulence to the tissues of the host, it favours a large development of branches in the parasite

Depth of sowing to avoid infection by *Cuscuta* is not a method of control that is advantageous to the lucerne, because from this point of view the resources of the parasite are much greater than those of the hostplant.

The process of "devitalisation" of the seeds of *Cuscuta* by means of heat seems scarcely to be a practical method, because at the temperatures recommended there is always a diminution in germinative activity and a reduction of germinating power in the lucerne. Heating to a temperature of 65° for 2 hours is the only method which could be of use. As a matter of fact, it is almost innocuous to the germinating power of the lucerne and also as has been ascertained by the previous experiments, this temperature causes a considerable lowering of the germinating power of *C. arvensis* and *C. Trifolii* (1)

To eliminate seeds of *C. Trifolii* from the seed of lucerne, sieves with holes 1.25 mm must always be used.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS

890 — **New African Coleoptera.** — BRYANT, G. E., in *Bulletin of Entomological Research*, Vol. XII, Pt. 4, pp. 473-475, figs. 4, London, Feb. 1922

GENERAL

Description of the following species

1) *Crioceris viridissima*, n. sp. injurious to *Asparagus* sp. in various localities in Kenya Colony

2) *Cercyonia citri*, n. sp., widely distributed on the Gold Coast, where it has been observed as seriously attacking young trees of *Citrus* spp.

3) *Argopistes oleae* n. sp., the larvae tunnel out holes in the olive leaves, found in Cape Town

4) *Arg. sexvittatus*, n. sp. found in Cape Province, Natal and in Orange Free State, where holes are observed in leaves of the wild olive

G. T.

891 — **The Cochineal insect *Icerya purchasi* in Provence (1).** — GUILLAUD, E., in *Revue de Viticulture*, Year XXIX, Vol. LVII, No. 1564, pp. 44-45, Paris, July 20, 1922

The Cochineal insect (*Icerya purchasi*) has recently made its appearance at various points in Lower-Provence, and has been specially noticed in the immediate vicinity of Marseilles. Its depredations, which are continually becoming more severe, are at present to be observed on trees of the *Citrus* family, *Acacia*, *Pittosporum*, etc.

It is feared that, in spite of the precautions taken, the Cochineal insect will spread further in the South of France

G. T.

892 — **Organisation of the Control of the Cochineal insect *Icerya purchasi*, in Morocco, in 1921.** — SCHENDLER, A., in *Revue horticole de l'Algérie*, Year XXVI, No. 5, pp. 89, Algiers, May 1922

MEANS  
OF  
CONTROL

The cochineal insect (*Icerya purchasi*) was very probably introduced into Morocco in 1920, with some contaminated plants coming from various parts of Europe. In July 1921, when the Cochineal insect had developed to an alarming extent at Rabat, the Department of Plant Diseases at the Cherifian Scientific Institute immediately organised its control by means of the Lady-bird beetle *Novius cardinalis*.

The Mentone Insectarium, was asked to provide some specimens and a first batch of the pupæ were immediately despatched and reared in the laboratory, beetles and larvæ of the beetle being then distributed among the crops attacked by the Cochineal insect.

The result was quite remarkable and three months later, on an area of about seven hectares, very few *Icerya* were found alive, but on the other hand the plantations were covered with the larvæ of *Novius* which not finding enough cochineal insects to feed on were eating each other.

Fresh centres of *Icerya* having been discovered in the district of Casablanca, attempts at colonisation were started at the end of October 1921, the results are not yet known. At the present time the cochineal insect

(1) See R. Jan. 1922, Nos. 131-132 (Ed.)

has disappeared from the Rabat district so that the Department of Plant Diseases has to obtain from the district of Casablanca the *Icerya* required for feeding a small colony of *Novius* which it is anxious to keep.

The beetle has also been introduced at the Agricultural Institute of Maison-Carrée (Algeria) for distribution wherever the cochineal insect is seen. In Algeria the two centres of infection are at present Bonfarik and Castiglione.

893 — *Leucopis* sp. a destructive Dipteron of *Aphis sorghi* and *A. gossypii*, Injurious respectively to *Sorghum vulgare* and to Cotton in the Anglo-Egyptian Sudan. — COTTAM, R., in *The Entomologist's Monthly Magazine*, Vol. LVIII, No. 694 (3rd Series, Vol. VIII, No. 87) pp. 61-64. London, March 1922.

During November 1914, the larva of a small fly belonging to the genus *Leucopis* was noticed feeding on the dura aphid (*Aphis sorghi* Theob.); the following year from February to April it was found possible to study its habits in the vicinity of Khartoum. At Mogren, a crop of dura (*Sorghum vulgare*) was heavily infested with *A. sorghi* and in company with the larvae of the syrphid *Syrphus aegyptius* Wd. and *Coccinella vicina* Muls. and *C. undecimpunctata* Linn., were large numbers of *Leucopis* sp. The combined efforts of these destructive larvae had a marked effect in checking the spread of the aphid.

In February 1915, a *Leucopis* sp. was further noted as being the only destructive insect attacking the cotton aphid, *A. gossypii* Glover infesting cotton on Tuti Island, near Khartoum North.

Throughout the period from February to April, when the dura crop was cut, all stages of the Dipteron were found on the leaves (described in detail by the author) indicating that breeding was continuous and that generations overlapped. The adults confined in breeding cages paired in the evening and the females commenced egg-laying two days after emerging from the pupae. Oviposition lasts two days and the females then died. Possibly under normal conditions the flies live longer. When laying, the female *Leucopis* hovers over the aphid infested leaves in the same manner as the female syrphid. The eggs are deposited singly on the leaves, close to the colonies of aphides, and are attached in a horizontal position to the leaf surface. On dura leaves the eggs were invariably found on the underside of the leaf but on cotton only on the upperside. They may readily be distinguished from the eggs of *Syrphus aegyptius* and the *Coccinella* spp. From breeding experiments it was found that the average number of eggs laid by a single fly was 34; under natural conditions possibly the number would be higher. The larvae occur among the aphides on which they feed. Under laboratory conditions the life-cycle from egg to adult is completed in 11 days. The entire life-cycle may, however, be considered as 13 days, as the adult female commences egg-laying two days after emergence.

There is no doubt that this small Dipteron constitutes a valuable check on the increase of aphides infesting the two main crops in the Sudan its short life-cycle compensating for the relatively small numbers of egg

produced by each female. The number of eggs found on 12 aphid-infested dura leaves picked at random, varied from 7 to 153 with an average of 93.

A chalcid so far undetermined has been bred from a pupa of the *Leucopis* sp.

G T

894 - **Natural Enemies of Mango Leaf-Hoppers (*Idiocerus* spp.) in India.** — SUBRAMANIAM I. V. in the *Bulletin of Entomological Research* Vol. VII 4th part, pp. 465-467, 2 plates (London Feb. 1917).

*Idiocerus niveosparvus* I. atkinsoni and *I. clypealis*, Rhyncotes belonging to the *Jassidae*, are very common in India where they cause serious damage to the mango crop (*Mangifera indica*).

Studies made at Bangalore (Mysore) have led to the discovery of the following natural enemies of *Idiocerus* spp.

1) *Pipunculus annulihemur* Brun. n. sp., an internal parasite of the three Rhyncotes named *I. atkinsoni* is the species least liable to attack.

2) *Pyrrhoxenus compactus* Picce, an internal parasitic coleopter on the adults of *I. atkinsoni* and *I. clypealis*; in one year 30% of *I. atkinsoni* and 15% of *I. clypealis* were found to be parasitised.

3) *Epipyrops fuliginosa* Tams. n. sp., an external parasitic lepidopter on of the three species of Rhyncotes.

4) A hymenopter on of the Dryinid family, an external parasite of the nymphs of these Rhyncotes.

G T

895 - **Natural Enemies of *Tortrix viridana* in England.** SCOTT H. in *The Entomologist's Monthly Magazine* Vol. LVIII No. (1) (11 Series No. 5) pp. 56-61 (London March 1917).

From four pupae of *Tortrix viridana* collected with a number of others from oak trees in a wood in the Southern part of Cambridgeshire in 1921, 43 chalcidae were obtained; almost all females of the Chalcid *Pteromalus deplanatus* Nees. In two cases 12 emerged from a single pupae.

Amongst the 8 other pupae of *T. viridana* collected at the same time in 1921, the following species of ichneumonidae were bred: *Phaeogenes stimulator* Graenicher (1 male and 5 females), *Pimpla brassicae* Po-dave (1 female), *Labronychus nigricornis* Wesm. (1 male).

Other enemies of *T. viridana* noticed in 1921 were *Calopteryx virgo* (fam. Odonata) at Queen's Bower, New Forest and a Dipter on of the fam. *Empidac* (probably *Empis livida*) at Brockenhurst.

Several occurrences of other enemies (Microlepidoptera) reported elsewhere in England are mentioned, and also the records of large swarms of the Chalcididae *Pt. deplanatus* in England, and of *Stenomalus muscarum* in England and Switzerland.

INSECTS, ETC.  
INJURIOUS  
TO  
VARIOUS  
CROPS

897 - The "Colorado Beetle" (*Leptinotarsa decemlineata*), in the Gironde. — FEYTAUD, J., in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VIII, No. 25, pp. 705-709. Paris, 12 July 1922.

The presence of the "Colorado Beetle" (*Leptinotarsa decemlineata* Say) has just been reported in France, in the Department of the Gironde. The source, which was without doubt incubating for over a year, was only discovered about the middle of June 1922. Numerous fields had already been invaded throughout almost the whole of the Canton of Blanquefort and of Castelnau in the south.

While the largest invasions recorded in Germany did not exceed three hectares of crops, the present invasion covers more than one hundred according to the statistics of the prefecture of the Gironde; according to the author calculations, the invaded area covers 250 sq. km.

As the insect is polyvorous, it attacks all kinds of Solanaceæ and egg-plants and tomatoes have been destroyed in the neighbourhood of the worst infected potato crops.

In certain districts, the numbers of this Chrysomelid were such that in June all the green parts of entire fields had been destroyed and the beetles had migrated in mass towards the surrounding crops. This occurred at the centre of dispersion, at the original source, at a point where several farmers clearly remember having seen the same insect in the middle of 1921. The flight of the full grown beetles from this point spread the evil in all directions. The predominance of winds from the north and north-west during a fairly long period and the greater abundance of potato crops in the southern part of the canton of Blanquefort, caused the trouble to extend especially in the direction of the communes situated to the west of Bordeaux.

The first measures of control were promptly taken by the prefecture of the Gironde. The application of arsenical treatments began within about a week after the discovery of the pest. The Directorate of the Agricultural Department recommended a formula combining arseniate of lead with Bordeaux mixture the formula which is in common use for the treatment of the vine for the pests known as "altise", "eudémis" and "conchylys". Arseniate of lead was placed free of cost at the disposal of the farmers by the Agricultural Department Office.

As soon as the presence of the insect had been reported, the Entomological Station at Bordeaux took in hand the work of fixing the boundaries of the infected area and giving the Directorate of the Agricultural Department of the province the technical advice required in the circumstances. While waiting for powers to apply radical measures in the worst invaded fields, measures which only the Government could order, the Station advised that arsenical sprayings on the infested fields or on the fields situated within the boundaries of the great centre were not sufficient, but that all the potato fields of the neighbouring communes for a space of at least twenty kilomètres round the centre, should also be treated as a matter of urgency.

In the interval, with the object of improving as far as possible the

process of arsenical spraying, the writer undertook, in collaboration with MONTEIL, assistant at the Entomological Station at Bordeaux, various observations and experiments, which were continued in the laboratory and in the field and of which the following were the first results:—

1) Spraying should be carried out under high pressure and profusely, aiming both at the upper parts and sides of the plants; it is not enough to treat the leaves only, for the stalks and the branches, which are difficult to reach with a superficial spraying, also provide though on a reduced scale, nourishment for the insect. In many fields where the treatment is carried out too quickly, the larvæ find food to live on; the owner, not seeing them any more on the surface of his field, thinks they are dead and is surprised to find them a few days later on fresh shoots, or to see numerous full grown beetles appearing from the ground after pupating.

2) The perfect insects, although generally very voracious, stand fasting much better than the larvæ; hence whenever the food available is, however, slightly displeasing, they leave it, so that the use of arsenical Bordeaux mixture in the sources of invasion may be a means of dispersing the pest; the larvæ also abandon the foliage covered with Bordeaux mixture and seek food on the grass until the growth of fresh unsprayed leaves or the washing of the leaf tops enables them to return to the potato plants. With Bordeaux mixture alone, without addition of arsenical salts, the result obtained is similar.

3) On the other hand, the addition of attractive substances, such as molasses, induces the insects to feed more readily on the poisoned foliage;

4) Comparing the effects of arsenate of lead with those of arsenate of soda, the writer has ascertained that the strength of about 5 ‰ of arsenate of lead obtained by the reaction of anhydrous arsenate of soda and neutral acetate of lead (6 ‰) is much less effective and has a much slower action than the dose of 2 ‰ of anhydrous arsenate of soda alone.

Arsenate of lead at the above strength (corresponding approximately to 1 kg. of powder or paste prepared from commercial arsenate of lead to 1 hl. of spraying liquid) was not sufficiently effective; the poisoning which it produces, even when it is presented in a non-repellant form, is not sufficiently rapid to destroy the older larvæ before pupation, at which period also their appetite is much reduced; the strength should therefore be doubled or should at least amount to 750 gm. per hl., say 1 kg. 100 of commercially prepared powder.

G. T.

898 - The "*Bombyx dispar*" (*Lymantria dispar*) injurious to Apricot Trees, in Vaucluse. — ZACHAREWICZ., in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VIII, No. 24, p. 679. Paris, 20 June-5 July 1922.

In the Department of Vaucluse the apricot trees are very seriously damaged by the caterpillar of "*Bombyx dispar*" (*Lymantria dispar* L.) which invades the trees from the month of May and affects the crop by destroying the leaves.

The author recommends as means of control:

- 1) the crushing of the felted masses of eggs on trunks and walls;
- 2) the spraying of the caterpillars with a mixture containing 1 % of arseniate of lead or lime, before the formation of the fruit, and the use of sticky bands or rings of a similar kind.

Many caterpillars can also be destroyed by placing, near the trees attacked, in the month of June, shelter traps formed of simple brush-wood or faggots ; the insects go inside to pupate and the traps are burned before the pupæ hatch out.

GENERAL INFORMATION

899 - **The Agricultural Problem of the South of Italy and its Dependence on Biological Conditions.** — V RIVERA, in *Atti della Società Agronomica Italiana*, Years II and III, No. 2, pp. 27-73. Rome, June 30, 1922

The author draws attention to the low yield of Italian agriculture using the following figures, which show the average wheat yield in various European countries expressed in quintals per ha.: Italy 11.0; France 13.0; Austria 18.0, Germany 20.0; Switzerland 20.0; Holland 24.0; Ireland 25.0; Belgium 25.0, Denmark 31.7

The problem of the low wheat yield of Italy has been treated from various points of view. Some believe that the progressive tendency which distinguishes agriculture in Northern and Central Europe, would if applied to Italy, cause field crops to flourish, even in the least productive part of the country; others including farmers, University professors and men of science, believe that owing to climatic and social conditions such crops are not really suitable for the South of Italy and that the growth of productive trees which suffer little from the effects of drought, should rather be developed.

The author has studied the problem of the crop returns in the South of Italy from the agronomic and economic points of view. During the 5-year period from 1909-1913, the yield fell to 9.59 qs. in Apulia, 8.3 qx. in Sicily and 7.1 qs. in Calabria, and never exceeded 20 qs. per ha. even in the best years.

From information collected in the district of Andria, the author has ascertained that the total profits from wheat are 300 to 400 lire per ha.,

DEVELOPMENT  
OF  
AGRICULTURE  
IN DIFFERENT  
COUNTRIES

from oats 100 lire and from barley 50 to 100 lire, while beans show no profit at all.

The vine yields on an average 75 qs. of grapes per ha. giving a return of 1000 to 1500 lire; cereals show a return of 200 lire. The olive alone can be cultivated with an absolute certainty of profit. The cultivation of mustard is being extended with satisfactory results.

In order to ascertain the reasons for these facts the author has carried on experimental research for 3 years at San Sisto, near Aquila, on the crops mostly grown in the district, where he has grown in the open field and by the most improved methods beans, lentils, wheat, maize, potatoes and the castor-oil plant. Organic fertilisers (manure) and super-phosphate have given very good results with crops carried in April and May, but leguminous plants and cereals cropped in June and July yielded no profits, for they suffered from drought during the transition from Spring to Summer.

An analysis of the results shows that crop growing was disastrous from the economic point of view as regards all the trials made, with the exception of that of wheat. The greatest loss was on the castor oil plant for which it averaged, for the three years, 620 lire per ha.; then follow, in decreasing progression, lentils with a loss of 227 lire, potatoes 178 lire, beans 85 lire, maize 75 lire; wheat on the other hand showed a profit of 175 lire 60. For this reason the peasants of Central and Southern Italy prefer to grow wheat.

The inferiority of the soil in the South of Italy depends on causes which it is difficult to rectify by means of improved methods and intensive culture. These causes are: the lack of water during the most important period of plant-life and the high temperature during certain hours of the day, which causes the closing of the stomata and consequently prevents assimilation; the luminosity of certain soils adds to the trouble by its injurious effect on the photosynthesis. The cultural factors are: bad tillage, excess of moisture in the initial stage of plant growth, etc. A comparison between the north and south of Italy shows that in the former there is an increase in the quantity of water and the height of the temperature from January to July, whereas in the latter, the water diminishes as soon as the temperature rises.

The propaganda in favour of the use of fertilisers in the dry districts of the south is considered untimely by the author as the fertilisers deprive the plants of their power of resistance to drought.

The author concludes by stating that the causes of the low agronomic and economic returns in the South of Italy are mostly due to climatic and biological conditions and that poor methods of cultivation have only a secondary influence. The measures adopted to remedy the evil should be based on the biological factors and the individual requirements of each plant as regards climate and exposure should be taken into account.

R. P

900 - **The Fertility of the Soils in Greece.** — BOUYOUKOS, G. (Michigan Agricultural Experiment Station), in *Soil Science*, Vol. 13, No. 2, pp. 63-72. Baltimore, Feb. 1922.

At the request of the Greek Government, the late C. G. HOPKINS, with the writer as his assistant, was sent to Greece by the American Red Cross and the War Board to investigate the soil productivity. Though the enquiry lasted only one year it led to decidedly interesting results. HOPKINS drew up a report which was addressed to the Government and the farmers of Greece. It was couched in a rather simple and popular form, and has not yet been translated into English. Had Dr. HOPKINS lived, he would no doubt have prepared a more scientific report. Yielding to the request of men of science, the author has now attempted to supply the deficiency.

Soil production in Greece is very low. For instance, the average wheat yield is only about 11 bushels to the acre, and this is produced only once in two years, or even in three years and during the interval the land is left fallow. The yield of all grain crops is low. As to legumes, only a few kinds are grown for human consumption. The culture of leguminous plants is practically unknown. The writer does not treat of fruit-growing.

The causes of the low yield are numerous. It is partly due to the use of unselected seed, to the high temperature and above all to the drought towards the end of Spring and during the Summer, which, in the absence of irrigation, renders cultivation difficult, but the chief cause is the sterility of the soil. The farmers do almost nothing to render the soil fertile. The majority of them have never used commercial fertilisers; farm manure is quite scarce, because in Greece the chief livestock consists almost entirely of sheep and goats which graze nearly the whole year on the mountains; the advantage of alternating cereals with legumes is unknown; the few leguminous crops grown are pulled up by the roots, so that the soil derives no benefit from the nitrogen. While lying fallow, there is no shortage of wild legumes, which are for the most part grazed by the flocks; the soils probably receive a little nitrogen from these plants.

Greece is a very mountainous country, but nearly all the cultivated land is of fine texture. It is rich in clay and silt, even when very stony. The chemical composition of the soil varies greatly, as is seen from about a hundred analyses given by the writer. For instance, for each ha. containing 2 250 000 kg. of soil, the nitrogen varies between 1687 and 1625 kg., the phosphorus between 236 and 13 185 kg., potassium between 2800 and 72 551 kg. and magnesium between 2000 and 51 918 kg.; the calcium variations are still greater, being 3200 to 140 000 kg., especially in the case of limestone, of which there is generally an excess, though sometimes it is entirely absent. As regards the soils deficient in lime some are acid, but these are comparatively rare. With very few exceptions, potassium, is generally abundant but phosphorus and nitrogen are often deficient.

The great influence of the chemical composition of the soil in Greece on its fertility is confirmed by two series of experiments made during the short time Dr. HOPKINS was able to work. Melilot was cultivated in 38 earthenware jars, and it was seen that phosphorus produced a marked

increase in yield. Thus in limestone soil the yield rose on an average from 32 to 105 gm. by the mere addition of acid phosphate. The melilot was afterwards partially dried and mixed with the soil in which the roots had been left. The result of planting millet in this was a much larger growth than that in the control. Eight field tests were also made in different parts of Greece. The writer only gives the results of two, in acid soils, namely, those to which limestone was applied at the rate of about 25 tons to the ha. and acid phosphate at the rate of about 5 qx. This caused a great increase in yield, which in one case rose from 150 kg. to about 3,100 kg. or twenty times more. The addition of lime or phosphate was much less beneficial. In general, during the course of this inspection in Greece, it was seen that the soils respond readily to fertilisers, especially to those containing nitrogen and phosphorus, and, if acid, of limestone. L. V.

901 - **Agriculture in the State of Parana (Brazil).** — MUNHOZ DA ROCA. *Mensagem dirigida ao Congresso Legislativo pelo Dr. Cactano MUNHOZ DA ROCA, Presidente do Estado, ao instalar-se a 2ª Sessão da 15ª Legislatura*, p. 106. Curityba, February 1, 1912 (1).

The importance of agricultural production in the national economy of the State of Parana is shown by the value of the exports during the financial year 1919-1920, dealt with in this "Message". The value of the exports taken as a whole reached the figure of 638 550 88 milreis of which 34 876 000 relate to maté — 11 991 500 to timber — 5 450 400 to live stock — 609 888 to coffee — 4 927 300 to miscellaneous produce. Maté thus represents more than 60 per cent of the State revenues.

With a view to placing on a sound basis and developing the two principal agricultural sources of wealth of the country, by the Decree No. 1201 of November 17, 1920, the period in which the picking of maté is allowed is confined to the season from May to October, and the analysis of the trade product is made obligatory under the guarantee seal established by Law No. 1956 of March 23, 1920: Law No. 1986 of April 5, 1920 fixed the times during which the felling of timber is permitted, and makes obligatory the reafforesting of clearings, leaving to the person concerned the choice of trees to be planted.

The State supports the following institutions for agricultural instruction and experiment: "Escola agronomica" of Curityba founded by Law No. 1788 of April 5, 1918, which had in 1920 93 students: "Instituto Bercachery" devoted to experimental plantations with the object of making a study of the crops best suited to the climatic and general local conditions of the State: this Institute has been attached to the "Escola agronomica" and selection experiments, trials of fertilisers, practice in agricultural work, manual and with machinery, are carried on there:— "Campo do Portao" an experimental farm also attached to the "Escola agronomica" — "patronato agricolo" an orphanage which prepares pupils for agricultural work and a staff of inspectors of agriculture. An experimental station for seed production is just about to be founded.

(1) For other information as to the agriculture of the various Brazilian States, see *R.* July 1922, No. 681 and the bibliographical note. (*N. d. R.*)

Subsidized colonization has come to an end, but the State encourages colonization either by giving facilities to the colonist for the acquisition of land vested in the Federal Government or in private undertakings, or by assisting communes to do the same, or finally by acquiring land on its own account for assignment to colonists. Law No. 1642 of 1916 fixes the conditions under which land can be granted to private persons: in application of this law 1 100 000 hectares of land have already been distributed in Parana, the greater part to Brazilian colonists, natives of Rio Grande do Sul.

F. D.

902 - **Agriculture in Martinique.** — *Bulletin Agricole de la Martinique, Revue trimestrielle publiée par le Service de l'Agriculture, Year IV, No. 22, pp. 40. Fort-de-France, 1922.*

*Department of Agriculture and Forestry: organisation and working.* — The inauguration of the Department of Agriculture coincides with the establishment of the trial plots at Tracée, Tivoli and at Prefontaine and of an agricultural laboratory; these were established by the law of March 11, 1904. The law of January 20, 1909 set out the duties of the department and the law of April 26, 1909 instituted new trial plots as well as agricultural instruction.

As at present organised, the essential aim of the department of Agriculture is on the one hand to improve the crop yield and the industrial output of sugar cane by the application of improved methods, and on the other to encourage the development of the so-called secondary crops, so as to safeguard the colony against the dangers of a single cultivation. At the present time it consists of two separate sections: that of agriculture properly so-called and the forestry section.

The functions of the agricultural section and its programme of action may be summarised as follows:

1. *Scientific and experimental research:*

a) in the laboratories of agricultural chemistry and technology, entomology and phytopathology.

b) in the nursery gardens and experimental plots, the subjects treated being sugar-cane and the so-called secondary crops: cacao, coffee, citrus fruits, etc.

2. *Agricultural instruction and propaganda:*

a) agricultural instruction in the primary schools, in the training colleges, in the secondary schools, and in a special school of agriculture;

b) propaganda and information, by means of consultations either through the post or by interviews and publications.

3. *Agricultural improvements and rural engineering* (drafts and plans, inspection of constructional work in progress and maintenance work).

4. *Encouragement of agriculture:*

a) prizes for secondary crops, for agricultural instruction, etc.;

b) payments and subsidies for permanent improvements such as drainage, irrigation, etc.;

c) agricultural shows and competitions;

d) co-operation and agricultural mutual aid through syndicates, co-operative societies, credit corporations, etc.

In regard to the *forestry section*, its functions include :

- 1) the oversight and preservation of the existing forests whether belonging to the State or to private persons ;
- 2) the scientific management of State woods and forests ;
- 3) reafforestation ; regulation of rivers and waterfalls.

The budget of 1922 includes : for administration and laboratories 48 000 francs ; trial plots 103 600 francs ; forests 60 600 francs. It includes further a credit of 50 000 francs for reafforestation and another credit of 30 000 francs for the encouragement of agriculture.

The essential business of the trial plots is to prepare and distribute free of charge to agriculturists who make application, seedlings, etc. of the best kinds of useful plants, sugar cane excepted. During the decade 1912 to 1921, more than 1 100 000 seedlings were distributed, of which 177 000 in round numbers were coffee plants, 64 000 cacao, 476 000 citrus fruits, 294 000 tobacco plants, and 183 000 miscellaneous.

The forests cover about 20 000 hectares, of which 7 000 belong to the estates of the Colony and 13 000 to private persons. The annual coefficient of increase may be estimated at from 5 to 6 cubic metres, representing an annual production of at least 100 000 cubic metres, that is to say double the consumption of the island.

*Sugar cane cultivation and subsidiary industries.* — Out of a total area of about 98 000 hectares, of which 76 000 are volcanic lands in the north and 22 000 are alluvial lands, the sugar cane occupies nearly 27 000 hectares, of which only 18 000 are cut each year, the remainder being partly under rotation (fallow, green manuring or pasturage) and partly planted with young canes. All the land suitable for the cultivation of cane is already planted, so that there seems no likelihood of any increase in the area covered by this crop. On the other hand it is possible to increase production by improving the methods of cultivation and of manufacture ; by these means the present production might be raised from 30 000 to 100 000 tons per annum.

At one time the yellow cane of Otaïiti or the Bourbon were almost exclusively cultivated, but for thirty years past, owing to the fact that the older varieties have undergone degeneration, numerous varieties obtained from seedlings have been introduced from British Guiana, Demerara and Barbadoes. On the Congo, these varieties also degenerate, those from Barbados sooner than those from Demerara. As a general rule it may be said that their introduction is useful, as tending to preserve, if not to develop the cultivation of the sugar cane

The first sugar harvest takes place 18 months after plantation : the second (first suckers) 12 or 14 months later ; the third (second crop of suckers) is left on the ground and used for pasturage for three or four years.

There are in Martinique at the present time 15 sugar factories. The sugar of the first flow reaches 98.8 degrees of polarisation : few sugar

factories have an output showing a lower polarisation than 97. The second flow polarises at 95 to 97 on an average. Local consumption absorbs about a thousand tons per annum: the remainder (30 000 to 40 000 tons of all types) is exported to France.

The cane-trash is used for fuel: one ton of cane supplies 200 kg., with 5 % of humidity, equivalent as fuel to at least 50 kg. of coal. The scum of the boiling is mixed with chopped straw and used as forage: 10 kg. is obtained per ton of sugar-cane. The molasses is used in the manufacture of rum. Generally it contains 54 to 58 % of absolute saccharine and from 20 to 30 % of directly reducing sugars as against 30 to 40 % of saccharose. The average density is 1.40 and the theoretical yield is 90 l. of rum at 55 degrees per hl.: the actual yield is 75 to 80 % corresponding on an average to 24 l. of rum per ton of sugar cane.

*Secondary crops and subsidiary industries.* — The most important of these is the cultivation of the cacao-tree which occupies about 1 500 hectares in the north of the island. During the five years 1917-21, an average of 400 000 tons of cacao beans has been annually exported against an average of 500 000 tons during the pre-war period.

The chief varieties cultivated are: Criollo, Venezuela, Calabacillo. The principal shelter-trees are: Glyricidia, Samana (*Pythecolobium Saman*). The annual production is about one kg. of beans per tree and in the better cultivated plantations as much as two kg.

There are three chocolate factories which can turn out 1 200 kg. of tablet chocolate per day, and two cocoa powder factories which can together work up 2 000 kg. of cocoa beans a day.

Coffee which was lately cultivated on a large scale, has been seriously attacked by two parasites: the eel worm (*Heterodera radiculicola*) and the butterfly known by the name of *Cemiosoma coffeola*, the larva of which eats the leaves. For some years past the replanting of the plantations with *Coffea liberica* and *Coffea robusta* has been proceeding.

The shade trees most usually planted are the sweet tamarind (*Inga edulis*) the samana and the glyciridia.

Since 1910 the cultivation of the lime-tree has been much developed, especially that of the *Citrus medica* var. *acida* which is used both for direct consumption, and for the preparation of the concentrated juice, and of citrate of lime, which is manufactured in four factories in the island, and also of the essence extracted from the rind.

Tobacco grows wild in Martinique as in all tropical America. The "Grand Martinique" must be an original variety. This was formerly a flourishing crop and is in a fair way to revival: the quality of the product is very good.

Cotton (*Gossypium arborescens*) is wild or cultivated all over the island, but cultivation properly so-called is very limited. It formerly covered thousands of hectares. The long staple variety (*Sea Island*) is the best suited to the island.

There is no textile industry in Martinique. Nearly all the natives make rope with aloe fibres, called "ox tongues" (*Agave rigida*), with manilla hemp or banana fibre (*Musa textilis*), with the bark of different plants, parti-

cularly the malvaceae of the genera *pavonia* and *pariptium* and of the boragaceae of the genus *cordia* called by the Martinique planters "mahot".

For making baskets, etc. the "aroua" (*Marantia juncea*) is used; for making fishing tackle bamboo; for ordinary hats, the leaves of certain palms, especially "latanier" (*Thrinax barbadensis*).

Vanilla grows well in Martinique, but its cultivation has been neglected to such a degree that in several years the production was not enough for local requirements. The average annual export during the last ten years was 1900 kg. The *Vanilla aromatica*, which is of little commercial value, grows wild: the two following kinds are cultivated: "Mexican vanilla" (*V. planifolia*) and the "vanillon" (*V. claviculata*).

There are unimportant exports of nutmeg and cinnamon and ginger; pepper and cloves are produced in scarcely sufficient quantities for local consumption.

*Stock breeding.* — This is quite inadequate for the requirements of the local food supply, the provision of draught animals and the supply of manure. There are approximately: 10 000 horses; 25 to 30 000 cattle; 30 000 sheep and goats and 20 000 swine. There are 12 000 hectares of meadow land and grass land in the island to which must be added 6 to 7 000 hectares of fallow, so that the effective area available at present might be doubled.

The creole horses are small (1<sup>m</sup>.30-1<sup>m</sup>.40) easily handled and hardy. They feed on Para grass (*Panicum molle*) or Guinea grass (*Panicum maximum*), green sugar cane tops at the time of cutting, cane scum, dry straw chopped and mixed with molasses.

There is no horse breeding properly so-called.

There are a fair number of mules: those of native breed are small (about 1<sup>m</sup>.30), while those which are imported from Porto-Rico or the United States are larger and stronger, but need more food.

The stock of cattle is made up of animals of small size originating in the crossing of the various breeds that have been successively imported into the colony. There are no special breeds of butchers' beasts or dairy cattle. The better cows give at most 4 to 5 litres of milk. The yield of butchers' meat is from 40 to 60 % and the meat is of ordinary quality.

The sheep own their origin to the crossing of the South American breeds with those coming from Senegal.

The swine are reared round the dwellings: they recall the Iberian breed.

F. D.

903 - **Agricultural Implements in Syria and Lebanon.** — *Service de l'Agriculture du Haut-Commissariat de la République Française en Syrie et au Liban. Enquête sur le matériel agricole se trouvant en Syrie à la date du 31 décembre 1921* (1), pp. 1-11. Beyrouth, Jan. 21, 1922.

Included is a table giving statistics for each kind of horse-ploughs, threshing and winnowing machines, implements, motor driven machines,

(1) Documents in support presented by the Temporary High Commissioner of the French Republic in Syria and Lebanon.

machines used in agricultural industries, etc.), of the agricultural implements in Syria and Lebanon on December 31, 1922. The report also shows: the type of the different machines, the districts possessing the greater number, the country from which sent if imported, the causes of their success or failure, improvements made or to be made in the construction or selection of types, where and by whom the trade in agricultural machinery is carried on and the terms of payment. The districts most adapted to the use of agricultural implements are also enumerated.

There are no contractors for ploughing or threshing anywhere in Syria. In the Province of Damascus some tractor owners let their machines out on hire to their neighbours. In the Province of Aleppo, in the Sanjak of Alexandretta and in the territory of the Alanites, the Agricultural Service has carried out contract work, allowed farmers the free use of various kinds of machines and in some cases has lent ploughs.

These advances have been well received.

The causes which operate against the use of agricultural implements in Syria are the following: the farmer supplies the material for the crops and when they are ready for the harvest the landlord advances the money necessary to carry out the work, the sum being calculated on the prospective yield. These advances are made at a very high rate of interest and after repayment there is a very small margin of profit; the farmer has no capital; there is a lack of practical knowledge and distrust on the part of the farmer and owner of every innovation; the implements imported, especially ploughs, mowers and reaper-binders are unsuitable for local conditions; lack of initiative on the part of the large landowners; the poor and weak condition of the draught animals; the lack of repair sheds and depôts for spare parts.

The following are recognised in this report as essential factors in the extended use of agricultural machinery: a change in the methods of farming, the opening of a credit fund by the Department of Agriculture, the spread of technical and practical instruction in agriculture, the extension of the knowledge of the results obtained by the use of agricultural machinery, the development of the breeding of draught animals, the adaptation of machinery, the building of repair sheds and depôts for spare parts and the establishment of companies for carrying out agricultural work on contract terms.

F. S

904 - **The Teaching of Soil Bacteriology.** — BROWN, P. F. (Professor of Bacteriology, Iowa State College, Ames), in *Journal of the American Society of Agronomy*, Vol. 13, No. 8, pp. 323-329. Washington, Jan., 1922.

AGRICULTURAL  
EDUCATION

It has been said that soil science is the basis of agriculture. It covers an extensive field and the fact that it is now taught in several courses is not only through pedantry but also because it has been found necessary in order to impart a thorough knowledge of the subject.

From experience gained at Iowa State College it may be taught with advantage in four courses, of which one is general and introductory, one final and applied and two intermediary on fertility (especially as connected with chemistry) and on bacteriology.

Soil bacteriology is a branch which has only recently been differentiated from agricultural bacteriology. In the *curriculum* of nearly all agricultural schools it has not yet been treated as an independent branch, but it is nevertheless of growing importance. At present soil bacteriology can no longer remain an accessory, almost fortuitous subject, included in agricultural bacteriology.

Up to the present time there is still a lack of special works on soil bacteriology ; instruction should therefore be oral, and enlivened by discussion and written work, which greatly tend to enlighten the mind.

Certain subjects, such as nitrogen fixation, nitrification, the carbon cycle, the sulphur cycle, the phosphorus problem, the part played by fungi, the occurrence of protozoa etc., should be emphasized particularly ; others of minor importance, such as denitrification, should be minimized. The subject matter should not be too technical and intricate, but simple and concrete and directed towards enlightenment in the practice of agriculture, tillage, manuring, liming, drainage etc. It should arouse the attention and keep up the interest of the pupils ; and should be completed by demonstration and laboratory experiments.

L. V.

905 - **Agricultural Instruction in Belgium.** — MINISTÈRE DE L'AGRICULTURE, *Situation de l'Enseignement Agricole, Rapport triennal avec Annexes, présenté aux Chambres Législatives par M. le Ministre de l'Agriculture, Years 1918, 1919, 1920, pp. XXIV + 219. Brussels, 1920 (1).*

Except for some schools, where the apparatus was completely destroyed in the war, courses and demonstrations have been resumed everywhere. Under the impulse given by the Administration, the subsidised schools are acting as far as possible on the new requirements created by the war : they are improving their methods, revising their syllabuses and completing their schemes.

*Chief Council for improvement of agricultural and horticultural instruction.* — This Council which was created by a Royal decree of 31 March 1919, and is composed of the most outstanding personalities of the educational and agricultural world, has brought to the task of the restoration of agricultural instruction in Belgium the fruits of a most careful collaboration. The Council deliberates on all questions and subjects relating to the progress of agricultural and horticultural instruction. It includes 12 members with the right to vote and a certain number with the right of speaking but not of voting. It consists of five sections : 1) Higher agricultural instruction ; 2) Ordinary agricultural instruction ; 3. Popular agricultural instruction ; 4) Ordinary and popular horticultural instruction ; 5) Farmhouse management.

*Higher agricultural instruction.* — Important modifications have been introduced into the organisation of higher agricultural instruction. The law of November 15, 1919, relating to agricultural instruction, has replaced that of April 4, 1890, and has made possible the creation of a Flemish

(1) See R. July-August 1920, No. 713. (Ed.)

**Agricultural Institute.** A new Royal decree of April, 8 1920, regulates the conditions of admission to the Higher Institutes of Agriculture and the ratification of the diplomas issued by these institutions. This decree established diplomas of "Licenciate in Agronomic sciences", to be given after two years study: it extends to 4 years the period of study for obtaining the diploma of "agricultural engineer" namely two years of general studies leading to the diploma of "candidate for agricultural engineering" and two years of specialisation leading to the diploma of: agricultural engineer, colonial agricultural engineer, engineer of Waters and Forests, rural engineer, horticultural engineer, engineer of agricultural industries or engineer, of chemical agriculture.

*State Institute of Agriculture at Gembloux.* — Courses were suspended during the academic year 1917-18. The admission of 200 students since the re-opening speaks well for the reputation of the institution. Changes have successfully been made in the system of farming, and the farm is now chiefly experimental and a demonstration ground.

*State Institute of Agronomy at Ghent.* — The State Institute of Agronomy at Ghent was established by the Royal Decree of May 25, 1920, in application of the law of November 15, 1919. The courses are given in Flemish. The first academic year opened on October 19, 1920 with 20 regular students. The State has acquired a property of 60 hectares, situated at Melde, as an experimental farm annexe to the new Institute.

*Higher Training Institute of Farmhouse Management at Laeken (1).*

*Intermediate Agricultural Instruction.*

*State School of Practical Agriculture at Huy.*

The programmes of work have been thoroughly revised and a year of preparatory studies has been arranged. New courses have been established including agricultural machinery and the Flemish language.

In drawing up programmes, recent advances of science have been kept in mind and practical courses on motorculture have been held.

There are at present 51 students. This figure is a decided advance on those of previous years. Several lectures have been given by members of the staff, with the satisfactory result of making the school better known.

*State aided schools of agriculture.*

*Carlsbourg School of Agriculture.* — The courses have as their special aim the questions of intensive production, motorculture and the improvement of rural life.

*Louvière School of Agriculture (Institute of St. Joseph).*

*Leuze School of Agriculture.* — The syllabus has been completed by lessons on stock breeding and the feeding of cattle. In view of the re-inauguration and reorganisation of stock breeding syndicates special courses have been given on milk analysis.

*Agricultural School departments in receipt of grants.* — These are the following: the intermediate agricultural departments at Aerschot, Avelghe, Brée, Brugelette, Buggenhout, Chimay, Dinant, Ellezelles, Enghien, Fleurus,

(1) See R. Oct. 1921, pp. 1295-97. (Ed.)

Hannut, Hasselt, Opwyck, Saint-Trond, Schadeck-Attert, Sotteghem, Thielt, Thuin, Tirlemont (Collège Notre-Dame), Tirlemont (Ecole Provinciale), Tongres, Virton, Visé, Waremmé, Wavre (Institut Saint Jean-Baptiste), Wavre (Ecole provinciale).

*Grant-aided Private Schools and Departments of Farmhouse Management.* — These schools are in a very satisfactory condition. An agricultural education given to girls side by side with a general education is much appreciated by those concerned, in spite of the marked tendency after the war to leave the country districts in search of an intellectual culture alien to the agricultural sciences.

The Farmhouse Management schools in receipt of grants are the following: farmhouse management school of Bastogne, Berlaer-lez-Lierre, Bouchout, Brugelette, Celles (Hainaut), Ciney, Cortemarck, Herve, the higher agricultural school for girls at Héverlé, the farmhouse management school at Locre, Marchet-les-Dames, Maulde, Overysse, s' Gravenwezel, Tessengerloo, Virton, Wavre Notre-Dame.

The Farmhouse Management sections in receipt of grants are the following: the farmhouse management section of Balegem, Brugelette, Champlon, Jodoigne, Ressegem, Vezon, Waremmé and Zeelhem.

*Courses of Agronomy in the State higher and Intermediate Schools.* — These courses were suspended in 1918, and resumed in the following year.

*Courses of Agronomy in the Intermediate Private Schools.* — 52 courses of agronomy have been organised in these institutions during the last three years.

*Elementary agricultural instruction.*

*Technical agricultural departments for boys.*

These departments are local and usually attached to the rural primary schools, or are travelling schools. The form of agricultural instruction followed in these winter courses is well adapted to the routine of agricultural life. Several new sections came into being during the three years under consideration, though on the other hand several ceased to exist.

*Schools of agricultural machinery.* — These with their highly specialised programme are much appreciated.

*Travelling Farmhouse management schools.* — After the armistice the schools restarted their activities to the great advantage of the rural population who much appreciate the instruction given. Five new schools, at Beirendrecht, Heyst-op-den Berg, Campenhout, Clytte (Reninghelst) and Yvoir, were established in 1919.

*Popular agricultural instruction.*

*Lectures given by the State Agricultural Experts.*

These lectures given on subjects of general interest to the cultivators of the district are always much enjoyed by their many listeners. The experts find these gatherings an opportunity of becoming acquainted with the farmers and of establishing valuable relationships with them.

*Agricultural lectures to adults.*

Beginning from the armistice these lectures are intended to draw the attention of cultivators to the means that can be employed to bring

about an immediate increase in agricultural production. In this connection peripatetic lectures were instituted in 1920 to introduce farmers to the method of sorting potatoes in sizes. There is at present a tendency to replace adult courses by these more detailed courses providing a more thorough and methodical instruction.

*Lectures for farmers' wives.*

These are a much appreciated type of agricultural instruction and also one of the most valuable.

*Courses in poultry rearing.*

These courses are well attended not only by amateurs but by farmers who are trying to improve the conditions of poultry farming.

*Bee-keeping courses.*

Courses in bee-keeping organized on the initiative of the bee-keeping federations are attended by bee-keepers anxious to learn and to improve their methods of management.

*Courses in agronomy for soldiers.*

In 1920 the Department of Agriculture instituted experimentally, courses for soldiers in barracks.

*Special lectures.*

A large number of special lectures have been given by the agricultural federations that are independently managed but under the inspection of State experts. These lectures are intended to give a fresh impetus to agricultural associations and to keep their members in touch with advances in agricultural science.

*Demonstrations in the scientific feeding of stock and in experimental plots.*

Whereas Belgium used to consume the largest quantity of fertilisers per unit of area, there has been a considerable falling off at the present time. On the other hand it has been impossible to renew sowing at the proper time and hence there has been deterioration in this respect also. Lastly prepared cattle foods have been used on a reduced scale only on account of their scarcity and high price. With the object of remedying these conditions and of bringing about an increase of agricultural production, the Department of Agriculture has instructed the State experts in agronomy to undertake the following experiments :

- 1) to show that in spite of their high prices the use of chemical manures is still profitable ;
- 2) to examine the question of the most economical fertilisers in the present circumstances ;
- 3) to spread information about fertilisers recently produced in any part of the country or as to possible sources of such production ;
- 4) to distribute good kinds of seeds ;
- 5) to prove the advantageous effect on milk-yield of an increase of protein in the diet.

Some of the experiments undertaken are given below .

a) trials on a uniform basis throughout the country dealing with the different nitrate manures ; the different phosphatic manures ;

b) trials on a regional basis of selected varieties of wheat, barley and oats, supplied by the Department, besides one or more local varieties supplied by the experimenter ;

c) trials, according to plans laid down by the State experts, bearing on the selection of seeds, especially potatoes, and on the effect of a second tillage on cereals ;

d) Experimentation on cattle-feeding.

*Department of Agricultural Information.*

The agronomic station at Gembloux consists at the present time of the station for agricultural chemistry and physics ; the dairy station ; the phytopathological station ; the rural engineering station ; the entomological station ; experiment station for seed improvement ; the forestry station.

*Inspection of agricultural instruction.*

The committee for administration and supervision, the inspectors of agriculture, the inspectresses of farmhouse management, and the State Agricultural Experts have had the oversight of the working of agricultural education in varying degrees. The reports prove that on the whole the different institutions fulfil their objects.

*Schools of horticulture.* — The State schools are: the Ghent school of horticulture and the school of horticulture at Vilvorde.

The schools subsidized by the State are those of Carlsbourg, Liège, Mons and Tournai.

*Temporary schools of horticulture.* -- In most of the centres of professional horticulture temporary schools were established with the object of making it possible for practical gardeners to profit by the practice in other parts of the country, and to apply the results of science to their own work.

There were also temporary schools where it seemed likely that market gardening or orchard work could be started. The number of schools amounted to 45 by the end of the period.

There are also courses on fruit growing and market gardening and lectures on fruit growing, market gardening and horticulture. F. S.

The writer observes that the "statistical" method introduced into physics and chemistry by MAXWELL by the study of the theory of heat, has been applied to industry, in which it has led, among other things, to manufacture in bulk and series ; its application has also been very successful in biology and agronomy. By means of statistical classification, it has been possible to make selection chronologically but spatially after a few years only, of the best types of plants and of the methods of fertilisation best adapted to soils, various cultures, etc. A statistical department has already been instituted in Egypt for plant selection (cotton, maize, etc.). The famous station at Rothamsted has

also founded a statistical laboratory. In Germany the adoption of the new method has been retarded owing to the fact that workers are still too much under the influence of the old experimental empiricism. In other countries, such as France, Spain, etc., scientists are still less up to date in the matter of agronomic research than in Italy, where each of the agricultural experiments carried out up to the present can bear critical examination.

In order that the data collected may be arranged mathematically, they should be sufficiently homogeneous, definite and numerous, hence the necessity of coming to an agreement with regard to publishing uniform standards for experimental work and observation on broad lines. The writer suggests that the " *Società Agronomica Italiana* " should take up the problem, entrusting the solution to a competent committee composed of agronomists, biologists and mathematicians. The Society, it should be noted, has already taken steps in this direction by organising collective research.

To carry out this aim considerable financial resources are required. The author calls the attention of the State, the local consumers' cooperative societies, agricultural institutions and farmers to the fact that the period of unaided science, is drawing to a close. To-day research-work needs definite financial support; the funds are used for cost of material, implements, staff, travelling for first hand investigate and controls. The author criticises the increase of stations poorly equipped and over specialised, such for instance as that for maize-culture; it would be better to limit the number but to provide a better equipment, and also substations for each particular crop and specialists.

The author proposes to the Society the following programme of research-work: 1) a soil map of Italy; 2) the nitrifying power and fertility of Italian soils; 3) comparative tests as to the effects of liming according to soils and cultures; 4) research and comparative tests on the most efficacious use of stable manure and organic matter; 5) research and comparative tests on the efficacy of phosphates and other phosphatic fertilisers; 6) the possible influence of superphosphates on the oligodynamic elements: aluminium, iron, arsenic, etc.; 7) research and comparative tests on the efficacy of new nitrogenous fertilisers; 8) research as to the most economic use of water for irrigation; 9) systematic research on "dry farming"; 10) study of the crop rotations best adapted to the different regions of Italy; 11) registration of the local species of the chief plants cultivated in Italy; 12) registration of the principal local breeds of cattle in Italy; 13) maintenance of fish ponds for intensive pisciculture; 14) revision of the methods of analysis for products useful for agriculture; 15) unification and standardisation of the methods used in agricultural experiments; 16) revision of the principles of agricultural statistics in Italy. After research on these and similar questions has been organised and successfully carried out during the required period of years, means should be devised for applying the results obtained to the improvement of agriculture.

R. P.

907 - **The Institute of Agronomic Research, France.** — BRUNO, A. (Inspecteur général des Stations Agronomiques de France), in *Chimie et Industrie*, Vol. 7, No. 6, pp. 1222-1224. Paris, June 1922.

On the July 30, 1922 a bill was presented in the Lower French Chamber for the foundation of an Institute for the development, promotion, organisation and coordination of scientific research in agriculture.

Before this bill was discussed, art. 70 of the Financial Law of April 30, 1921, was approved in the following form :

An Office for the development of Scientific Research as applied to Agriculture with the object of stimulating and intensifying agricultural production shall be established at the Ministry of Agriculture. This organisation, called "The Institute of Agronomic Research," shall be vested with independent powers in the administration of its civil and financial affairs. Its organisation, the conditions, under which it will work and the methods to be followed will be determined by a decree drawn up by the Ministries of Agriculture and Finance.

At the same time two millions were voted in Parliament for scientific research, and the Institute was founded with the following statutory orders, published in the *Journal Officiel* of Dec. 28, 1921.

To control, under the direction of the Ministry of Agriculture, the stations and laboratories already dependent on, and supported by, the Ministry, and also other stations and laboratories which it may be deemed expedient to open ; the cost of building and upkeep will be borne by the Institute. It will also aid other stations and laboratories which have hitherto been maintained by the Ministry of Agriculture, and have the power to make payments to scientific experts engaged upon agricultural research. Its essential duties will be : to coordinate the work of specialists, encourage research, giving it a bias towards practical utility rather than speculative science, to found a central library and publish a summary of the scientific work carried out both in France and abroad.

The Institute was built at the beginning of 1922 ; and ROUX, Doctor of Science and State Councillor, was appointed Director. His Board of Administration is composed of a chairman and 28 members appointed for a period of 4 years, 6 members being chosen by the Academy of Science, 6 by the Academy of Agriculture, and 16 by the Ministry of Agriculture ; among the latter are 3 Members of Parliament, 3 well known agriculturists or scientists, 3 members of Agricultural societies and one member proposed by the Ministry of Finance. The administration of the Institute resembles that of a municipality and an annual budget is issued. It is also in touch with the Sanitary, Scientific and Suppression of Fraud Departments. It has in its service 115 officials formerly attached to the laboratory service. It has under its direct control 24 stations or laboratories ; 24 others, already supplied with educational facilities receive from it the staff and funds necessary for research work ; and 36 other stations under the control of the Departments receive grants from the Institute.

Consequently the Institute can rely on the support of 84 regularly established bodies ; it is organised on regular lines and its system forms a

network of which the junctions are the centres of agricultural districts with branches in the places where research is to be carried on. An agronomic engineer is placed in charge of the central office of documentation.

A central laboratory which will direct the work in progress at the other laboratories and carry out the more intricate tests, is established at Chêvreteux (Rocquencourt) where 5 central stations will be erected on an area of 30 ha.: 1) one for physics and climatology; 2) one for cultivated soil; 3) one for plant breeding; 4) one for general pathology; and 5) one for zoology and agricultural entomology. The Institute will thus supply the present deficiency of specialised laboratories for science applied to human and animal food, for apiculture, oliveculture and dairy-farming. The existing laboratories will be assisted, strengthened, completed, and stimulated for their work; where required, new laboratories will be founded and placed in touch with the whole system.

The report made by the author describes the work which lies before the Institute of Agronomic Research. He is convinced that this task will be carried out methodically and at the same time vigorously and with set purpose, and that the Institute will not fail to contribute largely to agricultural progress.

R. P.

## CROPS AND CULTIVATION

908 — **Studies on the Reactions between Soils and various Chemical Compounds.** — SPURWAY, C. H., in *Michigan Experiment Station Bulletin* No. 51, pp. 5-29, bibliography of 10 works. East Lansing, Mich., 1921.

SOIL PHYSICS

In order more accurately to interpret the reactions between soils and chemicals commonly applied as fertilisers the author considered that it was necessary to extend his investigations and experiments on the effects of these compounds on soils of different kinds, taking into account the nature of the soils as well as the specific action of the fertiliser salts and the compounds employed. The author is convinced that whatever may be the explanation of the processes which bring about these reactions, further progress depends upon an increase in our knowledge of the chemical constitution of soils and the practical significance of the soil components, and in devising analytical methods for the estimations of these components.

The difference in the results obtained and in the conclusions arrived at by many of the investigators engaged upon this question, is probably due to the fact that they have carried out their experiments with materials of different chemical constitution and composed of chemicals belonging to different groups, and also to the diversity of the analytical methods employed. On consideration of the work done in this field there appear to be three main ideas, or lines of thought: 1) that between the soil and chemical compounds there are chemical reactions only; 2) that the phenomena observed can be explained by physical forces; 3) that both chemical and physical reactions take place at the same time.

The author describes his experiments, undertaken as a study of the reactions between neutral salts, bases and hydrolysing salts, and basic

or acid soils of various classes. In these experiments the soil reaction was always tested with litmus paper. In order to eliminate the possibility of secondary and continuous reactions, which undoubtedly occur with slow filtration, the decantation method was used. The procedure was always as follows: 100 gm. of air dried soil were well mixed for one hour with 500 cc. of solution, usually 1/50 Normal of the salt under consideration, at laboratory temperature. The liquid was then decanted and filtered rapidly through paper. The extracts so obtained were analysed by standard methods for the particular salt. All calculations of results were based on 500 cc. of solution.

I. — *Treatment with neutral salts.* — Experiments were made with soils of various types, e. g., sandy loams, silts and clay-loams, with and without carbonate, and with solutions of chloride, sulphate and nitrate of potash; sulphate and nitrate of ammonia; nitrate and sulphate of lime and chloride of magnesium. The analytical results obtained were recorded by the author in tabular form, and it appears that in practice in the reactions between the soil and neutral salts the cation only is retained. Practically all soils without exception precipitated the cations of neutral salts, and an equivalent quantity of another element contained in the soil was set free and passed into solution. The application of potassium salts caused the liberation of an equivalent quantity of other soil elements, particularly calcium and magnesium which went into solution. In the case of treatment with calcium, the calcium is fixed and magnesium goes into solution; with magnesium chloride the calcium is found in solution and a corresponding amount of magnesium is fixed. The actions were reversible in all the cases studied. After the reaction, with one or two exceptions, all the solutions were alkaline. Soils having an alkaline reaction fixed a greater quantity of cation than acid soils of the same class. There is strong proof that the reactions involved are chemical in nature and that the cause of fixation in soils is the presence of soil elements, chiefly calcium and magnesium, and that the degree of fixation is dependent upon both the kind and quantity of reacting elements present. A soil which has received an application of magnesium chloride is able to fix a larger quantity of lime than one not so treated.

II. — *Effects of Hydroxides.* — The same general methods were adopted as in the case of neutral salts. Experiments have been made with solutions of caustic potash and also with hydrate of lime. In these experiments it was found that soils of all types, whether of alkaline or acid reaction, fixed considerable amounts of potassium or calcium from their hydroxides without an equivalent exchange of other elements. After treatment with caustic potash the solution was alkaline to phenolphthalein and contained iron, aluminium and silica but the quantity of calcium was very small, much less in fact than the solubility factor for this element in the form of hydrate.

Evidently potash was fixed from caustic potash without an exchange of calcium or magnesium and in addition iron, aluminium and silica passed into solution in considerable quantities. The potash thus fixed could be

set free again and replaced by calcium on treating the same soil with solutions of the chloride or hydrate of calcium. In general it may be stated that soils having an alkaline reaction fix a larger quantity of cations than those with an acid reaction, although they may belong to the same class of soils.

III. — *Effect of Hydrolysing Salts.* — The same experimental methods were always followed in dealing with potassium orthophosphate, mono-calcium-orthophosphate, calcium acetate, potassium acetate, potassium oxalate and iron chloride.

These salts may be grouped into four classes according to their action on the soil : a) salts with an alkaline reaction ; b) salts with an acid reaction ; c) salts which form soluble salts by combination of their acid radical with the soil elements ; d) salts whose radical acid forms insoluble compounds.

In general it may be said that under certain conditions salts which undergo hydrolysis give results similar to those of neutral salts, but under other conditions the results are quite dissimilar. When the acid radical of the salt is capable of forming a soluble compound with the soil elements a reaction follows which is analogous to that obtained in the case of neutral salts. The soil cation is fixed and then a quantity equivalent to that of the soil element goes into solution. When on the contrary, the radical acid of the salt forms an insoluble compound with the soil element, usually in this case lime or magnesia, the two ions of the salt under consideration are fixed by the soil, but in different proportions from the chemical standpoint. This implies that the two ions can be fixed independently one of the other. As regards the basic or acid reaction of a salt, it can be seen that when the reaction is alkaline, that is, when the acid radical is removed, the result is the same as in the case of the corresponding hydroxide ; when the reaction is acid the final result is the same as that obtained on treatment of a soil with the corresponding acid. For example, on treatment with ferric chloride, a salt with an acid reaction, the amount of iron fixed by the soil is proportional to the quantity of lime found in solution, although it is only in the case of soils rich in lime that an appreciable amount is found in solution. The experiments indicate that it is doubtful whether the iron fixed by the soil can be replaced and that it is probably held in the hydroxide form. Hence the reaction would not be reversible. It may be observed that the alkaline soils fixed a greater quantity of cations from hydrolysing salts than the acid soils of the same class, and also, that greater quantities of cations were fixed from hydrolysing than from neutral salts.

The data accumulated in this research point strongly to the conclusion that when neutral salts, hydrolysing salts or hydroxides in solution, are placed in contact with soils, a chemical reaction results in which the cations or basic radicals of the added compounds are precipitated in the soil mass and the anions or acid radicals of the salts used form soluble compounds with calcium or magnesium, the resulting salts being found in the soil solution. When, on the contrary the radical acid forms an insoluble compound with calcium or magnesium, then that also is fixed or precipitated in the

soil. The results obtained are in accord with WAY's chemical hypothesis (*Journal Royal Agr. Soc.*, Vol. II, 13 and 15) and form an important demonstration of soil phenomena, particularly as regards the mineral constituents. These results justify the conclusion that almost all soils have acid and basic properties in common because they neutralise acids and also alkalies. The differences noted were quantitative only and these differences were generally in favour of alkaline soils over acid soils of the same type. Apparently the reaction of a soil is to a large extent determined by quantity relationships, the mass action of its components, above all by the quantities of the reacting masses involved.

A neutral soil then represents a case where the active masses of reserve alkalinity and acidity are equivalent.

The above is of practical value with regard to knowledge of soil fertility. In order that some fertilising element may be held, it is essential that the soil itself should contain some other reacting substances such as calcium or magnesium, which are probably present in the form of silicates.

This work shows the importance of making a special study of each soil if the best results are to be obtained from the use of fertilisers.

L. M.

909 - **Aluminium Salts in the Soil.** — DENISON, I. A. (Agricultural Experiment Station, University of Illinois) in *Soil Science*, Vol. 13, No. 2, pp. 81-106, bibl. of 16 works. Baltimore, Feb. 1922.

It is known that salts of aluminium are present in soils in considerable quantities and are partly responsible for soil acidity. The toxicity of these salts towards crops has been demonstrated by numerous investigations, but there is no definite information regarding their effect upon the processes of ammonification and nitrification. To solve this problem, the author carried out a series of investigations under the direction and with the aid of A. L. WHITING. Acid soils treated with distilled water left no trace of aluminium, so that this element cannot exist in a soluble form in the soil. On the other hand, it dissolved in a solution of potassium nitrate, the HOPKINS method for determining soil acidity. In this state it does not dialyse through a collodian membrane, and is present probably in the form of hydroxide. Under the influence of mineral acids which displace the aluminium, this hydroxide may give rise to soluble salts of aluminium which are the consequence, and not the cause, of the acidity. Aluminium salts stimulate ammonification, but act adversely upon nitrification, which is explained by the fact that they produce hydrogen-ions. Their influence gradually decreases, and after a couple of months the adverse action upon nitrification disappears. The same effect may immediately be obtained artificially by means of calcium carbonate, and in a lesser degree by tricalcic or monocalcic phosphate, because the calcium-ion precipitates the aluminium-ion. Under natural conditions, aluminium is never able to exercise a toxic action by means of its own soluble salts, even in acid soils, because it is rendered or kept insoluble by such actions.

L. V.

910 - **Nature of Soil Acidity in North-East India.** — CARPENTER, P. H., and HARLER, C. R., in *The Indian Tea Association, Scientific Department, Quarterly Journal*, pt. III, pp. 121-144, bibl. of 32 works. Calcutta, 1921.

Soil acidity is insufficiently studied in tropical and sub-tropical countries. The authors have studied it in the tea-growing districts of North-East India, where it diminishes production, either because it lowers soil fertility or because it facilitates the outbreak of certain diseases.

Soil acidity may be due to various causes. Its extent may be measured by numerous methods, which react in varying proportions on the factors which cause it; this explains why they do not agree among themselves. They are based on hydrogen-ion concentration (electric conductivity, calories, saccharose inversion, liberation of iodine etc.), on neutralisation by means of bases or salts with a basic action, carbonate, bicarbonate and hydrate of calcium, barium or sodium, calcium acetate, etc., on a solution of weak bases (aluminium or iron contained in the soil) by means of neutral salts (potassium nitrate, soda nitrate, etc.). The authors find that these methods, often too drastic, are all inexact or uncertain. The "Indian Tea Association" recommended the ALBERT method modified by LYON and BAZZILL. It consists of treating the soil first with barium hydrate, then with ammonium chloride. The authors have used it largely, but do not believe it is exempt from the criticism passed on the other methods. Though not perfect, they prefer HOPKINS' potassium nitrate method. It measures more especially the quantity of aluminium dissolved in the soil or capable of entering into solution. This method, then, not only enables the actual acidity to be measured, but also the potential acidity, that is, that which may be liberated, which is of equal importance. The first is united to soluble and ionisable aluminium silicates, the second to aluminium hydroxide derived from silicic minerals in soils undergoing laterisation; this colloid's degree of hydration affects the latent acidity of the soil.

Aluminium also dissolves easily in calcium hydrate. This is surprising, since calcium aluminate is insoluble; it is evident that the aluminium passes into solution as a silicate. It also dissolves in basic hydrates.

According to the authors, everything points to ionised aluminium as being the chief cause of the actual and potential acidity of the soils studied in India. In this connection, the authors remind us that CONNOR, ABBOT and DAIKUHARA have proved that aluminium and iron may be found in the soil in a state of solution as acid silicates in the absence of sufficient quantities of lime and magnesia to neutralise these salts; also that the aluminium in solution sufficiently explains the lack of fertility in acid soils, as it has a direct toxic action on the plants and bacteria of the soil, even in minute quantities ( $1 : 1\,000\,000$  of aluminium-ion).

The degree of acidity registered by HOPKINS' method differs entirely from that determined by steeping the soil in lime or other bases, but there is a close parallel between this degree and the fertility. This shows the influence of dissolved or soluble aluminium (ionised or ionisable) in regulating fertility, and proves the importance of these determinations.

According to the authors, the acidity caused by aluminium, which is common in the tropics, is favoured not only by the absence of lime or magnesia, but also by the imperfect drainage, heavy rains, irrational methods of culture etc.

Potash added to acid soils always diminishes their fertility at first because it renders the aluminium salts soluble and increases their toxicity. But if the soils are light and permeable, the aluminium is rendered soluble and afterwards quickly liberated, as proved by MIRASO; thus, after the first year, the potash is very beneficial; the soils become better adapted to tea culture, the yield is considerably increased and certain parasites, such as the *Helopeltis Thevora*, disappear. On clay soils, however, which cannot be easily leached out, the aluminium remains even after having been rendered soluble by the potash, which only does harm. As the clay soils cannot be leached out, they collect soluble aluminium, which is the cause of infertility.

Lime, in the form of carbonate, superphosphate, etc., also has a good effect, similar to that of potash. According to the authors, this is due to the fact that it precipitates aluminium, renders it impervious to attack even from the acids freed from organic manures and fixes it strongly and permanently in the soil. Besides this, it neutralises acidity; probably these two actions are to some extent connected, whereas, according to HOAGLAND, they are only coincident. L. V.

911 - **Soil Acidity and Bacterial Activity.** — STEPHENSON, R. E. (Agricultural College, University of Kentucky) in *Soil Science*, Vol. 12, No. 2, pp 133 144 and 145-162, fig 1, bibl of 13 works. Baltimore, Aug 1921

It has not yet been decided how and why soils become acid. In the decomposition of organic matter, bases and acids are formed, for instance, the processes of ammonification and nitrification. The products thus formed subsequently undergo changes; for instance, the acids react on the mineral substances of the soil, of which they hasten the disintegration and increase the availability, but which are sometimes precipitated, thus delaying their absorption by plants.

All these substances are partly absorbed by plants, which tend to keep the soil neutral by a process of auto-regularisation, plant growth being hindered by acidify; they are brought into contact with the water, which tends to acidify the soil by setting free its bases; the substances however are partly restored by vegetation and manuring. Many factors therefore unite to produce and regulate soil reaction. Among these, evidently decomposing organic matter exercises an important influence, but little research has been made on this question.

The author had already studied (1) the effect of the decomposition of some of these substances, nearly all of definite chemical composition; albumin, casein, dextrose, ammonium sulphate, starch, blood and alfalfa. But he wished to study other organic materials of more general use in agri-

(1) See R. 1919, No. 1084 (Ed)

culture, such as farm manure, cottonseed meal, dried blood, clover and other green crops, and oat straw. As in the earlier work, he used two soils, one rather sandy and light in colour, the other of the loam type, dark and fairly rich in organic matter ; tests were made in earthenware jars, fertiliser being added to the soil at the rate of 5000 lbs. per acre, on the basis of 2 000 000 lbs. of soil per acre ; straw was added generally in smaller quantities. In many tests he also used calcium carbonate precipitates in half the quantities above mentioned.

Soil acidity, as determined by the TACKE method by means of hyper-saturating with calcium, does not increase when decomposing organic materials are present, unless there is a large production of nitric acid. The addition of lime always increased nitrification ; it is evident that the lime, saturating the nitric acid, prevents the latter from becoming too concentrated, in which state at a certain moment it injures the bacteria which cause acidity and thus automatically stops the process of nitrification. With limestone, the nitrifiers become more active ; at the same time however ammonification becomes less intense. If nitric nitrogen and ammoniacal nitrogen be added, smaller quantities are found in limy soils, probably because the lime renders the micro-organisms more active, and these eventually assimilate and make organic the ammonia compounds and the nitrates, which no longer exist as such. Certain natural fertilisers, such as horse manure, produce small quantities of ammonia and nitrates, perhaps because they cause a vigorous growth of micro-organisms. Straw also reduces change and nitrification.

The soluble unknown non-protein nitrogen, not including the nitrates and ammonia compounds, showed little effect under the various organic treatments. Only the cottonseed meal gave any large increase. In all cases lining decreased the nitrogen content.

In practically all cases the soils show reaction under acid and organic treatment, but without greatly modifying the true acidity as determined by hydrogen-ion concentration. This is especially true of soils rich in organic matter and clay. Thus citric acid remained inactive in hydrogen-ion concentration. On the other hand, the acidity was always increased by the addition of a mineral acid, such as sulphuric acid. A similar action is certainly exercised by hydrochloric acid, acid silicates, etc., which are found in certain manures and fertilisers. It is interesting to note that neutral salts act in the same way as mineral acids ; for instance, ammonium sulphate is physiologically an acid because, while destroying the organic basic radical, the mineral-acid radical remains ; it is more active than a similar quantity of albumin because the latter forms nitrogenous bases which nitrify slowly ; on the other hand, it is more active than a like quantity of sulphuric acid. The addition of a mineral base decreases the acidity in every case ; certain neutral salts also act as bases : thus, limestone decrease hydrogen-ion concentration to a little over 8 pH, which seems to be the alkaline limit caused by limestone.

L. V.

912 - **Nitrogen Economy in Soils.** — BEAR, F. E. (Professor of Agricultural Chemistry and Soils, Ohio State University, Columbia) in *Journal of the American Society of Agronomy*, Vol 14, No. 4, pp. 136-152, bibliography of 35 works. Geneva Conference N. J., 9 figs., bibl. April 1922.

In 1840 LIEBIG stated that nitrogen in the form of ammonia dissolved in the rain was the source of the nitrogen used by plants. Estimations carried out subsequently by LAWES and GILBERT and exact determinations made recently by RUSSELL and RICHARDS prove that the amount of nitrogen supplied to the soil in the rainfall is usually not more than from 5 to 8 lb. annually, although occasionally the amount may be as much as 15 to 20 lb. per acre; but the quantity tends to increase with a greater rainfall and also with nearness to industrial centres.

Atmospheric nitrogen is fixed in the soil in considerable amounts by two distinct bacterial processes. One, termed symbiotic, is effected by *Bact. radiculicola* which exists in the roots of leguminosae. The work of this organism can be estimated by three methods: comparison between legumes and non-legumes; comparison of inoculated and non-inoculated legumes; analysis of the soil before and after the experiment, taking into account the nitrogen which may be added to or removed from the soil by any cause. The amount of nitrogen supplied to the soil by this means is considerable. ARNY and THATCHER have shown recently that melilot is able to fix nitrogen to the extent of 133 lb. per acre per annum, but as a rule the quantity is very much smaller. Nitrogen fixation is known to be stimulated by the use of phosphorus, potassium and lime, and leguminous plants are thus indirectly assisted as their nitrogen requirements are supplied. Nitrogen fixing bacteria are sensitive to acid conditions in varying degrees. FRED and DAVENPORT found the optimum pH for soybean to be 3.4 as compared to 4.3 for those of clover and 5.0 for melilot and lucerne. SALTER finds that the optimum for the soil is about 1 pH higher than would be expected from culture solutions. It may be possible, as suggested by LYON, to grow acid-tolerant legumes on soils in which nitrification is retarded. In addition to the symbiotic fixation of atmospheric nitrogen there is the non-symbiotic process carried out by free-living bacteria of which *Azotobacter* is the prototype. There are other organisms belonging to this group, which are able to function in acid soils unsuited to *Azotobacter*.

It has been shown by FRED and GOLDING that *B. radiculicola* has the capacity to fix nitrogen when free in the soil and absent from its host. The conditions which favour both symbiotic and non-symbiotic bacteria are similar and include the presence of carbonaceous and mineral matter. The non-symbiotic types are less active but time is on their side as they work continuously whereas the other form is active only in the presence of its host-plant; they thus play an important part in the supply of soil nitrogen. Investigators have estimated the quantity of nitrogen fixed by *Azotobacter* at from 15 to 14 lb. per acre per annum. All these organisms choose the line of least resistance for obtaining their food and after the available nitrates present in the soil have been utilised they then assimilate atmospheric nitrogen (BONAZZI). A third source of

nitrogen is that supplied by fertilisers which is more effective in some areas than others, for instance in Texas as compared with Ohio. This is related to the causes of the loss of soil nitrogen which vary in different districts. Nitrification actually entails a loss, as it renders nitrogen soluble and in this case if not immediately absorbed by plants it is easily washed away. Nitrification is hindered by acidity and assisted by alkalinity. In cold regions both nitrification and fixation of nitrogen are slow.

The opposite is the case in warm countries. The fixation of nitrogen by leguminosae is more rapid than the process of nitrification and in consequence a storage of nitrogen results. Experiments show that the greatest quantity of nitrogen is found in soils which are neutral or slightly acid and that there is an *optimum* reaction of about 6 pH.

Soil nitrogen is diminished by irrigation; LYON and BIZZEL, in the course of their lysimeter experiments shewed that this loss amounted to about 3.4 lb. per acre, excluding the first year in which cultivation of the soil increased the quantity; they also showed that the loss is closely related to the kind of crop grown. In the absence of vegetation the nitrogen loss averaged about 100 lb. per acre annually. This loss may be made up in practice by the cultivation of leguminous crops provided that phosphate and potash salts are applied, as was shown in the cylinder tests carried out at the New Jersey Station. The field experiments confirmed these results. On reviewing the subject it is seen that the nitrogen equilibrium is a result of many factors; rainfall, soil reaction, cropping system, temperature, manuring, irrigation, type of soil, presence of worms, insects, etc. The loss may be made good by sound methods of rotation and by so doing the amount of manure necessary will be reduced to a minimum. The most economical and the best plant growth is obtained when the losses and gains of nitrogen in the soil balance each other.

L. V.

913 - **The Isolation of Sulphur-Oxydising Bacteria from the Soil** (1). — JOFFE, J. S. (New Jersey Agricultural Experiment Station) in *Soil Science*, Vol XIII, No 3, pp 161-172, bibliography of 35 works. Baltimore, March 1922.

The author gives a general description of the sulphur-oxydising organisms, and abstracts are here made of some of his lesser-known studies. Apart from the classical sulphur-bacteria *Thiothrix* and *Beggiatota* he mentions the following groups: 1) *Rodobacteria*, already described by WINOGRADSKY, of which the typical species is given the name of *Thiorhodaceen*. They were discovered in 1826 by EHRENBURG, who named them *Monas okenii*; they are able to thrive in the light and need very little oxygen. 2) *Thiosulfobacteria* discovered by NATANSOHN in 1903; in 1904 BEIJERINCK described a typical species of *Thiobacillus thioparus* which was able to convert thio-sulphates into tetrathionate; 3) denitrifying *sulphobacteria*, discovered by BEIJERINCK in 1904 and studied by LIESKE in 1912. They are known as *Thiobacterium denitrificans* and thrive in the absence of oxygen, which they obtain from nitrates, and liberate nitrogen; 4) another

(1) See R. Aug. 1922, No 804. (Ed.)

similar group of sulphur bacteria is mentioned by DÜGGEI which are non-threadlike organisms termed by HINZE *Thiophysa volutans*, *Thiospirillum urinogradoki* Omeliansky, *Spirillum gralatum* Molisch. The author refers to the work of GICKLEHORN who described in a less exact manner a number of sulphur organisms.

With a mixture of soil, sulphur and basic phosphate of lime, the author was successful with a number of cultures carried out in a liquid containing neutral phosphate of potash, carbonate of lime or magnesia, nitrate of soda, sulphur and saccharose or dextrine. In the original cultures only 8 to 9 % of the sulphur was oxidised but the acidity of the mixture was increased; in many instances the cultures deteriorated but in two cases the oxidation of sulphur reached 18 %. The author tried to isolate the micro-organisms by employing the same media solidified with agar and obtained some bacterial colonies, both motile and non-motile and also fungi. Transfers of the bacteria to the liquid media did not produce an acidity equal to that of the original liquid culture medium. Platings carried out at a later stage gave no bacterial result. The author then replaced sodium nitrate by ammonium chloride as a source of nitrogen. He thus obtained a good medium in which the organisms were increasingly active and gave an acidity of 1.2 pH. He succeeded in obtaining by means of these transfers a pure culture of bacteria which were very active in the presence of sulphur. This organism in 150 days oxidised 48 % of the sulphur contained in the culture and gave a strong acid reaction below 2 pH. He has made experiments in collaboration with LIPMAN and WACKMAN which will be published separately. The author has shown that a number of micro-organisms are able to some extent to oxidise sulphur. Experiments were carried out with two fungi (*Mucor* and *Fusarium*) and also with two bacteria which grew well on CZAPPECK'S solid medium. These germs to some extent dissolved insoluble phosphate, no doubt owing to the action of the sulphuric acid produced. These germs interact amongst themselves. The author, for this reason, accepts the opinion expressed by LIPMAN that the process of sulphur oxidation in the soil is a result of the associated activities of different forms of micro-organisms, some of which bring about the oxidation which is then continued by others.

L. V.

914 - **A Method for counting the Number of Fungi in the Soil.** -- WAKSMAN, S. A. (New Jersey Agricultural Experiment Station, Department of Soil Chemistry and Bacteriology) in *Journal of Bacteriology*, Vol. 7, No. 3, pp. 339-341. Baltimore, May 1922

The spores of hyphomycetes and other fungi in the soil are estimated by the plate method with the same media and dilutions as are used for bacteria. As these bacteria are very numerous, the dilution of the soil is necessarily very high, but in these dilutions the fungi become so rare that very few appear on the plate in fact many plates are entirely free from fungi. The work therefore becomes impossible, or involves great error. But if the dilution of the soil be reduced, the bacteria become so numerous as to prevent the development and consequently the numbering of the fungi.

This difficulty was obviated by making use of acid media in which bacteria do not develop but fungi grow readily ; in this way a very low dilution of soil may be used. The author now gives the formula of an acid culture which gave very good results. In an experiment, he found 29 400 ( $\pm$  1700) germs per gram of soil, whereas with agar-agar and egg-albumen an impossible 460,000 ( $\pm$  94 000) were found, that is, 20 times as many ; the soil dilutions in these two cases were respectively, 1 000 and 200 000. The method may also be applied to the determination of the number of fungi in food preparations. The formula is as follows : glucose 10 gm. ; peptone 5 gm. ; acid potassium phosphate 1 gm. ; magnesium sulphate 0.5 gm. ; distilled water 1000 cc. Boil, add sufficient sulphuric acid or phosphoric acid to bring the reaction to 3.6 to 3.8 pH (usually 12-15 cc. are sufficient) ; add 15 gm. of agar, boil, run into tubes and sterilize as usual. The final reaction should be 4 pH. L. V.

915 - "Plant Cancers" and their Relation to the Soil: studied on the *Beta vulgaris*. -- LEVINE, M. in *American Journal of Botany* Vol 8, No. 10, pp. 507-525, bibl. of 18 works. Lancaster, Pa., Dec. 1921.

The numerous varieties of *Beta vulgaris* are subject to a sporadic disease which shows itself in the form of large tumors on the roots. There are two kinds, one called crown gall and the other tubercular disease. They are caused by two bacilli, respectively known as *Bacterium tumefaciens* and *Bacterium beticola*, which were discovered by SMITH, BROWN and TOWNSEND (1911). TOWNSEND (1915) concluded that the galls have no marked effect upon the size of the sugar beet and JENSEN (1918) found they had no detrimental effect on mangel wurzels. He observed that the large tumor-like formations on the sugar beet are of very irregular structure and that the tumor in almost every case is small in the garden beet. Many questions still remain to be decided : to ascertain more exactly the effects of the tumor on the roots and leaves of the plants attacked ; to determine the cause of the greater susceptibility of the sugar beet in comparison with other varieties of the *Beta vulgaris* ; to try to produce races proof against attack which will retain their qualities ; to differentiate the two kinds of disease from the histological point of view, and to study the relation of the disease to the soil.

The author undertook this last problem and proceeded to solve it by systematic research and weight determinations. He experimented on 3 varieties of *Beta* : mangel wurzel and two garden varieties. When the tap roots began to appear, he inoculated them with from 5 to 10 injections made with a needle dipped in a culture of *Bact. tumefaciens* ; 3 types of tumors were thus regularly produced : smooth, warty and mixed. For the pot tests, four kinds of soil were used : garden soil mixed with plenty of manure ; brown clay loam with manure ; the same without manure ; and sand. The growth of the plants decreased in the same order and that of the tumors also diminished in the same proportion. In the first soil a similar result was observed ; in the two highly manured lots, the inoculated mangel wurzels showed vigorous growth and the tumors on their roots were

large, whereas in the sandy unmanured lot the plants and tumors were poorly developed.

This disease therefore seems to develop more actively on the better nourished plants, especially those treated with nitrogen compounds. The writer recalls certain similar facts observed with regard to other plants. He also points out that the analogies of crown gall with animal cancer, recognised by SMITH, JENSEN, the writer and others, are increased by this action.

916 - **Soil Factors and Plant Growth.** — MOORE, B., in *Ecology*, vol 3, No 1, pp 65-83, 6 figs., bibl. of 12 works Brooklyn, Jan. 1922.

Among recent investigations on the importance of the soil in controlling plant growth and distribution, that of FERNALD on the distribution of *Pinus Banksiana* and *Thuja occidentalis* in connection with geological formation, and that of HESSELMAN on the importance of different kinds of humus in Swedish forests are deserving of attention. The beneficial influence of humus on plant life has long been recognised, but it was attributed solely to its effect upon the water-holding capacity of the soil and to its rendering the latter lighter and better ventilated, whereas HESSELMAN recognised that it is an effective agent in nitrogen production. The influence of soil reaction on plant growth has often been studied, but most attention has been given to acidity and alkalinity has thus been neglected.

The writer has studied the influence of humus and alkalinity on certain conifers (3 pines and a cedar. *Pinus rigida*, *P. Banksiana*, *P. Resinosa* and *Thuja occidentalis*), on a sugar maple (*Acer saccharum*) and on wheat. The soils were of pure sand, pure humus and a mixture of 80 % of sand with 20 % of humus. To eliminate the effects of the greater moisture-holding capacity of the humus, the soils were kept continually moist. For the plant-growth determinations, the height from the ground and the depth of the roots (of the pines only) were measured, the green weight was taken, and also the dry weight of wheat. Certain qualities, as indicated by appearance, colour, etc., were also noted.

On the whole, growth was difficult in sand, less so in the mixture of sand and humus and vigorous in humus, in spite of strong acidity. Evidently humus supplies nutriment which can be no other than nitrogen.

As regards conifer seedlings, the influence of humus was greatest in the case of *Pinus Banksiana* and *P. rigida*, less with *P. resinosa* and still less with *Thuja occidentalis*, which came up with difficulty in spite of the humus. These results lead to the conclusion that humus is especially beneficial to trees which in a natural state also grow on sterile soils; on the other hand, trees which require better soils find humus insufficient. The growth of wheat, a cultivated plant, was also little affected by humus with the exception that it favoured the growth of stems or shoots owing to its rich nitrogen content as compared with its carbon content. This accords with the observations of other writers.

Soil alkalisation was produced by the writer by means of quick-lime. He tried two types, one stronger (with 2.0 %, 2.4 % and 4.0 % of lime,

according to the soil type), and the other lighter (with 0.75 %, 0.8 % and 0.5 % of lime). Even a weak alkalisation still had a very unfavourable influence on seedlings, with the exception of those of the cedar. Sugar maple seedlings when transplanted all died immediately, except those planted in the sand. Numerous seedlings of other species also died; those which survived were poor in growth. The roots of the conifers became brown and shrivelled. This injurious effect diminished in time but was still marked after 40 days.

Large quantities of lime also had a decidedly unfavourable effect on wheat, not so much as regards height as weight, which was taken both before and after drying in an oven. This effect was more marked in cultures made in sand or with a little humus; it was hardly noticeable in pure humus cultures. On the other hand, moderate quantities of lime showed a favourable influence, especially on humus cultures, in which, with the addition of lime, wheat grew better than in the untreated soil.

Wheat therefore differs from trees in this respect, which shows that care should be taken in applying the results obtained with cereals to trees, and vice-versa.

917 - **Soil Acidity and Plant Composition of a Peat Bog.** — MOORE, B and TAYLOR, N. (Brooklyn Botanic Garden), in *Ecology*, Vol. 2, No. 4, pp. 258-261. Brooklyn, Oct. 1921.

Mt. Desert Island lies off the eastern coast of the state of Maine. The predominant vegetation is northern, with a number of arctic alpine plants, but southern forms are also found. A similar combination of northern and southern forms is found in the insect fauna of the island. On the south side of the island is a small bog 50 yds long by 25 wide, which is caused by an undrained depression in a granite formation which forms a great part of the island. The bog is covered with marsh plants, chiefly sedges. Its specific acidity is pH 4.5-4. The drying up of the water in summer, instead of making the acids stronger through higher concentration diminishes their intensity. Around the edge of the bog is a granite outcrop covered with vegetation. Under the roots of the *Empetrum nigrum* the acidity is lower, being pH 5.0 only.

Round the margin of the bog is a stunted growth of black spruce (*Picea nigra*) with a mixture of larch and other plants; here the acidity is still lower, being pH 6. In these three zones of varying acidity, the flora changes not only according to environment, but also according to origin. In the first zone, there are 25 % of arctic alpine plants, in the second 6.3 % and in the third, none at all. In the author's opinion, the first zone contains the older species and the other two zones contain a progressively increasing number of those subsequently introduced.

L. V.

918 - **Influence of Soil Reaction on Earth Worms.** — ARRHENIUS, O (Stockholm), in *Ecology*, Vol. 2, No. 4, pp. 255-257, bibl. of 7 works. Brooklyn, Oct. 1921.

After referring to the brilliant studies by C. DARWIN and P. F. MÜLLER, according to which the presence or absence of earth-worms largely determines the condition of the soil as regards acidity, the author mentions a hypothesis previously formulated by himself viz., that the two kinds

of soil depend, on the contrary, upon their hydrogen-ion concentration. Against this hypothesis it could be objected that the earth worms are capable of causing both the chemical reaction and the soil type. The author therefore wished to discover what modifications may be produced by earth worms on soils with different reactions. He modified the soil reaction by adding decinormal solutions of sulphuric acid and potassic hydrate or iodine hydrate, in each case with the same quantity of water (50 %). After the preliminary experiments, by simple interpolation calculations he prepared a series of soils measuring entire units of pH from 3 to 10. After having checked the hydrogen-ion concentration of this soil, he added a certain number of earth worms. After the first series of experiments in the "Treublaboratorium of's Lands Planentune", Buitenzorg, with the usual Javanese earthworm *Perichacta indica* Horst, the worms, after 4 or 5 days, were living and vigorous. In pH 6 and 7 concentrations, there had even been propagation, whereas, in the other concentrations, the worms were dead or dying. In another experiment in the Laboratory of Soils and Bacteriology, in the University of California at Berkeley, the results were even more convincing with *Lumbricus terrestris* L. After 3  $\frac{1}{2}$  days the worms only remained alive in the pH 6 and 7 concentrations. This proves that earth worms not only cause soil reaction but are themselves strongly influenced by it. This is in accord with the experiences of other authorities. For instance, PRISCOU informed the author that in Egypt there are no earth worms in the best soils, and from the observations made by the author, nearly all good Egyptian soils have a pH above 7.5. The observations of A. F. SHOHL and SH. H. KWIIZ may also be quoted, according to which the irritability of the earth-worms (*Allobophora foetida* Sav.) is proportionate to the hydrogen- and hydroxyl ion concentration.

To conclude, in the author's opinion, the reaction is the primary factor in the soil type.

L. V

919 - **Quantity of assimilable Phosphoric Acid and Potassium in Soils.** BRIOUX, CH. in *Annales de science et d'agriculture* Year XXXIX No. 2, pp. 82-100. Paris, March-Apr. 1922.

Agronomists and chemists still disagree as to the utility of chemically analysing arable land, such analysis as yet being far from a sure guide as to what, if any, fertiliser should be used. From deductions made which have been disproved in practice, the utility of this analysis has been questioned. It has been confined, in fact, to determining the four principal elements forming the fertilising reserve of the soil: total nitrogen, phosphorus, potassium and calcium, the last three being soluble in concentrated boiling acids. It is useful to know the quantity of nutritive reserves, but this will only be of relative value if the proportion of fertilising elements which may be available for plants, cannot be estimated at least approximately; this proportion indicates the degree of fertility.

Some important data have already been ascertained. The problem is to find the solvent to be adopted which would have an action comparable to that of the roots of the plants cultivated, or preferably, to that of

the general phenomena of solubility through which the plants can be nourished. The author tries to find solvents which, with the present means of analysis, will give results more in conformity with those obtained in practice. Among other experiments, the author makes a comparative study of two methods for estimating the assimilable phosphoric acid and potassium viz., B. DYER's and TH. SCHLOESING junior's afterwards A. DE SIGMOND's, methods.

DYER, who had at his disposal at the Experimental Station of Rothamsted soils which had received applications of fertilisers for 30 years of which the action was perfectly well known, employed the following method: after having determined in a large number of plants the acidity of the sap contained in the fresh roots, which is about 0.85 %, he treated them with a solution of citric acid at 1 %, finding between the parts untreated and those phosphated a ratio of 1 : 1.7 for the total phosphoric acid, soluble in boiling hydrochloric acid, and 1 : 6 for phosphoric acid soluble in weak citric acid. It may be presumed that the latter only dissolves the phosphoric acid which can be assimilated by the plants and is found in small quantities in the untreated parts; hence the marked difference between the terms of the second ratio. DYER obtains similar figures for potash. On comparing the results of the analyses with those of the cultures he confirms the fact that citric acid acts on phosphates and potash in nearly the same way as the natural solvent formed by the plants.

He gives the following practical rules: arable soil should contain at least 5.10 % of phosphoric acid soluble in 1 % citric acid for cereals and an appreciably higher percentage for root cultures. Though it is difficult to foresee whether the addition of potassic salts is beneficial, the figures for potash are the same.

GAROLA in applying DYER's method, increased the limits slightly, generally using phosphatic fertilisers when he found only 0.1 to 0.2 % of assimilable phosphoric acid. When the phosphoric acid soluble in citric acid reaches the figure of 0.3 %, the utility of these fertilisers ceases from the economic point of view. The utility of potash in an assimilable form continues up to 0.15 %; these methods indeed appear to agree in results with those obtained when fertilisers are applied to cultivated soils, provided the latter are not calcareous. DYER himself thinks that for these a larger quantity of citric acid is necessary so as to neutralise the carbonate of lime they contain. Further, for soils containing 15 to 20 % of carbonate of lime, which is not unusual, the method is uncertain in its results; the citrate of calcium formed, covers the seeds with carbonate of lime and limits its action; the evaporation and calcination which follow should also be taken into account.

These reasons induce the author to give up citric acid as a solvent and make a comparative study of the method, the principle of which was invented by TH. SCHLOESING Jun. and its technical application by DE SIGMOND. SCHLOESING divides phosphates into two distinct groups: those which are soluble in 0.5 % citric acid and those soluble in about 1 %. In the first of these groups, the phosphoric acid dissolved should belong to

phosphates with a calcium, magnesium and alkaline base, but not to those with an iron and aluminium base, which dissolve at an acidity of over 1 ‰. Soils from which the excess of phosphoric acid is separated with very weak acids are the same as those from which this excess is removed by water and other solutions with which they come contact. Hence it is concluded that this phosphoric acid belongs to the first group. DE SIGMOND confirms the existence of these two groups of phosphates, finding in 12 of the 14 kinds of soil examined that the quantity of phosphate dissolved, at acidities between 10 ‰ and 1 ‰ per unit of nitric acid, is invariable. In operating on 100 samples in which the need for phosphoric acid had been proved by experiment, he observed that though there is no constant connection between the total phosphoric acid content and the phosphate requirement of soils, there is a very close connection between the amount of phosphoric acid in an assimilable form and the need of a soil for phosphatic fertiliser.

The author adopts SIGMOND's method, applied in such a way that the final acidity is always between 200 and 1000 mg. per unit of nitric acid, and preferably about 500 mg. He uses a titrated solution of nitric acid of which 1 cc. = 100 mg. of nitric acid and a solution of potassium hydrate of which 1 cc. = 10 mg. of nitric acid.

In a large number of soils, more or less rich in carbonate of lime, the author, by using the official, DYER's and SCHLOESING's methods, also determines the quantity of assimilable potassium dissolved in nitric acid at a concentration of approximately 0.5 ‰. He gives two tables in which the soils are grouped according to increasing basic content which give an exact explanation of the two methods.

DYER's method gives a higher return of phosphoric acid than SCHLOESING-DE SIGMOND's, this being due to the fact that citric acid at 1 ‰ is a good solvent both of iron and aluminium phosphates and also of soil and alkaline soil phosphates in slight combination.

HALL and DEMOLON maintain that all the phosphate combinations found in soil appear to be represented in DYER's citric solution, for besides calcium there are organic matter and salts of iron and aluminium. A possible objection to DYER's method is that it is not easily applied to all soils, calcareous or otherwise, and that it dissolves iron and aluminium phosphates too easily, which phosphates are considered to have less easy access to plants than calcium and magnesium phosphates. This method, however, has been of great service in the analysis of silicious soils containing lime or clay.

The SCHLOESING-DE SIGMOND method has the advantage of rapid and easy application to non-calcareous soils as well as to those which are highly calcareous. It also appears to allow a better classification of soils which are to be treated with phosphate applications.

The relative assimilability however of the soil phosphates in slight combination, soluble in nitric acid at 0.5 ‰, and the more or less gelatinous iron and aluminium phosphates which are to be studied, should be borne in mind.

The quantities of assimilable potash separated are smaller than those of phosphoric acid, probably because potash enters into less varied combinations. The limits which show a poorness in the soil content of potash may be considered as being 0.20 ‰ by DYER'S method and 0.30 ‰ by SCHLOESING'S.

In conclusion, the author thinks that soil analysis limited to the study of its four principal elements is insufficient for fixing the phosphoric acid and especially the potash needs of the soil. He admits at the same time that the DYER and SCHLOESING-DE SIGMOND methods mark a great advance and are, together with the official method of determining by concentrated boiling acids, almost exclusively employed up to the present, of great help in these researches.

R. P.

920 - **Necessity for defining Soil Types in Investigations on Yield.** — BROWN, P. E (Professor of Soil Bacteriology, and Chief in Soil Chemistry and Bacteriology in the Experiment Station, Iowa State College, Ames, Iowa), in *Journal of the American Society of Agronomy*, Vol. 14, No. 5, pp. 198-206. Geneva, N. Y. May 1922.

Until comparatively recently there has been a tendency to make a general application of culture investigations, the results of which, on the contrary, apply only to the soil used. The numerous disagreements and contradictions in the results obtained by different investigators, and even by the same investigator, should be attributed in a great measure to the fact that conditions were different and above all that different soils were used. Many of the failures of farmers when applying these results to field work are due to this; hence the distrust in these experiments felt by practical men. Nevertheless, agriculture is greatly indebted to experimental work, which has proved of inestimable economical value and needs no apology.

Few of the results of experiments apply to *all* soils; generally, the particular soil type should be taken into account. Numerous investigators continue to ignore this essential feature. This is partly explained by the fact that they wish to make the best of their results by applying them generally; at the same time the farmers ask for advice which may be put into practice without difficulty and with the fewest possible restrictions. It should be remembered also that the experimental stations and scientific laboratories have a tendency to publish as much as possible and that the investigators desire to make themselves known early and to acquire honours, which blunts their critical sense and leaves their published work defective. There is a tendency to arrive at hasty and too generalised conclusions which leads to disillusion. Applications should be more specific.

Care should be taken however not to fall into the opposite extreme, as LIPMAN and LINHART have done, according to whom fertiliser tests are of very limited application, of no practical value and do not justify the expenditure of energy and money involved. This hypercritical attitude has no foundation; unfortunately it influences the uninitiated and brings discredit on soil experimental work in the minds of other scientists, farmers and co-operative societies.

What is of importance is to determine the soil type when making investigations. Once this is done there can be no question but that under the same conditions results on the whole will be similar. After a very long experience, the writer is convinced that the classification by the U. S. Bureau of Soils gives a sound definition of soil types. This classification includes several hundreds of types; in some cases even the distinctions are so fine that it is impossible to distinguish the types described and this involves too much of the personal equation. In spite of this defect however, it is fundamentally sound and offers a firm basis for scientific and practical men.

To prove the different reactions of dissimilar soils treated with the same fertiliser, the writer describes numerous field experiments carried out on 10 soils to which he applied 5 kinds of fertilisers and on which he cultivated oats, clover and maize, and also pot experiments on 9 soils treated in the same way and on which wheat and clover were grown. Certain fertilisers proved beneficial, though in varying degrees, to certain cultures on all the soils; thus, lime to clover and manure to maize and oats. Other treatments however gave very different results with the same crop on different soils. Thus, in a pot test, a complete fertiliser gave an increase of 60 % in clover yield over the control in one soil, and 900 % more in another. Different soils, therefore, may respond in a very different way to fertilisers and correctives. This fact is well known as regards sulphur, potassium, etc. The influence of fertilisers as regards the nitrogen content of tops and roots varies; that on bacteria also varies, and the author has made a special study of this question. Other investigations have been made by him to determine the relation between the soil type and its chemical composition.

L. V.

921 - **Relations between Soil Type and Root Form of Pine Seedlings.** — HAASTIS, P. W. (United States Forest Service) in *Ecology*, Vol. 2, No. 4, pp. 292-303, 3 figs., bibl. of 8 works. Brooklyn, Oct. 1921.

While studying the natural reproduction of *Pinus ponderosa scapularum* at the Fort Valley Station, Flagstaff (Arizona), the writer has been trying during the last two years to correlate the character of root development of the young seedlings with the types of soil. He has made a study of 286 plants divided into six age classes. The soils, almost all of basaltic origin, but some also composed of cinders (volcanic), were divided into five groups: 1) *Stony-clayey*, compact, stiff, but modified by stones and stony rocks; 2) *Gravelly-loamy*, light and moderately porous, not baking or crusting when dry and with a few stones (these two types are the most frequent in the area studied); 3) *Loamy-rocky*, mellow, dark-coloured, moderately rich in humus, with many stones (a little less common than the two foregoing); 4) *Clayey*, very compact, least porous, not well aerated, deep, retaining moisture and most fertile; 5) *Cindery*, loamy, porous, with coarse cinders below or in the middle (the least frequent). The roots, complete, with all their lateral rootlets, were divided into 8 categories: filiform (only met with in the first stage of growth), bifurcate,

muscoid, obconical (like an inverted cone), clavate, fusiform, cylindrical and ramified (without main root). The main roots may have one of these types. There is a special form of fan-like ramification. The most usual forms were obconical and cylindrical, next came the clavate and fusiform.

In clayey soils, lateral roots were scarce; they were more frequent in stony-clayey and gravelly soils, and abounded in loamy-rocky soils. In the coarse-cindery soils, the largest number of ramified roots were found; these were rather rare in the other soils, especially the clayey ones. The same was noted in the case of the fan-like ramifications.

In general, two extreme root growths were observed: one, in clayey soil, was characterised by a minimum number of laterals and by "branching"; the other, in coarse-cindery soils, by a maximum of laterals and branching.

The more clayey the soil, the longer is the root and the smaller the ratio between top and root; the more loamy the soil, the shorter the root and consequently the greater the above ratio. This had already been observed by WEAVER. It is not in direct relation with the available moisture of the soil and in fact tests have proved that the smallest quantity of available water was held by stony-clayey soils and the largest quantity by coarse-cindery soils.

L. V.

922 - **Influence of Irrigation on the Composition of the Soil.** — GREAVES, J. E. (Department of Chemistry and Bacteriology, Utah Agricultural Experiment Station, Logan), in *Journal of the American Society of Agronomy*, Vol. 14, No. 5, pp. 207-212, bibl. of 7 works. Geneva, N. Y. May 1922.

Water has a double action on the soil. It assists or hinders the normal development of the processes in the soil, and its most manifest influence is over the process of nitrification, of which the maximum is attained when the soil contains 60 % of its water-holding capacity. Above or below this concentration, there is a decrease; and nitrification ceases when the quantity of water reaches or exceeds 90 %. As regards nitrification, therefore, an excess of water is more detrimental than an insufficiency. Under good moisture conditions, from 50 to 100 lb. of nitric acid may be produced in an acre of soil during a season; it is a well-known fact that this acid is of great assistance in the liberation of phosphorus and potassium. The moisture content acts similarly, but in a less degree, on ammonification, the maximum production of which is also reached when the soil contains 60 % of its total water-holding capacity. All the other processes which take place in the soil are also dependent on its water content: for instance, the production of carbonic acid gas, which may be as much as 60 l. per acre per day; it also plays an important part in the solution of tricalcium phosphate. Finally, it influences the production of lactic, acetic, butyric, sulphuric, and other acids, which help to dissolve potassium, etc.

The other fundamental action of irrigation water is that it brings or carries away plant food; it impoverishes or enriches the soil. To gain an idea of the enormous quantities of substances that water may carry

off from the soil, it is only necessary to consider the constituents of river water. The substances in solution such as for instance, sodium chloride are not generally of any importance in agriculture, but useful substances, such as potassium, nitrogen and phosphorus, are not lacking. The writer describes certain analyses on this question. Some irrigation drain waters are still richer; certain of them contained as much as 133 pounds per acrefoot.

When irrigation is carried out properly, the water, as it evaporates, deposits the substances it contains, as in the case of the Nile. Thus, in Utah, the waters used for irrigation contain 0.79 to 59.0 parts of potassium per million, or an average of 5 parts which may be used by the soil. Irrigation waters contain besides potassium, nitrogen and other useful soluble substances; they are therefore capable of improving the soil. The great point is to irrigate *in moderation* in order not to *wash out* the soil. Irrigation may transform the desert into a garden or render the most productive fields barren, according as it is well or ill done. L. V.

**METHODS  
OF  
CULTIVATION**

923 — **The Culture of Cereals in Furrows.** — CHAPLIN, M. S., in *La Gazette Agricole du Canada*, Vol. IX, No. 2, pp 120-125. Ottawa, Mai-Avr. 1922

The development of Saskatchewan is due to its wheat and oat production. To keep the soil moist and destroy weeds, the farmers let the land lie fallow once every two, three or four years, according to local conditions of soil and climate. This system generally gave good results in the different districts so long as land was cheap and the selling price of wheat and other cereals comparatively high; also provided the soil kept its original firmness sufficiently to prevent the plants being lifted by the wind.

At the present time certain factors compel the Prairie farmers to modify this system.

It would be difficult to say which is the chief among these factors, but each of them has an influence.

In many districts, trouble is caused by dust storms. Fallow land is exposed to the weather the whole year round and there is consequently a displacement of soil. The effects of the dust storms are so evident that it is needless to allude to this point (1).

The market prices of cereals are no longer maintained at the high level due to the war. Means must be found for producing at prices sufficiently low to compete with other countries in the world markets.

In certain districts the price of land has risen to such an extent that the interest and taxes on an acre of fallow-land have become a considerable burden, eliminating all hope of profit on wheat production, even when they do not show a loss.

This being so, it is clear that at the present stage of development in Canadian agriculture, all crops cultivated in furrows which can replace at least a part of fallow-land will be considered useful. Some farmers

(1) See R. Feb. 1922, No. 143. (Ed.)

are trying maize, others potatoes. These crops are useful over a very limited area, but something must be found which can be cultivated extensively so as to replace a considerable part of the present fallow-land.

Guided by previous experience the author has decided to carry out experiments at Saskatchewan to see if grain culture in furrows can replace the fallow-land.

Some preliminary experiments were made in 1921. The plots on which they were carried out were rather large, measuring 0.4 acres each and gave very encouraging results. Trials were made with wheat, oats and barley. Each crop was sown in groups of 3 rows, with 30 inches distance between each group and in groups of 2 with 36 in. between them. For comparison, a table is given showing the yields from both methods of the first and second crop after the land had been lying in fallow during the summer. The grain in furrows was sown on soil which had borne oats the previous year, 1920, and various crops in 1919, and had not lain fallow in 1918. The following is the grain and straw yield in kg. per ha.

Method of sowing	Grain Kg.	Straw Kg.
<i>« Marquis » wheat.</i>		
Ordinary on fallow land . . . . .	42	4.10
Ordinary on Autumn tillage . . . . .	42	3.67
Double rows with 91 cm. between . . . . .	20.95	1.07
Triple rows with 76 cm. between . . . . .	25.02	1.27
<i>« Banner » Oats.</i>		
Ordinary on fallow land . . . . .	94.55	5.90
Ordinary on Autumn tillage . . . . .	67.95	3.07
Double rows with 91 cm. between . . . . .	67.47	0.85
Triple rows with 76 cm. between . . . . .	72.35	1.07
<i>« Hannchen » Barley.</i>		
Ordinary on fallow land . . . . .	67.02	3.62
Ordinary on Autumn tillage . . . . .	63.97	2.77
Double rows with 91 cm. between . . . . .	42.27	0.63
Tripled rows with 76 cm. between . . . . .	55.92	0.80

The Department of Animal Industry has also sown oats in furrows as pasture, to replace summer fallow, with very satisfactory results.

924 - **The Sowing of Seeds and Scattering of Chemical Fertilisers simultaneously in parallel and close Lines.** — BANDRY, A., in *Comptes Rendus des séances de l'Académie d'agriculture de France*, Vol. 8, No. 20, pp. 574-580. Paris, 1922.

Low crop yield is due less to the insufficiency of chemical fertilisers used than to their imperfect utilisation by the crops. It was decided to place within immediate reach of the young plants the mineral nutriment needed by them from the earliest stages of their growth. For 15 conse-

cutive years the author studied the application to extensive cultures of the simultaneous scattering of chemical fertiliser and seed grain in close parallel lines. The results obtained are as follows :

1) The maximum profit in practice from crops, both of cereals and pulse, has always been obtained by using quantities of chemical fertilisers varying from 300 to 400 kg. per ha.

2) With more than 400 kg. of chemical fertiliser the value of the increase in weight of the crops did not correspond with that of the increase in weight of the chemical fertilisers used.

3) The yield per ha. of useful dry matter from the crops obtained by using 200 to 400 kg. of chemical fertilisers spread in lines has been at least equal and often superior to that obtained on the same soil by using 600 to 1000 kg. of the same fertilisers distributed in the usual way.

4) Chemical fertilisers sown in lines at a depth of 2 to 3 cm. in close proximity to the seed have a beneficial effect on the young plants.

The author concludes that this method of rational utilisation of chemical fertilisers is so effective that it has become possible to reduce the quantities hitherto judged necessary to ensure the maximum practical profit from crops by 50 to 60 %.

**925 - Thirty Years of Field Experiments with Crop Rotation, Manure and Fertilisers. --**

MILLER, M. F., and HUDLSON, R. R., in *Missouri Agricultural Experiment Station Bulletin*, No 182, pp. 1-43. Columbia, Missouri, April 1921.

The author proposed to ascertain the effects of crop rotation and continuous cropping upon unmanured and manured soil respectively. They realised that experiments over a long period are necessary in order to reduce to a minimum the influence of seasonal variation and to secure reliable results from the various rotations.

The data here reported include the results of 30 years experiments (1888-1918) with different systems of crops, manures and fertilisers, designed to ascertain not only the effect upon crop yields, but also upon the soil.

The soil of the experiment field was a silt loam of a dark brownish grey colour, the surface drainage was generally good and the soil fairly uniform in fertility. The field was divided into 39 tenth-acre plots at first, though these were afterwards reduced to one-thirteenth acre and subsequently to one-fourteenth acre. The plots were planted with continuous crops and rotations of maize, oats, wheat, clover and timothy.

These crops were grown at the same time on untreated plots, on plots given manure, plots given chemical fertilisers such as nitrate of soda, muriate of potash and superphosphate, as well as on plots receiving both manure and fertilisers.

The applications of manure were much larger than is usual on the average farm (7-9 tons per acre); hence the effects upon the soil and crops were intensified, but weed growth was encouraged so that the grass and clover crops sown with the crops were smothered, and lodging was induced in wheat and oats.

The fertiliser treatment was based on the quantitative chemical analyses of the crops, the different elements being added in the same proportions that they were removed in maximum crops. The plot on which wheat was continuously grown received sufficient nitrogen, phosphorus and potassium to equal the amounts contained in a 40-bushel wheat crop and the accompanying straw.

From the experimental data collected by the authors it appears that :

1) *on untreated soil*, rotation gave very superior results to continuous cropping. In the case of maize, the yield is increased by lengthening the period between the crops, as is shown by the following figures :

20.9	bushels with continuous cropping
32.6	" " 3 years rotation
38.5	" " 4 " "
41.5	" " 6 " "

In the case of the other crops, the maximum yield is obtained from 4 years rotation.

In the opinion of the authors, the low yield obtained by continuous cropping is due to several factors among which are insect enemies, weeds and disease, which are all favoured by growing the same crop on the same field year after year.

2) *On soil treated with manure* so as to maintain its fertility, rotation gave better results than continuous cropping, although the differences in the yields of the various crops were not so great as in the case of the experiments carried out on unmanured soil.

The use of manure greatly increased the yield of continuous crops, especially in the cases of maize, wheat and oats, the average increase recorded being as follows :

Maize	14.0	bushels per annum per acre
Oats	10.1	" " " " "
Wheat	8.6	" " " " "
Clover	827	lb. " " " "
Timothy	2325	lb. " " " "

The above figures show the high value of manure on wheat, maize and timothy, the effect on continuous clover not being so good.

In the course of the long experiment period, it was found that a three-year rotation on an unmanured soil gives lower yields than are obtained from continuous crops on manured ground, whereas with a long rotation (4-6 years), better results are obtained than from continuous crops grown on manured soil. Judging from the soil analysis, it is evident however that manure is more effective than rotation in maintaining the fertility of the soil. In fact, although by means of careful rotation it is possible to some extent, to relieve soil exhaustion all the elements required cannot be supplied by this means. A combination of rotation and manure is best.

3) *On soils treated with chemical fertilisers* the yield of the crops was

kept up as well as when manure was used. On comparing the different results obtained it is seen that maize does better with manure, but wheat and oats are better with fertiliser. In general, this relative response of the different crops to manure and fertiliser agrees with the results of numerous other experiments made at the Missouri Experiment Station and at the Rothamsted Experiment Station in England, and the Pennsylvania Experiment Station.

Chemical fertilisers, especially phosphates, are particularly to be recommended for wheat.

In the case of plots receiving fertilisers only, even in the one cropped continuously with wheat the soil was not appreciably more compact than that of similarly cropped plots without treatment, contrary to the generally received opinion that large quantities of sodium nitrate tend to deteriorate the soil texture.

4) *On soil treated with half manure and half fertiliser*, better results were obtained than with chemical fertilisers alone; therefore mixed fertilisers are the best to employ as they also maintain the soil fertility. To determine the effect exerted on the soil by different methods of cropping, the authors had recourse to chemical analysis. At the end of 25 years samples were removed from the different plots and the nitrogen content was taken as an indicator of the amount of organic matter in the soil. Maize was found to be the most exhaustive crop as regards the nitrogen, after which come oats and wheat. Timothy appears to exhaust the soil least. As a rule, rotations are less exhaustive of soil nitrogen than any single crop. This may be due to nitrogen fixation by bacterial agency.

Chemical fertilisers, even when used in large quantities, did not keep up the soil nitrogen. Evidently most of the nitrogen not immediately used by the crop was removed by leaching, or denitrification. Manure on the other hand proved very effective in maintaining the nitrogen supply.

This long series of experiments proved that, in general, *crop rotation gives better results than continuous crops*. Among the rotations used the four-year rotation of maize, oats, wheat and clover gave somewhat better results than the others. In order to obtain good crops the soil must also be manured. As a rule, farmyard-manure and chemical fertilisers proved of about the same value from the point of view of crop yield, but farmyard-manure was more effective in maintaining the fertility of the soil.

The application of a mixed fertiliser has proved to be the best method to maintain heavy crop yields without exhaustion of the land. L. M.

926 - **Relation between Nitrogen in the Soil and Livestock Farming.** — WILLIAMS, C. (Director of the Agricultural Experiment Station, Wooster, Ohio), in *Journal of the American Society of Agronomy*, Vol. 14, No. 5, pp. 159-162. Geneva, N. Y., May 1922.

Since 1910 the writer, has been making comparative experiments at the Station which he directs, in livestock farming and the direct utilisation of the various crops. The rotation followed is maize, soybeans, wheat and clover. Each area receives 2 tons of ground limestone and 700 pounds of 16 % acid phosphate per acre, per rotation. In the first system, all

the crops except wheat are fed to livestock or passed into the manure as bedding and the manure is applied to the maize crop ; in the second, the maize, soybeans and wheat are removed and sold, the hay and straw being left upon or returned to the land ; and the clover is not harvested, but allowed to stand until ploughed under the following spring. The comparison shows the superiority of livestock farming, which increases the crop production and the nitrogen content of the soil. L. V.

927 — **Fertilisers in Indo-China.** — MANGIN, L., in *Comptes Rendus des Séances de l'Académie d'Agriculture de France*, Vol. 7, No. 37, pp 794-803. Paris, Nov. 30, 1921.

MANURES  
AND  
MANURING

The author, acting for the Economic Agency of Indo-China states that this country has imported very little chemical fertiliser up to the present. In 1913 not more than 3 419 qx. were imported, including chloride of potash, nitrate of soda, nitrate of potash, superphosphates and other fertilisers. During the war the quantity was still lower. In 1920 the Central Government had 433 tons of potassic fertilisers sent from Alsace on account of several planters' associations.

With the progress made in agriculture, the use of chemical fertilisers, based on a knowledge of the chemical composition of the soil and the necessary fertilising elements, will doubtless become more extended.

The Central Government has had analyses and enquiries made in the countries of the Union of Further India (" Union Indo-Chinoise ") in order to ascertain the sources of fertilising matter in each district, their need of fertilisers and the most effective way in which to extend their use. The results of the enquiries are as follows :

*Cochinchina.* — Without taking into consideration farmyard manure, the fertilisers from local sources are : silk-worm waste, bat guano, fish offal and the remains of fish and crustacea left over from the manufacture of *Nouc-mam*, a kind of pickle used as seasoning, arachis oil-cake, copra, sesame, castor-oil, etc., barley waste from the distilleries and waste from the rice-crushing mills.

The Works of the Indo-Chinese Distillery Co at Cholon can produce 2000 kg. of dry barley waste, phosphated or otherwise, daily.

M. VIEILLARD, Inspector of the Agricultural Services, has classified the soils of this country from the chemical point of view as follows :

- 1) Alluvial marine soil of old or recent formation ;
- 2) Alluminous soils ;
- 3) Alluvial soils from the valleys ;
- 4) Grey soils ;
- 5) Red soils.

Natural phosphates may be applied to nearly all the soils of Cochinchina except the red earths.

Mineral superphosphates, bone superphosphates and basic slag might be imported from France, but in most cases the natural phosphates of Tonkin and Cambodia will also be effective and cheaper.

*Cambodia.* — This country up to the present has only imported crab fertiliser for pear culture. The amount imported annually may be

estimated at 1000 to 2000 tons, of which the greater part comes from the Malayan Archipelago and the Province of Bach-Cia, in Cochinchina and a small part of South Annam. With this exception, the natives use no fertilisers and consider the periodical inundations sufficient. In other districts, owing to the sparse population, they burn the bush and forests in order to improve the land temporarily, repeating this operation over more distant areas, to the great detriment of the forest resources of the country.

Agriculture, as it develops, will find in Cambodia itself phosphates as rich as those of Tonkin, and the fish offal of the great lakes and the Mékong, which at present is wasted, would supply fertilisers rich in nitrogen and phosphoric acid. For the cultivation of crops for which large concessions have already been asked and obtained, the fertilisers imported will be of the same kind as those for Cochinchina, especially in the case of red and grey soils, which cover millions of hectares in Cambodia.

*Annam.* -- The fertilisers from local sources, in addition to farmyard manure, are the waste products of copra, of *Candlia* and *Calophyllum* from domestic presses in the different provinces, and cinders from factories and works used in tobacco and coffee culture. With the exception of a small quantity of phosphate imported from Tonkin, the natives as yet only use these local fertilisers. There is no doubt however that the use of chemical fertilisers, would cause a remarkable increase in many crops in Annam.

*Tonkin* -- The Works of the Indo-Chinese Distillery Co. can produce from 1200 to 1500 kg. of distillery refuse, phosphated or otherwise. This is in excess of the present demand.

There are numerous beds of natural phosphates worked by the Tonkin Phosphate Co. In 1920 this company manufactured more than 7000 tons. The greater part is used in Tonkin itself; a small quantity, less than 500 tons, was exported to Cochinchina, Annam, China, the Dutch Indies, and Siam. Consequently the planters of this country appreciate the advantage of replacing farmyard manure largely by chemical fertilisers, the production of the manure requires considerable capital and is uncertain on account of frequent outbreaks of disease amongst animals. In addition to the local phosphates, potash and nitrate fertilisers should be used. Such are: nitrates, sulphate of ammonia and cyanamide, especially for valuable crops such as tea, coffee and tobacco. They would always command a high price owing to the greater yield they produce.

*Laos.* -- Owing to the sparse population, the extent of uncultivated land and the backward state of civilization the question of fertilisers in this country has not yet been considered.

The Economic Agency of Further India suggests the following measures for extending the use of chemical fertilisers:

- 1) Comparative experiments at the Experimental Stations of the Economic and Agricultural Departments,
- 2) Posters in the languages known and spoken in the country: French and Quongu, and in Chinese characters;

3) Instruction in the schools and discussions after the school period.

M. DEVRAICHE, Chief of the Economic Department of Cochinchina advises the Agricultural Syndicates to sell fertilisers at very low prices, even at a loss at first if necessary.

The Chamber of Agriculture for Cochinchina thinks that the best propaganda would be the gratuitous distribution to the principal villages of a sufficient quantity of the fertilisers applicable to the intended cultures.

Finally, M. VIRILLARD proposes the sale of compound fertilisers, mixed and ready for use, for tobacco, rice, the sugar-cane, etc.; these fertilisers should be prepared by specialists and adapted to the intended cultures and the soil.

The application of these measures of propaganda in favour of the use of chemical fertilisers would give a considerable impetus to agriculture in Further India.

931 - **The Relation between Organic Matter and the Assimilation of Mineral Phosphate.** - BAUER, J. C. (Agricultural Experiment Station, University of Wisconsin), in *Soil Science*, Vol. XII, No. 1, pp. 21-41, bibliography of 45 works. Baltimore, July 1921

The use of mineral phosphate in conjunction with organic matter in a state of decomposition has been recommended, as it is considered that organic, nitric and carbonic acids present in the decomposing matter attack the phosphates and render them more available. This view however was not upheld by the laboratory experiments carried out for its confirmation. Although in practical farming, phosphates give the best results when associated with large quantities of organic substances, when chemical methods are used, it does not seem possible to prove that the phosphates themselves are actually rendered soluble to any appreciable extent, and various attempts have been made to explain this contradiction.

TROUG was of opinion that phosphates when first precipitated in the soil in the form of very small particles are protected by a film of organic matter; TOTTINGHAM and HOFFMAN held the view that most of the phosphorus made soluble is utilised and organised by bacteria in such a way as to escape analysis. On the other hand many investigators have shown that plants possess to a greater or less degree the capacity of utilising insoluble phosphates. As a rule cereals are less capable than leguminosae, crucifers and buckwheat which can make great use of insoluble phosphate. This has been attributed to the secretion of organic and carbonic acids by the roots. CHIRIKOV has shown that plants which possess this capacity assimilate lime readily and TROUG considers that the quantity of lime contained in plants is related to the property of assimilating insoluble

phosphate. It would be advisable to have recourse to these plants in order to render the insoluble phosphates available.

The author suggests that in laboratory experiments up to the present time, carried out on mixtures of insoluble phosphate and organic matter in a state of decomposition, enough care had not been taken to remove at the moment of its formation any soluble phosphate of lime; as soon as the chemical equilibrium is established the reaction ceases and in consequence only very small quantities of phosphorus and lime are made soluble. On the other hand plants remove them in proportion as they are produced; in consequence the chemical reaction continues so long as there is complete utilisation of the phosphorus.

The author has carried out various experiments with a view to the continuous production of soluble compounds of phosphorus and lime. The experiments were made in pots filled with sand, or an acid sandy soil containing little phosphorus (0.59 parts per million); the decomposing organic matter employed consisted of melilot or buckwheat hay to which was added finely powdered mineral phosphate. On the supposition that soluble phosphate of lime would be formed he arranged for its removal by means of lixiviation with water and by capillarity methods so that the water in the lower layers was constantly renewed while evaporation was taking place on the surface. He also tested the action on mineral phosphate of decomposing plant extracts and of extracts from soil vegetable matter. It is unnecessary to remark that controls were not overlooked.

The author was unable to prove that organic matter in a state of decomposition had any effect in dissolving mineral phosphate.

The non-success of the preliminary experiments led the author to conclude that the acids produced by the organic matter were sufficient only to combine with bases found in the soil, which prevented their having any action on the phosphates. However, as shown by TOTTINGHAM and HOFFMAN, as soon as a small quantity of soluble phosphorus is produced it can be utilised by bacteria. This explains the negative results of the analysis. As the available data relating to chemical resources were not sufficient to explain the action of decomposing organic matter on insoluble phosphates, the author wished to make a thorough investigation as to the capacity of plants to make use of these phosphates in the presence of such organic substances. He arranged a series of cultures of maize in pots filled with sand to which were added different quantities of organic matter derived from lucerne, buckwheat or oat straw, together with mineral phosphate and with or without lime. The organic substances had a prejudicial effect on the growth of the maize and introduced complications, but the effect was very small in the presence of lime. In every instance, except in the case of the oat straw, the cultures were so poor that the experiment had to be abandoned.

In spite of this detrimental influence the actual growth of the maize was more vigorous in the pots containing both organic matter and phosphates than in those which contained an equal quantity of one or the

other only of these substances. An examination was made as to the weight of dry matter present which showed conclusively that the maize had been able to take advantage of the phosphates in those cases where the phosphates were mixed with decomposing organic matter, which confirms the experimental data. The author has proved by a number of analyses the presence of a high percentage of phosphorus and lime, both soluble and insoluble, in maize and other plants.

In order to explain the way in which plants utilise mineral phosphate in the presence of organic matter in a state of decomposition, the author suggests two theories: 1) the acids derived from the organic matter are able to dissolve the phosphate, or 2) the plants themselves are able by some means to effect its solution.

In order to study the power which plants may possess to dissolve mineral phosphate without the cooperation of organic matter the author carried out a series of cultures with 15 plants in sand to which was added mineral phosphate or superphosphate, with or without lime and a further number of controls without any additions. The results have shown that plants are able to some extent to make direct use of basic phosphate, but in a less degree than soluble phosphate. In this respect melilot showed the greatest capacity as its coefficient of utilisation reached 83 % as compared with soluble phosphate. The roots of the plants which had to utilise basic phosphate were generally better developed if lime was present. This fact explains how under such conditions plants become more energetic in order to obtain the phosphorus which they need.

The only exception was melilot which was able to absorb insoluble phosphorus without any further development of its root system.

No connection has been recognised between the amount of phosphorus contained in plants grown in the presence of soluble or insoluble phosphate and the acidity of their sap or their different parts. Neither has it been possible to find any definite relation between the lime content of plants and their capacity to utilise insoluble phosphate.

The author then attempted to test the capacity of plants for the absorption of another insoluble mineral element, namely, potassium as contained in feldspar. It is not understood how this absorption is effected, but in this case it is certain that the lime contained in the plant does not assist the reaction.

The experiments were made on four plants only, viz. buckwheat, which can make good use of insoluble phosphate with a capacity of 72.1% as compared with soluble phosphate, but was only able to absorb a small quantity of insoluble potassium, 23.3 % as compared with potassium sulphate. On the other hand, oats which have only a relative capacity to utilise 41.5 % of insoluble phosphate, absorb potassium from feldspar to the extent of 107.6 %, a contrast which even the different development of the root systems does not explain. Buckwheat is similar to maize, but melilot which can use 83 % of insoluble phosphate, relative to soluble phosphate, has in the case of potassium from feldspar a capacity of 106.5 %. In the last experiment melilot grew extraordinarily well in a mixture compos-

ed exclusively of siliceous sand, feldspar, mineral phosphate and lime, moistened with distilled water; maize on the contrary made very poor progress.

There are many nutritious plants similar to melilot, maize and buckwheat. Melilot possesses the greatest capacity for dissolving mineral phosphate and feldspar in order to utilise the mineral matter in the production of organic substances.

The problem of the rotation of cereals with plants of this order is very important from a practical standpoint, as such plants are able to supply nitrogen, and to assimilate phosphorus and potassium from comparatively insoluble minerals.

L. V.

932 - **The Availability of Potash in some Soil-Forming Minerals.** — FRAPS, G. S., in *Texas Agricultural Experiment Station Bulletin*, No 284, pp. 5-16, figs. 3. College Station, Brazos County, Texas, December 1921.

The availability of the potash in biotite, muscovite, orthoclase, microcline and many other mineral constituents of the soil is a matter of great importance to soil chemistry. It is particularly interesting to know whether there is any relation between the solubility of these minerals in acid and the amount of potash they can supply to plants.

With a view to solving this question and with the special object of testing the effect of granite which had been proposed as a fertiliser for Texas soils, the author carried out three series of experiments. In the two first series he studied the general problem, but in the third he confined himself to the study of the fertilising effect of granite.

In the first series of experiments, only 500 parts of potash were used per million parts of soil, in the second series the amount of mineral potash added was 4000 parts per million of soil.

Nitrogen and phosphoric acid, in the form of nitrate of soda, or of ammonia, and superphosphate were used in both the above experiments, and in two sub-series, carbonate of lime and sawdust were added respectively

Pots were used throughout the experiments and as in no case was any potash applied except in mineral form, the amount of potash removed from the soil by the different crops can be measured from the quantity taken from the minerals. A large number of minerals were employed in these experiments including microcline, orthoclase, biotite, muscovite, leucite, nephelite, pinite, stilbite and chabazite, and they were compared with sulphate of potash. Cotton, maize, millet and sorghum were planted in the pots, the sowing being so arranged as to obtain 4 crops.

The tables given by the author give the results obtained in the two first series of experiments. The average amount of potash removed from the soil by the crops of the first series varied from 1 % (microcline) to 38.7 % (sulphate of potash). The different substances used may be placed in the following ascending order: microcline, orthoclase, pinite, muscovite, biotite, stilbite, chabazite and sulphate of potash. The largest recovery of potash was usually made with the first crop. The results obtained with leucite and nephelite were not satisfactory, but probably, as the author suggests, this was due to the small number of experiments.

The relation between the availability of the potash and the different minerals and their solubility in acids may be ascertained by noting: the amount of potash present in each mineral, the percentage of potash dissolved by fifth-normal nitric acid, and the percentage of potash removed by each crop. These data are to be found in the following Table.

*Relation of Average Potash removed by One Crop to Total and Active Potash of Minerals.*

	Micro- cline	Ortho- clase	Musco- vite	Phlute	Biotite	Stilbite	Nephe- lite	Sul- phate of potash
Total potash % . . . . .	10.14	11.81	10.20	5.80	9.62	0.28	2.86	50.04
% total potash soluble in N/5 nitric acid . . . . .	0.9	1.1	17.1	5.4	26.4	34.00	49.3	100
% total potash removed per crop (1st series) . . . . .	1.0	3.8	11.1	—	13.2	—	7.4	38.7
% total potash removed per crop (2nd series) . . . . .	0.7	1.2	7.5	1.6	11.2	13.6	—	32.9
% available potash remov- ed per crop (1st series). . . . .	110	350	70	—	52	—	15	39
% available potash remov- ed per crop (2nd series). . . . .	80	110	60	30	45	40	—	33

The amounts of potash taken by one crop from microcline average the same as the quantity dissolved by fifth-normal nitric acid. The amount utilised from orthoclase is somewhat more than that dissolved by the acid, the relation varying from 1.1 to 5.5. One crop removed from muscovite on an average 30 to 70 per cent of the potash dissolved by fifth-normal acid, from biotite 30 to 50, from stilbite 40 and from sulphate of potash 20, 30, 40 per cent.

In the third experiment, maize and sorghum were grown in pots containing different kinds of soil to which was added granite containing 4.94 % total phosphate.

At the same time, and under similar conditions, other experiments were made in which some of the pots received no fertiliser, while others were given a complete fertiliser (ammonium nitrate, dicalcium phosphate and sulphate of potash).

The results of these experiments showed that granite has little or no effect as a fertiliser owing to the insolubility of the contained potash.

The author carried further the researches of other investigators especially those of J. K. PLUMMER (*Journal of Agricultural Research*, XIV, No. 298, 1918), and proved that the potash removed by crops in the presence of nitrogen and phosphoric acid is related to its solubility in fifth-normal nitric acid.

Minerals which contain potash easily soluble in strong hydrochloric

acid give up their potash more readily to plants than those containing potash less soluble in strong acids.

The results the author obtained as to the non-fertilising effect of granite are in complete agreement with those already published by HARTWELL and PEMBER (*Rhode Island Experiment Station, Bulletin* 129).

933 - **Potassium Nitrate Ratio of Red Clover as influenced by Potassic Fertilisers.** —

EMERSON, P., and BARTON, J. (Assistant Professor of Soils and Assistant in Soils, Iowa State College, Ames) in *Journal of the American Society of Agronomy*, Vol. 14, No. 5, pp. 182-192, bibliography of 17 works. Geneva, N. Y. May 1922.

The most important question before soil investigators to-day is to obtain maximum crops by means of a practical method of manuring. Excessive application would lead to waste. Attention should also be given to the fact that crops may be stimulated to such an extent that the soil is impoverished by loss of its constituents, which will undoubtedly have an effect on fertility during the following years. Very little is known as regards the specific physiological effect played by each mineral element in plant nutrition. It is recognised, however, that absorption may vary to a considerable extent. Potassium is, for example, indispensable, but the amount of absorption is variable as has been proved by several investigations. Beyond a certain limit it is doubtful whether the potassium is used (HALL), or whether it is only tolerated (HOPKINS and AUMER). The authors have undertaken pot-culture tests with red clover to investigate the potassium absorption question. To silt loam were added various potassium salts, viz. potassium chloride, potassium sulphate or kainit at the rate of 100 lb. and 400 lb. per acre, lime was applied at the rate of 4  $\frac{1}{2}$  tons per acre (double the lime requirement by the TRUEOG method). In most cases, manure or superphosphate was applied, separately or together. The solubility of potassium increased with applications of chloride, sulphate and kainit. The kainit had also a beneficial effect on plant growth. Applications of lime had practically no effect on the solubility of potassium, but may stimulate nitrate production and consequently plant growth. The potassium absorption increases only in relation to the stimulated growth but taken as a whole the potassium nitrate ratio is reduced from 1 : 5.6 to 1 : 3.5. Applications of manure or phosphates, separately or together, increased the potassium solubility, but there is no corresponding increase in nitrate solubility. Manure has a depressing effect ; the ratio is therefore still further narrowed.

A combination of superphosphate, potassium sulphate and lime produced the maximum effect ; further addition of manure reduced the yield.

934 - **Supplies of Nitrogen Fertilisers.** — HASKELL, S. B. (Director, Agricultural Experiment Station, Amherst, Massachusetts), in *Journal of the American Society of Agronomy*, Vol. 14, No. 5, pp. 167-175. Geneva, N. Y., May 1922 (1).

A comparison of the data collected for 1918 with that of other years, has led the author to estimate that approximately one-half of the total

(1) See R. Feb. 1922, No. 144. (Ed.)

supply of fertiliser nitrogen is derived from organic sources and the remaining half from mineral products. There is a tendency, however, for the consumption of organic nitrogen to decrease and that of mineral nitrogen to increase. Cottonseed meal supplies less than one-fourth of the fertiliser nitrogen, which would be better used as a livestock feed which should be encouraged. Dried blood, leather waste, tankage (coming partly from Argentina), fish by-products etc. are other sources of nitrogen.

Five-eighths of the mineral nitrogen fertiliser is furnished by nitrate of soda; the importation is on the decrease, and some solution must be found.

The remainder is supplied from cyanamide and sulphate of ammonia etc. The cyanamide is obtained chiefly in Canada, from the American plant which uses the Niagara Falls as a source of power.

The great bulk of the sulphate of ammonia is derived from the by-product of the coke ovens. The consumption of by-products is continually on the increase. The author strongly recommends a more systematic use of available resources

L. V.

935 - **Effect of Nitrates on the various Stages of Wheat Development.** — See No 947 of this Review.

936 - **The Manufacture of Nitrates by the Biochemical Oxidization of Salts of Ammonia.** — BOULLANGER, E., in *Annales de l'Institut Pasteur*, Vol. 36, No. 4, pp. 305-338, 1 fig. Paris, April 1922

The author had already experimented in the laboratory on the nitrification of sulphate of ammonia in solution, to which he added carbonate of lime in suspension; with this liquid he sprinkled peat or pozzolana impregnated with nitrifying bacterial cultures and obtained nitrate of lime and of gypsum. He also successfully used a solution of carbonate of ammonia (mono- and bi-) (1).

After these preliminary tests he has now made a semi-industrial attempt at production on a large scale with 9 masonry containers, each of about 800 litres capacity, and has found that the use of carbonate of ammonia is preferable in order to avoid the formation of gypsum which obstructs the process. The author describes these tests in detail. They have not however any economical value for the trade price of nitric nitrogen is the same as that of ammoniacal nitrogen, whereas the author produces it from the latter, making it bear the total cost of production (including the cost of evaporating the liquid by heating) as well as the cost of sinking fund and the inevitable loss of nitrogen. This is therefore an anti-economical process and might have been of value only during the war, when the author began these tests and when nitrates were necessary for war industries; during the war, this aspect was ignored and economy did not receive special attention. Today there is not a sufficient quantity of carbonate of ammonia on the market to supply an industry of this kind on a large scale. The process might be rendered practicable by using ammonia in combination.

- 937 - **Notes on the Composition and Stabilisation of Ammonium Nitrate in Presence of Oxidisable Material.** — FINDLAY, A., and ROSEBOURNE, C., in *Chemical Industry*, Vol 41, No 4

A report of experiments made on the decomposition of ammonium nitrate, in presence of oxidisable material and possible methods of retardation. Decomposition takes place at temperatures much below the normal decomposition temperature of salt. Owing to the extensive use of ammonium nitrate, the question of retardation is highly important.

A water bath at 100° C was employed, and a reaction mixture of nitrate of soda and woodmeal. The gaseous products of decomposition were measured and analysed daily.

The gases given off consisted almost entirely of carbon dioxide and nitrogen, only rarely a small percentage of carbon monoxide was evolved.

The water condensed during the experiment was neutral to methyl orange, which proved the absence of acid oxides of nitrogen from the gaseous products of decomposition. According to the authors it is highly probable that decomposition is brought about by the nitric acid formed by the hydrolysis of ammonium nitrate, and that oxidation is accelerated by traces of nitrous acid. Following these lines, it was expected that the addition of carbamide would retard oxidation by destroying the nitrous acid and experiment shewed that carbamide is an effective stabiliser of ammonium nitrate.

Diphenylamine and phenyl benzyl ether have also been tested as stabilisers but have not given satisfactory results. L. M.

- 938 - **The Function of Manganese Fertilisers.** — In a report by BOCHER, H., Member of the Higher Council on Agriculture at the Agricultural Academy of France ('Membre du Conseil Supérieur d'Agriculture à l'Académie d'Agriculture de France'), sent by M. LOUIS DOP, French Delegate Vice President of the International Institute of Agriculture.

It may be said that today no farmer is ignorant of the action of manganese fertilisers, and also that among scientists few know the function and value of salts of manganese in agriculture. Nevertheless, everyone has heard of the manganese fertilisers placed on the market in 1910 by a commercial firm who advertised them widely. They were also well known after the long and minute researches made by M. BRÉTRAND, Professor at the Sorbonne and Pasteur Institute, who proved the following facts:

- 1) Plants need manganese for the development of their cells;
- 2) Manganese is a catalytic substance and a soil fertiliser.

M. PICARD of Paris in 1898 also pointed out to the Academy of Science (*Académie des Sciences*) the presence of manganese in the greater number of plants and proved its very important physiological function, especially at the beginning of plant life, at the moment of germination and early growth. M. GRANDLAU, Chief Inspector of Agronomical Stations, had also observed that manganese exists in all plants and that its presence seems necessary to plant growth. Further researches made by scientists of all countries have substantially confirmed these assertions.

Manganese acts in a variety of ways: directly or catalytically as fertiliser, stimulant, antiseptic and anticryptogamic; it accelerates germination and maturation, increases the yield and improves the crop.

Experiments made everywhere, in Europe and Japan, have given results varying in importance but rarely negative. Difference of opinion arises not as to the actual principle of the function of manganese, which is incontestable, but as to the form in which it should be used. Many consider that oxides are ineffective; sulphate and chloride have given doubtful results, but carbonate and especially lime with manganese have been almost unanimously approved. The author next reviews all the researches which have been made in this matter up to the present, and hopes that further investigation will soon solve the remaining problems.

BERTRAND has proved that the action of manganese is catalytic and influences the composition of various bodies without itself being modified, a suitable application of manganese stimulates the microfloral activity of the soil and ensures the better utilisation of the existing food material.

BOULLANGER has proved the great difference in the catalytic power of manganese according as the soil is rich in nitrogen, phosphoric acid and potash. In poor soil, chloride of manganese gave only a slightly increased yield of potatoes, but in rich soil, it showed an increase of 32 %. CANDA, in Italy, also maintains that manganese has an indirect catalytic effect and dissolves the previously existing fertilisers. In poor soil, its action may even be injurious. KELLEY, on the contrary, maintains that the stimulating action of manganese is positive in poor clay-silicic soils, slight in rich soils and negative in acid soils.

STEYN and BURGERS in Holland, observed that after the use of manganese, maize showed much greater development, the leaves became much larger and there was an increase in yield of 100 ox. Also in Japan, SOLOMON in Italy and DUMONT in France were also in favour of its use.

Investigations on the beneficial effect of manganese on plant life and especially on the acceleration of germination were made by the following: GAROLA, CROCHETELLE, NOTTIN, BARTMANN, LOEW, BOULLANGER, VOELKER, BAUER and MOLINARI.

Experiments by RAY, PRADIER and BARTMANN prove that manganese accelerates maturation.

The increase in yield through manganese has been proved by numerous experiments. THOMASSIN obtained an increase of 20 to 35 % in oats and 15 % in beets; BOULLANGER an increase of 12 % in oats with lime and manganese only, and of 40 to 48 % by the addition of other fertilisers; ASO in Japan obtained an increase of 30 % in the rice yield; and BARTMANN's experiments on maize, cabbages and potatoes were equally conclusive, as well as those by GARDA on flax, LEBLANC on asparagus and BLANCHARD on onions.

Manganese not only increases the yield, but in many cases considerably improves the quality; this is especially the case with beets. GAROLA observed that manganese sulphate not only increases the weight of beets,

but their sugar content also, by 50 %; manganese chloride, which increases the weight still more, on the contrary increases the sugar content only by 25 %. GRÉGOIRE attributes to manganese an increase in sugar content and a corresponding decrease in weight, so that there is neither gain nor loss. DELORME and BOULLANGER observed that barley for malting did not increase in weight but improved in quality, the grain becoming larger, whiter and better nourished. J. M. SAULNIER obtained very favourable results by using manganese salts (1).

As regards its antiseptic and anticryptogamic qualities VON BAUER observed that manganese causes chlorosis spots on diseased plants to disappear. CLAUSEN HAIDE successfully used manganese against oat jaundice. DEMOLON, SIROT and JORET proved that slags used in agriculture contain from 4 to 5 % of manganese to which they attribute some of the useful effects of basic slag which were previously thought to be due to phosphoric acid and lime.

To sum up, from all scientific research, and in addition from the results already obtained on farms, the importance of manganese becomes evident. It remains to be seen:

- 1) In what form manganese salts should be used.
- 2) On what soils and crops they give the best effects.
- 3) Whether they should be used alone, or mixed with other fertilisers.

The author concludes by insisting on the urgent necessity of further and numerous experiments to determine the exact value of this new fertiliser.

A. D. B.

939 - **Inoculation of Leguminous Crops.** -- ARNY, A. C., and MC GINNIS, F. W., in *Journal of the American Society of Agronomy*, Vol. 13, No. 8, tables 6, bibliography of 14 publications. Washington, Nov. 1921.

The use of commercial cultures for inoculating the seed of leguminous crops has not proved altogether satisfactory.

The application of soil from a field used for a leguminous crop to another field involves labour difficulties, especially if the second field is far away. As a general rule 100 to 300 lb. of soil per acre or more is required.

The authors have tested a new method, namely that of applying inoculated soil to the seed of leguminous crops. Seeds of soy bean, alfalfa and sweet clover were used with water, and concentrations of glue and sugar,

(1) Reference is made to the important experiments made by SAULNIER in 1898-1900 in the trial plots at Suessola, organised on the model of the Experimental Station at Rothamsted by the late Prof. I. GIGLIOLI. Of 8 series of plots in which wheat was cultivated and to which a dressing of manganese dioxide, mixed in each case with other and different fertilisers, was applied, 4 gave good results, namely those treated with nitrate of soda, manure, superphosphate and sulphate of ammonia, superphosphate with sulphate of ammonia and sulphate of soda. Manganese dioxide proved more favourable for grain than straw. -- See ITALO GIGLIOLI, " *Cultura del frumento, Esperienze con biossido di manganese. Campo sperimentale di Suessola, 13° anno di coltura continua del frumento e granturco* ", pp. 133-147. Portici, 1901. (Ed.)

and the soil made to adhere to the moist seed, afterwards dried and sifted and prepared for inoculation purposes. Tests were made both in the greenhouse and in the field. The trials made with sand and sterilised sand were not satisfactory and were discontinued.

The same weight of soil was added to certain seeds at the time of sowing and the results compared with untreated seed, and with the seed with the commercial culture

The first mentioned method gave good results and with one or two exceptions, a large number of nodules were produced, and the plant was well developed. Still more satisfactory results were as a rule obtained with the commercial culture.

A comparison was also made as to the efficiency of water, glue and sugar solution at 5 % and 30 %. But these did not give satisfactory results, and the glue and sugar solution method of obtaining soil adherence is not therefore recommended. After inoculation with soil or with commercial cultures, the seeds may be stored in a suitable place for one month or more without any injurious effect.

Exposure of the soil to sunlight for 3 hours, and of the commercial culture for a half-hour in October, did not alter the efficiency of these means of inoculation with soybean seeds, but for alfalfa there appears to be some reduction in efficiency. Exposure of the seed to more intense heat of spring and summer sun might prove harmful and should be avoided whenever possible.

940 — **Root Development in Barley and Wheat.** — BRENCHELY, W. D., and JACKSON, V. G. (Rothamsted Experiment Station) in *Annals of Botany*, Vol. 35, No. 140, pp. 533-556, figs. 4 London, Oct. 1921.

AGRICULTURAL  
BOTANY  
CHEMISTRY  
AND  
PHYSIOLOGY  
OF PLANTS

Study made of root development and the correlation between root and shoot development. Pot cultures were made with heavy soil from the Experimental Farm with the addition of 10 % sand. These served for control purposes; to others were added the following fertilisers: sodium nitrate, superphosphate, sodium nitrate + superphosphate, potassium sulphate + superphosphate. Measurements were taken after drying and the rate of growth is shown in diagram form.

A strong root system for barley was shown, especially with sodium nitrate and even more marked with sodium nitrate + superphosphate.

The differences in growth between the various cereals, except when nitrate of soda + superphosphate was used, decreased or disappeared after 5 to 6 months. Relatively speaking, there was also a more marked development of shoot growth, but no parallelism can be drawn; it may be considered, however, that the shoot-root ratio attains the maximum with superphosphate + potassium sulphate and the minimum with superphosphate + sodium sulphate.

With wheat, the actual effect of the fertilisers on root development was not apparent; at certain stages, the root development seemed to be inferior to that of the control, especially when sodium nitrate was used. There is however, a more evident development of shoot system. The most

marked effect as regards roots was with superphosphate + potassium sulphate, and by superphosphate + sodium nitrate.

The types of root system both for wheat and for barley are more or less similar. A certain number of primary roots were developed vertically, lateral formation was then noted at the bottom of the pot; the actual appearance and habits of these lateral roots, described in detail by the authors, varied inherently with the fertiliser employed.

In the open field, the barley roots are thinner and more abundant than in the pots and are found near the surface. Oats behaved in the same manner; the wheat penetrated deeper.

In every case, both in pots, in the field, and more especially in water cultures, the *white roots*, distinguished by their thickness, and waxy appearance were prominent. Laterals are rarely seen; some of the longest roots bear a few short laterals near the crown, formed after the others and found in greater abundance early in the spring, especially in the case of barley. After a time, laterals are produced and gradually lose their characteristic appearance; finally it is impossible to distinguish them from ordinary roots. The "white root" formation was increased with barley after the application of superphosphates + potash; the wheat appeared to be unaffected. These changes are difficult to explain and offer a promising field for research. A comparative study of the anatomical structure of the ordinary and white roots has been started by one of the authors.

It is noticeable also that the slender roots produced laterals whilst still very small, especially towards the tips. These remained for some time and finally adopted the characteristics associated with the ordinary roots.

941 - **Influence of Wheat Growth on the Hydrogen-ion Concentration of Plant Food Solutions.** — JONES, L. H. and SHIVE, J. W. (New Jersey Agricultural Experiment Station, Department of Plant Physiology) in *The Botanical Gazette*, Vol. 73, No. 5, pp. 391-400, bibl. of 18 works. Chicago, Ill., May 1922.

Certain solutions used in experiments on plant physiology show rapid and remarkable modifications in their hydrogen-ion concentration when used for plant growth; others, on the contrary, show few changes because they contain salts capable of fixing the hydroxyl-ions.

In connexion with this question, the writers have studied 20 formulae advanced by several investigators. They placed young wheat plants in the solutions and made the determinations by the Gillespie method in the course of 52 hours. Results showed that in certain solutions the hydrogen-ion concentration presented very slight modifications; for instance, the CRONE and SACHS solutions remained at 6.6, 6.7 pH; hydrogen-ion concentration is generally reduced; it passes from 4.2-4.8 pH to 5.3-6.1 pH in 6 solutions; the reduction was greater in more concentrated solutions; in 6 LIVINGSTON-TOTTINGHAM types containing 3 salts it was also reduced, passing from 3.6-4.6 pH to 5.4-5.8 pH; in 2 modified TOTTINGHAM solutions, on the contrary (replacing potassium nitrate by ammonia sulphate), the concentration rose slightly, from 4.8 to 4.2 pH. These last solutions, therefore, are quite suitable in the case

of crops for which it is not desired that the hydrogen-ion concentration should vary appreciably under the influence of plant growth. They also have the advantage of being able to take up iron in a form which can be assimilated by growing plants.

L. V.

- 912 - **Effects of Borax upon Plant Growth.** — NELLER, J. R. (Formerly of the New Jersey Agricultural Experiment Station) and MORSE, W. J. (Maine Agricultural Experiment Station) in *Soil Science*, Vol. 12, No. 2, pp. 79-105, 13 plates, bibl. of 17 works. Baltimore, Aug. 1921.

The experiments reported in this paper are based on numerous observations made by farmers and scientists regarding the harmful effects of boron compounds (boric acid, potassium borate, sodium borate, borax, etc.) added to manure as larvicides or contained in certain chemical fertilisers.

The writers more especially proposed to ascertain if the above-mentioned action is due solely to boron, and what is the maximum quantity which can be applied without injury. They made numerous pot experiments, using a compound fertiliser made from sodium nitrate, acid phosphate and potassium sulphate, to which was added commercial borax containing 67.2 % of anhydrous borax; the experiments were made on maize, beans and potatoes.

The beans were tolerant to a maximum quantity corresponding to 3 pounds of anhydrous borax per acre, maize as much as nearly 5 pounds and potatoes a little more. If, instead of being applied in the drills, the boracic fertiliser was well mixed into the soil, the plants were not quite so easily affected. A commercial fertiliser containing borax was found to be considerably more toxic than an equal quantity of boracic fertiliser used by the writers. The toxic effects were variable; the writers describe them with full details.

During the experiments the soil was kept at an average optimum water content of 19.2 % with but little modification. By reducing the soil moisture, the toxic action of the borax was increased, and vice-versa.

Certain previous observations led to the conclusion that salts of lime diminish the toxicity of various organic substances. The writers confirmed the fact that limestone effectively limits the toxicity of borax as regards the first three plants experimented upon; gypsum and manure only protected maize, no effect being observed on the other two plants.

Some writers have reported that small quantities of boron act as a stimulant, but the authors only observed a doubtful action, and that with maize alone.

L. V.

- 943 - **Effect of Röntgen Rays upon the Growth of *Oryza Sativa*.** — KOMURO, H., in *The Botanical Magazine*, Vol. 36, No. 421, pp. 15-17. Tokyo, Jan. 1922.

Investigations by YAMADA (1917), carried out on an aquatic variety of *Oryza sativa*, proved that a weak irradiation (3 H and 5 H) of the seeds gives an increase of amount of crop. Investigations by NAKAMURA (1918) on another aquatic variety gave similar results.

The author did not confirm these results. He used a third aquatic

variety and employed rays of 4.5 — 6° intensity; the exposures were 5 to 15 H for steeped and air-dried seeds, and 3-7 H for steeped seeds; and the experiments were carried on both in pots and in the field, but not on a large scale. The author thinks that his predecessors were to some extent mistaken in their observations.

I. V.

- 944 — **Sulphur Content of Alfalfa.** — HALL, E. H. (Hull Botanical Laboratory) in *The Botanical Gazette*, Vol. 73, No. 5, pp. 401-411, bibl. of 15 works. Chicago, Ill., May 1922.

The author confirms the fact that the sulphur content of alfalfa greatly varies; in hay grown in different parts of the U. S. he found 3.3 to 5 kg. per ton; so that if the alfalfa yield is 12 to 20 tons per ha., it removes 40 to 100 kg. of sulphur per ha. from the soil, an amount which is in excess of the atmospheric sulphur returned by rain. From WOLFF's old ash analyses, it was assumed that plants contained but little sulphur, and that it was not necessary therefore to furnish fresh supplies. But we know now that plants consume a great deal and that it is one of their principal elements, like nitrogen, potash and phosphorus; the same may be said of calcium and, in certain cases, of magnesium.

The greater part of the sulphur was in the organic form; that in the inorganic form was never more than 10 % of the total, while in certain samples of alfalfa there was none at all. The average was 4.35 %. These results differ from PETERSON's determinations, who found the ratio to be 1 : 1.

The author also made nitrogen estimations but does not give the results.

This investigation was carried out under a research fellowship from the Gypsum Industries Association.

**PLANT  
BREEDING**

- 945 — **S. B. Y. and Blo. 38, Two new Varieties of Sweet Potato obtained by Selection in the Philippines.** — MENDIOLA, N. B., in *The Philippine Agriculturist*, Vol. X, No. 5, pp. 177-189, 1 pl. Los Baños, Laguna, Dec. 1921.

This work gives the results of a series of investigations and researches carried out at the Agricultural Experiment Station in the Philippines with a view to improving the sweet potato by selection.

The initial experiments were carried out, and results obtained, from the following varieties: Samar Big Yellow, which, in December 1919, gave the highest yield, Binandera, Binglo, Boled Zooling and others unidentified but distinguished by the letters B. C., and D.

The offspring of these varieties show great variability in leaf shape, yield in tuber, colour of skin and flesh and flavour of the tuber.

The following table shows the comparative weight of yield of some offspring of Binandera.

*Weight of tubers per Plant produced by Seedling offspring of Binandera.*

Offspring No	Wt. of tubers produced gm.	Offspring No	Wt. of tubers produced gm.
1	127	6	95
2	380	7	340
3	1 090	8	2.333
4	75	9	430
5	107	10	70

This variability may be taken as an indication that some of the varieties of sweet potato which have been propagated asexually are heterozygous with respect to a number of characters.

The author made a careful selection of a large number of seedlings.

It is well to note in this connection that a one-year test is not sufficient to decide which are superior. The final selection should therefore be made with care and only after a sufficiently long period has elapsed.

Selection has already led to the isolation of two good types S. B. Y. and Blo. 38 the first from Samar Big Yellow and the second from Bingle.

Their description is as follows:

S. B. Y. 98. — Stem, 5 metres long and 3 to 6 mm. in diameter; colour pale green with slight tinge of purple which becomes more distinct with age; hairs not abundant. Leaves cordate, mature leaf 7 to 9 cm. long and 6 to 7 cm. wide; first purple with slight tinge of green, then green with purplish veins, petiole 7-11 cm. long. Growth vigorous, matures early, tubers roundish or somewhat elongated, medium to very big and almost free from disease; skin, reddish purple; flesh, outer portion yellowish, with ring of purple next tinged with slight yellow, central portion more yellowish. Cooked tubers have a faint pleasant odour, turn to a light purple and yellow colour and are rather sweet; good pastry may be made from them. This variety is an excellent yielder.

Blo 38. — Stem, 3.5 m. long and 4-6 mm. in diameter, green, hairs abundant, leaves, cordate, 8-10 cm. long and 7-9 cm. across first purple with green tinge, then green, petiole, 6-14 cm. long. Growth not very vigorous; matures early; tubers, roundish or somewhat elongated; medium to very big; not entirely free from disease; skin, light purple; flesh, cream-coloured with circular ring tinged with purple. Cooked tubers sweet and have pleasant odour, the skin becomes dull purple and the flesh creamy yellow. A good yielder.

These new varieties will be tried on outlying farms

G. A.

946 — **Investigation on Hard Seed Germination.** — GIRON, E. G., in *Boletín de Agricultura Técnica y Económica* (Estación Central de Ensayo de Semillas de la Moncloa), Años (years) XIII and XIV, Nos. 151-154-159, pp. 230-240, 596-608, 821-828. Madrid, 1921 and 1922.

The author first briefly reviews the different methods of treating hard seeds which have been followed up to the present; he divides them

SEEDS

into 3 groups : mechanical, physical and chemical, and says a few words on their advantages and disadvantages. He afterwards quotes the experiments made by Professors LOVE and LEIGHTY on red clover seed by treating it with sulphuric acid, and finally describes the experiments made at the " Estación central de Ensayo de semillas de la Mencia " on " algarrobo " seed (*Ceratonia siliqua*). A description of these experiments and their results are given below.

The seed used was taken from one among a number of lots at the corn market ; they were not a wide and most representative (closely conforming) selection, as is generally the case. The treatment consisted in steeping lots of 100 seeds each in sulphuric acid for varying periods. They were afterwards carefully washed until all trace of the acid had disappeared.

They were germinated both on sand and in filter paper bags, care being taken in the first case to bury the seed at a depth of 4 to 5 mm. only. The root thus appeared near the surface, and the plant could be observed taking root without its being necessary to turn up the sand and risk injuring the young organs.

In Tables I and II the details and results of these first trials are shown. Two other tests were then made with " ungerminated, healthy " seed, details of these latter tests are given in Tables III and IV.

From these experiments the author draws the following conclusions.

- 1) The germination of " algarrobo " seeds is encouraged by their being subjected for a certain time to the action of sulphuric acid.
- 2) The various groups of seed tested showed the best results after being treated for a period of 30 minutes.
- 3) Intermittent treatment is still more beneficial, a sufficient number of days being allowed to elapse between the partial treatments.
- 4) The plants obtained grow normally.

The author concludes his investigation with some notes on the relation between the attack of mildew, observed during the experiments on seeds of which the tegument was injured, and on the duration of the sulphuric acid treatment. He concludes that the percentage of seeds attacked by mildew is smaller in proportion as the duration of the treatment approaches the beneficial maximum.

TABLE I — " Algarrobo " seed test. Germination in sand beds for 26 days.

No of seeds in group	Duration of sulphuric acid treatment	germinated	No of seeds	
			ungerminated	
			healthy	spoilt

947 - The Effect of Nitrates applied at different Stages of Growth on the Yield, Composition and Quality of Wheat. — DAVIDSON, J. (Plant Chemical Laboratory, Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C.) in the *Journal of the American Society of Agronomy*, Vol. 14, No. 4, pp. 118-122. Bibliography of 2 works. Geneva, N. Y., April 15, 1922.

CEREALS  
AND  
PULSE CROPS

An experiment made by the author in collaboration with LA CLERC showed that the application of sodium nitrate during the early period of growth increased the yield of wheat; when applied at the time of heading the quality of the grain was improved, but the use of nitrate at the beginning of the milk stage had no effect either on yield or the

quality of the crop. The experiment was carried out in the year 1919 at College Park, Maryland. The period between the resumption of the growth of wheat in the spring and the time of heading was divided into three sub-periods. Each of three corresponding sets of plots received nitrate of soda or nitrate of calcium at one of these sub-periods; the experiments were repeated to make sure of the effect of the nitrates; the number of plots was thirty-six.

The effect of nitrate in increasing the yield decreases consistently as the time of their application approaches the stage of heading.

The effect of nitrates in increasing the protein content ( $N \times 5.7$ ) of the grain increases as the effect on yield decreases. The deeper colour of the grain showed qualitative modification. L. V.

948 - **The Milling Quality of Saskatchewan Wheat.** — CHAMPLIN, M and GOULDEN, G H, in *Scientific Agriculture*, Vol II, No 8, pp 283-305. Gaidenvale, P Q, April 1922

The actual value of wheat grain cannot be estimated by the plant characters of the variety, and only to a slight extent from the appearance of the sample after threshing. The actual value or quality can only be ascertained by means of a milling and baking test.

For the past eight years the University Field Husbandry Department has been carrying on field tests with the leading varieties of wheat and each year samples of these wheats have been sent to some reliable wheat testing laboratory in order to have their milling and baking qualities determined. The data obtained from these tests are now available and serve to indicate the relative values of wheats and some of their qualities. A description of the methods of analysis is also given. The different varieties of wheat are arranged in groups, each group having in common some particular qualities which distinguish it from the rest.

Group I: Marquis, Red Fife, Kitchener, Red Bobs.

Marquis and Red Fife both possess excellent milling qualities. These results are in accord with those reported by other investigators (1). The remaining members of this group are high quality wheats, especially Kitchener which was considered to be one of the best milling wheats.

Group II White Bobs, White Fife, Taylor's Wonder

All these are white wheats. Taylor's Wonder is a soft wheat, lacking in baking strength, but has given fairly good results. White Fife is at least equal to Red Fife.

Group III Prelude, Pioneer, Preston, Chelsea.

Fairly good milling value, but with no outstanding results.

(1) *Marquis Wheat* — BALL, C R and CLARK, J A, U S. Department of Agriculture D C. *Farmers' Bulletin*, No 732 SANDERSON, T, Milling and Baking Results of Marquis v. Blue stem and Fife wheats — in *North Dakota Agricultural Experiment Station, Special Bulletin*, Vol 2, No 32 Food Department. ARNY, A C and BAILEY, C H, Marquis Wheat in *Minnesota Agricultural Experiment Station, Bulletin* No 137 *Report of the Dominion Grain Research Laboratory*, Winnipeg, Man., 1920. Submitted by RICHARD, F. J. (Ed)

Group IV : Ruby ; no great milling value, but promises well as an early wheat in the northern districts

Group V : Club, Redstone, Alaska, Kinley, Stanley : — Medium value for milling. Although the Alaska variety has large ears, results after analysis have proved unsatisfactory (1).

Group VI : Kubanka, Acme, Pélissier, Monad and Amber Durum varieties : — Suited to warm localities with a dry ripening period. Acme and Monad give high yields, and are resistant to drought and rust ; the poor quality straw however renders them unsuitable for heavy soils. Kubanka is acknowledged to be the best milling variety of durum wheat and is used chiefly in the manufacture of macaroni, spaghetti and for blending purposes.

Group VII : Red Durum (D5)

This grain is hard, bright and vitreous, it is immune from stem rust (*Puccinia Graminis*), but the flour is weak and not satisfactory either for baking or for macaroni

The author supplements his report with a table giving the principal varieties of wheat harvested in 1920, their protein content, absorption capacity, loaf volume, colour, texture and the general appearance of the bread made from them.

A number of experiments were made during the years 1915 and 1916 in order to ascertain the influence of the time of harvesting on the value of Marquis Wheat as regards milling and baking, and the following deductions were made :—

- 1) Loaf volume increases directly with the maturity of the grain.
- 2) Flour colour improves with maturity, flours from early cuttings were all slightly greyish
- 3) Gluten content increases directly with maturity.
- 4) Weight of loaf and water absorption decrease slightly as the grain ripens.

In conclusion it may be stated that it is very important to allow the wheat to reach at least the dough stage before cutting. The wheat is much improved by allowing it to harden fully, but the difference is not sufficient to warrant the farmer taking any risks in getting his crop harvested. Immaturity is undoubtedly detrimental to the value of the wheat grain.

*Importance of the Milling and Baking Test in Wheat Breeding* — A milling and baking test must be made upon the grain as soon as the selection has reached a stage where a sufficient quantity is available for the purpose. This will give an accurate indication of any improvement in quality and will allow the breeder to eliminate poor quality strains at the outset. Thus labour and expense will be saved and the distribution of a poor quality wheat prevented.

949 - **Influence of Wheat Development on the Hydrogen-ion Concentration of nutritive Solutions.** — See No 941 of this Review

950 - **On Root Development of Barley and Wheat.** — See No 940 of this Review.

951 - **Smooth-Awned Barleys.** — HAYES, H K, and WILCOX, A N (Minnesota Agricultural Experiment Station, Division of Agronomy and Farm Management), in *Journal of the American Society of Agronomy*, Vol 14, No 4, pp 113-117, bibliography of 9 works. Geneva, N J, April 15, 1922

Farmers find the presence of awns in wheat and barley uncomfortable in handling and for this reason breeders have devoted much of their attention to the production of awnless varieties. It has however to be noted that the awns have definite physiological functions, which have been brought out by several investigators. If the awns are removed a quite noticeable reduction takes place in transpiration which is particularly active at the time of carbohydrate formation in the seed, which it appears to stimulate. A reduction of about 10 % also occurs in the volume and weight of the seed according to PERLITUS while the spikes become brittle owing to the deposition of dry matter which in the case of normal spikes takes place largely in the awns according to HARCAN and ANTONY

It is still more important that awnless varieties give a smaller yield than awned as has been discovered by GRANTHAM for wheat and proved by experiments carried out at the Minnesota Station with awned and awnless hybrids resulting from the same crossings

Attempts have been made to obtain the physiological advantages of the awns and at the same time to eliminate the discomforts they cause in handling, by cultivating varieties of wheat and barley with smooth or flexible awns, which at present have merely a botanic value. HARLAN is responsible for this solution which has been studied for several years at the Minnesota Station where varieties of barley with smooth awns have in certain years produced a fair yield, in other years the yield has been considerably reduced as these varieties show themselves highly susceptible to *Helminthosporium sativum*.

New crosses and more resistant strains have now been tested. In 1920 and 1921 an average yield was obtained superior to that of Manchurian barley which is awned. These varieties have also given good transpiration results, one gramme of water per hour for 10 heads of smooth awned barley and also for Manchurian, while certain barleys both awned and awnless gave much less. The new varieties therefore seem to be very promising

L. V.

952 - **North African Barley and Malting.** BOEUR in *Revue Agricole de l'Afrique du Nord*, 20th year, No 155, pp 458-463. Algiers, July 21, 1922

The author classifies the barleys used in brewing, mentions the qualities most sought after in them, and describes the characteristics of North-African barleys

A table accompanies the description, showing the percentage of moisture, dry matter and nitrogenous matter contained in two-rowed barley and

winter barley from various districts collected in 1910 and 1911. The author replies as to certain faults found with North-African barleys, and after having indicated certain improvements to be made in their cultivation, he draws the following conclusions: the winter barleys cultivated in North Africa are adapted to malting and are largely used in high fermentation brewing; they may form 15 to 20 % of the total used in low-fermentation brewing.

The better kinds should be selected, cleaned and distributed in suitable quantities.

Two-rowed barleys do not degenerate in North Africa. The kinds which combine industrial qualities with a good yield and sufficient resistance to rust and smut, should be placed at the disposal of farmers in order that their cultivation may be extended. F. S.

953 - **Date of Sowing for Maize.** - BROWN, E. I. and GARRISON, H. S. (Office of Cereal Investigations), U. S. Dept. of Agriculture, *Bulletin No 1014*, pp 1-14. Washington, Jan. 11, 1922.

Report of investigations in progress from 1915-21 at the Arlington Experimental Farm, Rosslyn, Va. near Washington D. C. It appears that although the total growth of stalk was greatest for spring sown maize (May and June), the rate of growth was slower than with June and July sowings, and the earing was also deferred. The pollen period was longer, but the number of ears, the size of the ear and the sucker growth did not appear to be affected.

With very early sowings (April), not only was the rate of growth slower, but the stalks were usually shorter. In 1917, for example, the April sowings produced plants with stalks only 75.6 inches in height; May sowings 86.4 in. stalks; June sowings 88.8 in.; July sowings, 76.8 in. Earing and ripening were somewhat hastened. L. V.

954 - **Fenugreek in Algeria.** — DUCELLIER, I (Professor at the Agricultural Institute of Algiers) in *Revue Agricole de l'Afrique du Nord*, Year 20, No 133, pp 106-109. Algiers, February 17, 1922.

FORAGE CROPS

Trigonal fenugreek (called "helbe" or "helba" in Algeria) has become much less important as a forage crop, especially in the Mediterranean district, but is still valued in the East, in India and in the Valley of the Nile, both as a forage plant and for its seeds; in Tunisia and Morocco it is cultivated chiefly for its seed production. Morocco exports an average of 70 000 quintals of fenugreek seed per year, and most of it comes from the Casablanca district. In Algeria this legume is at present very little cultivated.

There are several varieties of fenugreek: only one with angular seeds, is cultivated in Tunisia, Algeria and Morocco. Another variety from Khartoum with smaller and rounded seeds, tried at Maison-Carrée, did not give such good results.

In Algeria the forage-yield of fenugreek generally varies from 25 to 30 tons per ha., which corresponds to 4-6 tons of dry hay. In fertile soil the yield of green forage may be as much as 50 to 60 tons.

Fenugreek produces 10 to 12 qx. of seed per ha. ; the latter in North Africa often includes seeds from other casual plants, such as *Bupleurum protractum*, rye grass (*Lolium multiflorum*), brome grass, barley, oats, etc. The presence of wild ray-grass seed or corn-seed among that of fenugreek is rather advantageous than otherwise from the point of view of forage-production; rye grass, growing among fenugreek improves the quality of the forage given by the latter and helps it to dry.

The weight of a hectolitre of fenugreek seed including admixtures varies from 70 to 75 kg. in Algeria; when dressed the seed may weigh as much as 78 kg. F. D.

OIL BEARING  
AND NARCOTIC  
PLANTS

955 - **Sunflower Growing in Rhodesia.** — MAINWARING, C., The Common Sunflower, in *Bulletin No 423, Department of Agriculture, Salisbury, Rhodesia*, pp 8. June 1922.

The Sunflower is very often employed as an accessory crop in the mixed farms of Rhodesia. The seeds are chiefly used in poultry-feeding and to some extent mixed with other fodder as a cattle-food: a certain amount of oil extraction also takes place.

In Rhodesia the sunflower is highly drought-resistant and in 1921 the area under cultivation was 3974 acres with a yield of 23 204 bags of 103 lb. apiece. The acreage for 1921 was nearly double that of the preceding year but the yield per acre was somewhat lower, viz 15.8 sacks as against 6.7. An analysis of the air-dried leaves of Rhodesian Sunflowers gave the following figures: Water: 14.87 (78.73 % for fresh gathered leaves) — Ether Extract: 2.82 — Protein: 16.50 — Carbohydrates 42.15 — Crude Fibre: 7.87 — Ash: 15.79 %. The corresponding figures for United States Sunflower leaves were respectively: 12.51 — 4.09 — 10.15 — 38.83 — 13.16 — 21.26 %. Thus the Rhodesian Sunflowers were over 62 % richer in protein and 47 % lower in crude fibre and 31 % lower in fat than the American.

After the removal of the seeds the Rhodesian sunflower heads gave on analysis: Water: 11.73 — Ether Extract: 3.18 — Protein: 8.86 — Carbohydrates: 46.42 — Crude Fibre: 18.19 — Ash: 11.6 %. For United States sunflower heads the corresponding figures were respectively: 7.40 — 5.07 — 9.91 — 39.79 — 18.44 — 19.39 %.

Of the three principal cultivated varieties, the large white seeded, the small black seeded and the striped seeded, the second is the most largely grown in Rhodesia.

The sunflower takes four to five months to mature and is comparatively free from diseases and insect pests. An average crop gives a yield of about 12 to 14 bags (of about 100 lb.) to the acre which can be doubled in exceptionally favourable conditions.

The oil is used for the table and also for general commercial purposes. It is claimed to be superior to most oils for soap-making. F. D.

956 - **Greek Tobaccos.** — HASSIOTIS, S. P. in *L'Economista d'Athènes*, 1st year, No. 23, pp. 355-356. Athens, Apr. 15, 1922.

In Greece before the war 23 to 24 million kg. of tobacco were produced. Home consumption only absorbed about 4 million kg. and the rest was

exported. During the war there was a great demand for Greek tobaccos, and this helped to extend their culture. But in 1918 the demand decreased and prices fell. This fall, and the reduced demand which caused it, discouraged cultivators. In 1921 production fell to 17 or 18 million kg.

Tobacco growing is one of the most lucrative branches of national production. The soil and climate of Greece are very favourable to the production of all kinds of tobacco, from the exceptionally fine quality Xanthian and Eastern Macedonian to the inferior but treble-yielding quality of the Nauplia-Agrinio district.

The average yield is 80 kg. per stremma (800 kg. per ha.).

After garden crops, this crop is the most profitable to the grower, whose wife and children may be employed in the work of cultivation.

If the manufacture of cigarettes for export were developed on a large scale in Greece, a great and profitable industry could be carried on under very favourable conditions.

957 - **Cultivation of the Opium Poppy in Bulgaria and Macedonia.** — NIKOLOFF, M., in *Списание на земеделските изпитателни институти в Българска за природонаучни и стопански изследвания из областта на земеделието.* (*Review of the Institutes of Agronomical Research in Bulgaria etc.*), year II, No 3-4, pp. 217-241 (abstract in German, p. 242) Sofia, 1922.

The opium poppy (*Papaver somniferum*) succeeds very well in all parts of Bulgaria and its culture and preparation is of growing importance. In 1919 the poppy covered 9 340 ha., and produced 379 193 kg. of seed and 2 034 kg. of opium. Of these, 7 840 ha. producing 329 083 kg. of seed and 971 kg. of opium belong to old Bulgaria and the rest to the Petritsch and Melnik districts in Macedonia.

Investigations made by the author showed that the Bulgarian poppy products (seed, oil, opium) are of excellent quality. The seeds are very rich in oil up to 49 % and the opium in morphine as of 119 samples of opium analysed, 27.8 % contained 10 to 15 % of morphine; 41 %, 15 to 17 %; 21.3 %, 17 to 19 %; and 6.8 % 19 to 21 %. The poppy in which an early incision is made generally contains a higher percentage of the narcotic. In opium kept a long time, the morphine content diminishes, even when every care is taken (1).

The manufacture of poppy oil is defective in Bulgaria; the oil-cake contains 8 to 19 % of oil (2).

I. D.

(1) See R. Apr. 1922, No. 428.

(2) The defects in the seed-oil industry are general in Bulgaria. There is a lack of appliances in the numerous small oil-mills erected during the war. A series of analyses of various seed-cakes and especially of sunflower seed cake, made at the Agricultural Experiment Institute at Sofia, gave 8 to 20 % of fats and 20 to 40 % of proteids (KULUMOFF, CHR. J., *Sur la composition chimique de nos tourteaux oléifères, Revue des Instituts de Recherches agronomiques en Bulgarie*, Year II, No. 3-4, p. 255). Sofia, 1922. (Ed.)

ARBORICUL-  
TURE

958 - **A new Test for the Maturity of Fruit.** — MURNECK, A. F. (Oregon Agricultural College, Experiment Station, Department of Agriculture) in *Station Bulletin*, No 186, 28 pp., 9 figs. Corvallis, Oregon, Nov 1921.

Experience shews that pears, unlike other fruits, must be harvested in a comparatively unripe condition, thus Bartlett's, when picked hard and green, ripen perfectly and attain the highest quality.

In most districts the harvesting season of this variety lasts about a month, whereas it may take 6 to 8 weeks from the date of the first picking to the time the fruit becomes fully ripe on the tree. It would be useful to know exactly the right moment for picking in order that the highest keeping and eating quality may be realized. For this purpose it would be necessary to know exactly the changes that take place as maturity advances.

Many tests have been used to ascertain the stage of maturity of pears and the best time for picking: the colour of the skin, the colour and toughness of seeds, the sweetness, the ease with which the fruit stem will separate from the spur, the ease with which the finger may be pressed into the fruit, the disappearance of starch, as tested by potassium iodide, etc. Ordinarily for Bartlett's the largest transverse diameter (about 2 1/4 inches on an average) is taken as an index. All these tests, are however, uncertain. The Oregon Agricultural Experiment Station has therefore endeavoured to find a simple but reliable test. This problem has been made a part of the pear harvesting and storage investigations, which were begun in 1917 and have already formed the subject of two reports.

It has been recognised that the amount of pressure required to wound the fruit, that is, its resistance to pressure, gives a good, practical and delicate test.

To measure this pressure exactly, an apparatus was constructed after several attempts, a kind of pressure register, which solves the problem pretty well. The pressure required for a small metal cylinder to penetrate to a determined distance is registered in pounds on a scale.

To eliminate individual variations, it is well to examine lots of from 10 to 15 pears. The test should be made 6 hours after picking, and Bartlett's, under good harvesting conditions, should register, on an average 35, and not less than 25 pounds. If they register more, they are very ripe and may be used with advantage for canning or preserving. The Bosc variety should register 26 to 20 pounds when picked.

The author has applied the test to other varieties of pears and to apples and several fruit growers in the States of Oregon and Washington have already adopted it. The author has also studied the increase in diameter and weight of Bartlett pears during development. The transverse diameter increases each week 5.1% on an average, and the weight 17.7%, until the maximum development has been attained. The ratio of percentage increase in weight to that in diameter is therefore about 1 : 3.5; but deviations and exceptions render this criterion uncertain and not very practical.

L. V.

959 - **Production of Table Olives in Italy.** — VIVARELLI, F., in *La Propaganda agricola*, Vol. XIV, No. 14, pp. 185-191. Bari, 31st July 1922.

The production of table olives in Italy varies, on an average, from 3000 to 3500 qx. per year. It does not give rise either to specialised culture or specialised industry with the exception, in a very slight degree, of some parts of the province of Ascoli-Piceno.

This production might be greatly developed, seeing that in Italy the olive covers 2 291 000 hectares of pure and mixed culture. On the Adriatic side of Central and Southern Italy it has become of growing importance in the last few years owing to the high prices paid for pickled olives. The Italian varieties most appreciated are: the Ascoli, Naples Beauty, Andrian or St. Augustine, Spanish Beauty or "plum" olive, "Rossanese", "Olivone", "Carmelitana", "Cucca", Black Olive of Ferrandina, etc.

The author more especially treats of the table-olive production of the Andria district (Province of Bari) which represents  $\frac{1}{8}$  of the total production of the country. The St. Augustine and Spanish Beauty varieties (described by the author) are mostly cultivated there. The fruit of the first-named although smaller are preferred, as their pulp is softer, and the stones are smaller. The mode of preparation is also described. F. D.

960 - **The Forests of Lettonia.** — *Viribus Unitis*, Year I, Nos. 6-7-8, p. 7. Warsaw, Oct., Nov., Dec., 1921.

FORESTRY

In Lettonia, 65 000 ha., i. e. 29 % of the country is covered by forests. These forests, comprising  $\frac{1}{5}$  deciduous and  $\frac{4}{5}$  conifers, are under State control. The annual yield (in timber) is 172 500 000 c. ft. (4 884 000 m<sup>3</sup>) of which 63.7 % is used for local needs, 22.3 % for roads and industry and 14 % is exported.

The forests are under the management of the Forests Department of the Ministry of Agriculture. At the High School there is a special forestry section for the training of forest-keepers. This Forestry Branch is conducted in an exemplary and scientific way and is entrusted to specialists.

During their occupation, the Germans cut down many forests which are not included in the statistics.

Saw-mills are now being erected. The wood-industry is showing renewed activity. In addition to wood, it is intended to export tar, door and window frames and wood for matches. By the terms of the peace treaty with Russia, Lettonia has the right to fell timber over an area of 100 000 desiatines (10,925 ha.) near the Lettish frontier. The rivers of Lettonia are suitable for rafting. The wood industry of Riga was very important before the war. A considerable quantity of wood is prepared for export. Steps have likewise been taken for the utilisation of wood by means of chemical processes (turpentine, tar refining, wood-spirit, cellulose, etc.). The paper industry already partially revived, is of special importance. Before the war, the Lettish mills showed a total production of 1 705 000 poods of paper (27 927 900 kg.) of which 1 000 000 poods (16 380 000 kg.)

were exported. By the exploitation of peat and the construction of the electric central power station, worked by means of water power, the home consumption of wood, will be diminished considerably, and its exportation increased.

## LIVE STOCK AND BREEDING.

### HYGIENE

962 - **The Duration of the contagious Period in Foot-and-Mouth Disease (1).** — LEBAIL, C., in *Comptes rendus de l'Académie des Sciences*, Vol. 174, No. 24, pp. 1580-1582 Paris, June 1922..

The contagious period of foot-and-mouth disease is generally supposed to last for some weeks.

The Sanitary Authorities impose at least 15 days' quarantine after the recovery of the last case of this disease when it has broken out on a farm.

The author has found in his researches on cattle that any susceptible animal which is in contact with a diseased individual between the time of the initial rise of temperature and the rupture of the aphthae infallibly contracts the malady. If however the healthy animal is not introduced into the cattle shed until 4 days after the appearance of the first aphthic lesion which generally follows an attack of fever and salivation, the animal is not infected.

In the development of foot-and-mouth disease two periods should be distinguished; the first is the more dangerous, in that the only external symptom is a rise in temperature, but the second is the more distressing to the animals. When, however, salivation has taken place for 4 days they are no longer infectious, for the virus of foot-and-mouth diseases dies on the spot.

The malady is spread by infected animals only during the periods of its incubation and inception which last a very short time. This explains the inefficacy of sanitary measures applied after the epizootic has developed to a certain extent. Even the most radical measure such as slaughtering the stock is no more effective than careful supervision and the seizure of the first centres of infection. At times when foot-and-mouth disease is epizootic, no animal, however healthy it may appear, should be introduced into a sound herd until it has been in quarantine. F. D.

963 - **The Angermünde Disease of Foals.** — HOBMAIER, M (Oberassistent am pathologischen Institut der tierärztlichen Hochschule, Berlin), in *Berliner tierärztliche Wochenschrift*, Year XXXVIII, No. 16, pp. 181-184, figs. 3. Berlin, April 20, 1922.

In several parts of Prussia, the horse-breeders annually lose many of their foals from an epidemic diseases of which the cause is at present unknown. The author calls it the Angermünde disease after the village near which it is most prevalent.

(1) See April 1922, No. 444. (Ed.)

The absence of any microorganisms of bacterial, or protozoon character, was proved by a thorough macroscopic and microscopic examination of the organs of a foal killed after it had been suffering from the disease for about 2 months.

On the other hand, there was a large number of intestinal worms present, among which far the most numerous were the larvae of Sclerostomidae (*Nematoda*, *Strongylidae*). The whole mucous membrane of the intestine was covered with round, blackish cysts the largest being no bigger than a pin's head and each containing an embryo of *Sclerostomum* (*Cyathostomum*) *tetracanthum*. An anatomical pathological examination of the internal organs revealed the presence in the liver of the characteristic lesions of hepatic cirrhosis, while the lymphatic glands were seen to be greatly distended and the walls of the small arteries in the lining of the intestine had undergone considerable degeneration. This complex of morbid symptoms is due, in the opinion of the author, to the enormous number of Sclerostomidae mentioned above.

Although the author realises the necessity for carrying out further experiments on the subject, he believes that the following measures should at once be adopted for the control of the disease.

1) The excrement of all animals supposed to be infected should be examined to ascertain whether it contains any eggs (1). The results obtained are nearly always positive in the case of mares and negative in that of foals, as the latter never harbour sexually mature Sclerostomata.

2) All infected animals must be removed from the field and treated with ordinary antihelminthics.

3) The diseased individual should be treated by fumigation as this induces a lack of oxygen and the generation of excessive heat thus destroying the parasites which require for their development moisture and moderate heat. This method is called biothermic by KOURAND and has proved effective against the larvae of Muscidae and almost all embryos of intestinal worms.

4) Change of pasture; this is absolutely necessary, for though the eggs may be killed by frost, the embryos of the parasite, even if completely frozen, are able to regain their former activity as soon as the warmer weather returns, that is to say, Sclerostomata overwinter in the larval condition and infest the pasture again next year.

E. F.

964 - The "Berne" Fly (*Dermatobia egniventris*) Macquart, 1840 (2) in Brazil. — OLIVEIRA, M. (DE) (Ingénieur agricole en mission d'études du Gouvernement des Etats-Unis du Brésil en France, Ecole vétérinaire d'Alfort), in *Revue de zootechnie*, No. 9, pp. 913-915, figs. 3. Paris, June 1922.

The "Berne" fly is very common in the forest zones of nearly the whole South American continent, Mexico, and Central America. The Brazilian

(1) Cf. HOBMAIER, M. and TAUBE, B., Die Kochsalzmethode bei Untersuchung au Haustierparasiten, in *Berl. tierärztl. Wochenschrift*, Vol. XXXVII, 1921, No. 44, p. 521. (Author's note).

(2) The author calls this fly *Dematobia noxialis* Brauer (née Goudot) 1860, but the above name has the right of priority. (Ed.)

States most infested are Minas Geraes, Rio de Janeiro, São Paulo and Goyaz, next come Paraná and Rio-Grande do Sul. The warm, dry regions of N. E. Brazil are entirely free from this pest.

The fly attacks in decreasing order of frequency cattle, dogs, human beings, goats and sheep, only solipeds seem to be immune.

The eggs of the parasite are deposited on the abdomen of certain *Culicidae* and *Muscidae* and thus transported to the skin of the animals attacked. The larva, as soon as it leaves the egg, bores into the subcutaneous tissue leaving open the hole by which it has entered.

The "berne" fly does a considerable amount of damage, for no means of controlling it are as yet known. Cattle attacked by the parasite lose flesh and their hides are depreciated in value by the holes left by the insect. It is well to remember, although no explanation of the fact has hitherto been found, that black-coated cattle are more infested than others, indeed, the rearing of the Aberdeen-Angus breed in pastures surrounded by forest is a matter of great difficulty. In the author's opinion this is an additional reason in favour of the introduction into Brazil of the French Charollais breed

965 - **Osteomalaxy in Brianz Cattle and Osseous Cachexy in Swine, Diseases caused by Malnutrition.** — BONAUGURI and CLERICI, I' Osteomalacia in Brianza e nel circondario di Menaggio, *La Clinica Veterinaria*, Year XLV, No. 5, pp. 215-224. Milan, April 1-30, 1922. — II SPARAPANI, G. C., I' cachessia ossea dei suini, *Allevamenti*, Year III, Part. 7, pp. 259-261. Palermo, July 25, 1922. — PROVENZALE, F., La vitamina e le malattie dovute ad alimentazione insufficiente, *Ibidem*, pp. 253-256.

I-II-III. — PROVENZALE gives an accurate account of all that is at present known respecting vitamins and the phenomena of avitaminosis, or diseases due to malnutrition, and expresses his opinion that the osteomalaxy of Brianz cattle studied by BONAUGURI and CLERICI and the osseous cachexy of swine (1) described by SPARAPANI must be classed under the head of diseases caused by malnutrition.

#### FOODS AND FEEDING

966 - **Quantitative Botanical Analysis of Artificial Stock Feeds.** — IJZENDAM, JOH. A., in *Verslagen van Landbouwkundige onderzoekingen, der Rykslandbouwproefstations*, No. XXV, pp. 1-83, fig. VIII 1's. Gravenhage, 1921.

The author begins by describing and discussing the methods hitherto employed in the quantitative analysis of artificial feeds. As regards those applied to linseed cake, he considers that the methods of PESCH and SCHAFFNIT are not practical. SCHAFFNIT's system is tedious even after modification by the author. It is suitable only in the case of linseed cakes. The same may be said for the methods of GRÉVILLIUS and SCHOUTE respectively. The Dutch method can be used only for the analysis of linseed and colza cakes. The author has come to the following conclusions regarding the methods adopted in the quantitative analysis of other foods: V. WEINZIERL's mechanical and optical analysis is not sufficiently accurate and is only suited to special cases; KUHN's method is excellent for the quan-

(1) See R. Aug. 1922, No. 840 (Ed.)

titative analysis of samples possessing a much higher, or lower, specific gravity than the food examined, which is of very rare occurrence; HINTNER's method is applicable if the particles of the substance analysed are coarse and easily recognised, and KOLE's method can be employed in analysing the testae in cotton-seed cake. ARTHUR MEYER's method, like that of HUSS, can be used if the constituents are measurable. The author's first method, which is based on the number of particles, may give very discordant results when the matter analysed differs but little in fineness from the substance analysed; he therefore tried to devise a method that did not depend upon the fineness of particles.

He first studied the cells in rice husks and found the average size of an epidermal sclerenchymatous cell to be  $100 \times 150$  micra. Having obtained this unit, he calculated the number of squares that each particle could cover in an area of  $150 \text{ micra}^2$ . To obtain the % of rice husks in the sample thus analysed, the author divided the total of the squares of all the fragments by the "normal figure" (viz the figure representing the number of  $150 \text{ micra}^2$  covered by the fragments in an area of  $1 \text{ cm}^2$  in the case of a sample weighing 1 gm. and containing 1 % of the substance analysed), or else, which was more satisfactory, by factors found for the purpose. This method is therefore not based upon the number of particles present in a given amount of the sample, but upon the surface covered by these particles.

*This method can be applied to.*

I. — *The quantitative analysis of the rice husks in rice meal, or other artificial foods.*

In the chapter entitled as above, the author studies the general method to be adopted for the determination of the "normal figure". He found in the course of his investigations that in order to avoid obtaining too great deviations in the results, it is advisable to take a sample weighing at least 1 gm. and only to consider mixtures containing 2.5 %, 5 %, 7 % and 10 % of the substance analysed leaving out of account those with 1 % and 20 %. The minimum number of particles investigated should be 200. The "normal figure" thus obtained for rice husks is 436.

II. — *The quantitative analysis of the barley husks in barley meal, barley bran and other artificial feeds.*

In the quantitative analysis of barley husks the author's method has to be based upon the area of the external epidermis cells. Therefore instead of macerating the sample with nitric acid and caustic potash, he boiled it for 30 seconds in aqua regia, then added 2.5 cc. of 15 % caustic soda and finally 7.5 cc. of glycerine (1 part water for 1 part glycerine). This stains the husks yellow and makes them easier to distinguish. The author was obliged to alter his method of finding the "normal figure" on account of the irregularity with which the barley husks occurred in the samples. He passed 10 gm. of unground material through a 1 mm. mesh sieve and then carefully removed with forceps all the barley husks from the mass left on the sieve after freeing them from all the adhering flour. The remainder was added, after milling, to the finer portion that

had passed through the meshes. From the entire mass he then took 1 gm. and subjected it to quantitative analysis. From the results obtained he was able to ascertain the total percentage of husks in the sample by adding to this partial result (made up to 10 gm.), the amount of barley husks he had removed after sifting.

The "normal figure" thus obtained is 65.

### III — *The quantitative analysis, of the pea-nut shells found in pea-nut flours and other foods*

The author's method can also be employed in the analysis of pea-nut shells, if the surface area of the fibres is used as a basis. The "normal figure" thus obtained is 25.8. When it is a question of the analysis of samples containing 10 % or 20 % of these shells two or more analyses should be made, as only  $\frac{1}{2}$  gm. can be used at a time which does not allow accurate results to be obtained. If the pea-nut shells are very large, the method devised for barley husks can be adopted. In order to find the total amount of husks present in feeds such as the flour of small seeds where small fragments of the shell occur together with pieces of the pea-nut itself, both the above mentioned "normal figure" and also the figure found for these mixtures can be used. This "normal figure" calculated on the basis of the superficial area of the hypodermic cells is 90.

#### *Quantitative analysis of foreign bodies found in artificial feeds*

The husks of rice and barley as well as pea-nut shells are frequently met with in linseed cake, wheat bran and many other feeds, and can be analysed by one of the above mentioned methods. Other foreign bodies, such as the endosperm of coffee beans, or the pods of cacao, are also of common occurrence.

The author tried making a quantitative analysis of these by means of his own method.

#### I — *Quantitative analysis of the endosperm of coffee-beans occurring in artificial feeds*

The author's method in this case had to be based on the superficial area of the endocarp cells. The "normal figure" is 36.5. If the fragments are large, the method suggested in the case of barley husks can be adopted.

#### II — *Quantitative analysis of cacao shells in artificial feeds*

In this analysis, the author takes as his basis the size of the sclerenchymatous cells and of the epidermis cells on the exterior of the seed integument. The "normal figure" is 27.7.

#### III — *Analysis of useful foreign bodies found in artificial feeds*

Useful substances as well as worthless matter are frequently met with in artificial feeds. It is sometimes worth while knowing the percentage of the valuable substances, but often they cannot be quantitatively analysed owing to the lack of any unit of measure, which only exists in foods that have not become altered during their preparation, or that have undergone such transformation as to have a constant composition. In the majority of cases, however, all that is necessary is to determine the presence of these foreign substances.

#### IV — *Quantitative analysis of the soy-bean content of artificial feeds.*

In the author's method of analysing pieces of soy-bean, the cells of the palisade-tissue are measured. The "normal figure" to be used is 5.7. If the soya-bean is mixed with a food that is not very resistant to chemical maceration, it is best to take a large number of samples, or else to plot out on a larger surface the number of squares covered by the fragments, as this is of great assistance in calculation.

.V. — *Quantitative analysis of the degree of purity of linseed cake and linseed bran.*

Percentage of substance analysed	Amount analysed	Superficial areas measured	Normal figure
Straw 5 % . . . . .	1 gm.	7.2 cm <sup>2</sup>	22
Small gramineae 10 % . . . . .	1 "	3.6 "	55
<i>Setaria viridis</i> 10 % . . . . .	1 "	3.6 "	35
<i>Chenopodium ambrosioides</i> 10 % . . . . .	1 "	4.8 "	19.5
<i>Chenopodium album</i> 5 % . . . . .	1 "	9.6 "	18.7
<i>Sinapis arvensis</i> 10 % . . . . .	1 "	4.8 "	18
<i>Camellina</i> 10 % . . . . .	1 "	8.4 "	18.5
<i>Spergula</i> 10 % . . . . .	1 "	7.2 "	21
Gramineae of average size 10 % . . . . .	1 "	10.8 "	12.6
	1 "	12 "	
	1 "	14.4 "	
<i>Centaurea</i> 10 % . . . . .	1 "	7.2 "	18.2
<i>Brassica</i> 10 % . . . . .	1 "	6 "	21
		6 "	
<i>Gallium</i> 10 % . . . . .	1 "	8.4 "	20.3
<i>Polygonum</i> 10 % . . . . .	1 "	8.4 "	19.4
<i>Agrostemma</i> 10 % . . . . .	1 "	12 "	14.6
<i>Vicia</i> 10 % . . . . .	1 "	10.8 "	12.2

The author's method is based upon the measurement of the area occupied by the impurities and from this he deduces the degree of purity. The advantage of this system lies in the fact that a larger number of impurities are used in estimating the area which they cover. The quantitative analysis of a sample of linseed cake takes about an hour if this method is adopted.

The Table gives the "normal figures" found by the author for most of the impurities met with in linseed cake.

By means of these "normal figures" it is possible to estimate the degree of purity of linseed cake. Another Table gives the different factors employed in the analysis of various impurities, the analysis being based on a surface of 1 cm<sup>2</sup> divisible by 1 to 9 rows.

The author also gives a Table to assist calculation of results.

Stress is laid upon the fact that the success of this method chiefly depends upon the accuracy of the "normal figure" used. F. S.

967 - **Figs as Food for Livestock.** — See No 989 of this *Review*

968 - **Selection as a Means of improving Domestic Animals.** — FRATEUR, J. L. in *Annales de Médecine vétérinaire*, year 67, No 7, pp 289 311 Brussels, July 1922

Selection was formerly governed by the one great theoretical principle that "like begets like" Now however selection as applied to stock-breeding may be defined as the reasoned choice of progenitors with a view to the improvement of the race It is a question of choosing animals capable of impressing their own good points upon their progeny, therefore the whole value of selection depends upon the prepotency of the parents, i. e. their power of transmitting their qualities to their descendants

Selection acts only on hereditary characters, on the genotype which is wholly distinct from the environment and does not depend upon environment for its transmission and hence for its effect in improving the breed

The question has been asked whether selection is only effective in the case of native breeds The old indigenous races of a region are homozygous as regards a certain number of characters which are therefore fixed characters This is due to the fact that breeds naturally protected from any considerable amount of crossing have become progressively and automatically pure as regards a certain number of characters which are then for the most part homozygous, or duplicated

Selection should be more effective with these simple types than in the case of breeds possessing complicated characteristics How is it possible to select from material where all the individuals have the same genotype, that is to say, are pure? In all breeds, even the oldest, there are always a certain number of heterozygous characters, that is to say with two dissimilar sets of factors, and when it is desired to use farm stock for improving the domestic animals it is always necessary to begin by selecting individuals that have retained certain given characters of the breed indigenous to the country

The breeder will thus have at his disposal a large number of homozygous forms which will form the basis on which to build up pure lines Finally, the author states the rules, which govern heredity and make it possible to obtain accurate results of practical utility by means of selection He draws a distinction between phenotypic and genotypic selection

#### 1) *Phenotypic selection*

Phenotypic selection has been advocated because the effect of environment can continue for one or two generations, being handed down by the progenitors, especially those on the maternal side This however cannot be a question of hereditary transmission properly so-called, for the effect disappears after a certain lapse of time when the effect of the environment which gives rise to the variation has ceased Selection only gives good results when systematically carried out Methodical selection offers the best opportunities, not only in the case of phenotypes but also in that of genotypes (definitive selection) The following are some practical rules to assist in selection

Individuals should be chosen which present extreme variations. These

individuals should be isolated and allowed to interbreed only amongst themselves. Improvement by selection nearly always means the isolation of a specially good genotype, its propagation and further selection, so that it can eventually replace the original breed which in its entirety is less satisfactory. Therefore, in order to succeed, the selected individuals must be subjected to the most rigorous isolation. The best phenotypic results are obtained as a rule when isolation has been most complete.

## 2) *Genotypic selection.*

Genotypic selection is based on the hereditary factors of the required characters. It is a scientific operation, whereas phenotypic selection is empiric.

The theoretical aim of selection is to obtain pure lines, that is to say a group of individuals with the same hereditary formula and all the factors of this formula in duplicate. In the case of our domestic animals, it is impossible in spite of sex separation to obtain really pure lines. The appended Table shows the progressive improvement of autogamous individuals. The author mentions in this connection the analogy of the results obtained in the case of autogamy and absorption crossing.

The final object of all selection is therefore the isolation of lines that are pure, or capable in the course of time of producing pure lines. Selection possesses no creative power, it can only isolate and sift. Once however the products of the sifting have been obtained, they must be kept free from all contamination, otherwise the work will have been in vain.

*The work of genotypic selection.* — The aim of selection is to obtain offspring similar to their selected parents. Therefore only those males should be kept for breeding purposes which probably possess the genotype of the desired characters. Pure lines can only be attained by means of such males.

The different breeds of animals however are formed of a mixture of genotypes that are very rarely pure even as regards their extreme variations. Fortunately the knowledge we now possess is already sufficient to be of great assistance in obtaining animals with pure characters all homozygous, or having a duplicate set of similar factors, in which case, there are no discarded individuals. In practical work, several cases may arise, thus:

1) The hereditary characters may be well known. When these characters are the result of recessive factors, or even of extreme variations of a quantitative nature, they are pure.

When on the contrary, the characters depend on dominant factors, they are impure in the majority of cases. After the second generation there will however be a certain number of homozygous individuals, from which selection can be made, but it is better to discard all individuals that are heterozygous as regards the required characters. To do this recourse must be had to the purity reaction.

On the other hand, in the case of quantitative factors, it is often pos-

sible to distinguish between pure and impure factors. The extreme variations of these characters are pure.

2) The genetic nature of the characters to be selected may not be known.

In this case, some of the best individuals are chosen and mated together for several generations the results obtained in each generation being carefully recorded. The percentage of rejected individuals in each generation serves to indicate the course to be followed. After the third generation there should be a sufficient number of homozygous individuals to allow the trial of the purity reaction.

3) It may happen that only one of the parents (the male, or the female), possesses in a perfect degree the desired character.

In this case selection must be combined with absorption crossing. In the next generation, various results may be obtained.

a) the character of the bull may have been transmitted to all its progeny. This shows that the factors of these characters are dominant. All the offspring of the first generation are however mixed, and if the new selected variety is to be fixed, it is necessary to carry out absorption crossing.

b) the character of the bull may have been transmitted to none of its progeny. This shows the character to be due to recessive factors and the individuals of the first generation must be re-crossed with the same bull and a new selection made of all the descendants having the character of the sire; in this way a small nucleus of individuals is formed which are crossed together. The character is then fixed.

c) in the  $F_1$  a character may be obtained that is intermediate between that of the bull and cow respectively, in this case also an absorption cross must be made

The application of these general rules must vary according to circumstances. The breeder should however always keep in mind that the object is to obtain a homozygous line. Although this method does not always yield good results and entails a certain amount of danger from in-breeding, the author is of opinion that in many cases it is the only one to adopt and is also the surest way to arrive at the desired result.

*Table showing the autonomous purification of autogamous individuals by crossing an individual having the pure A character with an individual not possessing this character.*

Crosses	Results			Pure %		
	A					
P $A_2$ + P				0	0	0
$F_1$ + $F_1$	25 $A_2$	50 A	25 $a^2$	50	25	25
$F_2$ + $F_2$	37.5 $A_2$	25 A	37.5 $a^2$	75	25	25
$F_3$ + $F_3$	43.75 $A_2$	12.5 A	43.75 $a^2$	87.50	43.75	43.75
$F_4$ + $F_4$	46.875 $A_2$	6.254 A	46.875 $a^2$	93.75	46.875	46.875

*Absorption Crossing of heterogamous individuals*

Crosses	Results		Pure %		
	A		Total A <sub>2</sub>		
P A <sub>2</sub> + P			0	0	0
F <sub>1</sub> + F <sub>1</sub>	50 A <sub>2</sub> ;	50 A	50	50	0
F <sub>2</sub> + F <sub>2</sub>	75 A <sub>2</sub> ;	25 A	75	75	0
F <sub>3</sub> + F <sub>3</sub>	87.5 A <sub>2</sub> ;	12.5 A	87.5	87.5	0
F <sub>4</sub> + F <sub>4</sub>	93.75 A <sub>2</sub> ;	6.25 A	93.75	93.75	0

The number of homozygous individuals  $x'$  in each generation is expressed by the formula  $x' = x + \frac{y}{2}$ , in which  $x$  = the number of homozygous individuals in the preceding generation and  $y$  = the number of heterozygous individuals in the preceding generation.

STOCK  
BREEDING

970 — The Live-Stock of the Tavoliere di Puglia (1). — SPEZZATI, M., in *Allevamenti*, year II, No. 12, pp. 414-416, fig. 1. Palermo, December 31, 1921; year III, No. 3, pp. 65-70, figs. 5. Palermo, March 1922.

CATTLE. — These are of the Podolian breed; bulk medium; coat white; long lyre-shaped horns; dewlap long; withers sunken; legs long. The animals are fed sparingly being turned out to grass and only given a little straw and some handfuls of hay. They are kept almost entirely in the open and driven into rough shelters during the coldest part of the winter. When no longer able to work, these cattle are usually slaughtered. The author draws attention to the fact that if the oxen were kept until they were 9 or 10 years old instead of being sent to the butcher's when 4 or 5, and were then given a fattening ration for 30-40 days, such as grass supplemented by hay, oats or ground beans, these animals would put on much flesh at smaller expense, the beef would gain in flavour and higher profits would result.

HORSES. — These are of Eastern origin, their ancestors having been imported by the Greek Colonists. Fifty years ago many pure-blood horses were bred and sold in large numbers at fairs held at Foggia, Andria, and Gravina, chiefly to the Military Commission. Subsequently, machine-

(1) Information regarding stock-breeding conditions in Italy and the Italian Colonies can be obtained from the following original articles: R. JAPPA, The Cattle Industry in Italy at the Present Day, R. May 1914, pp. 598-606, June 1914, pp. 712-716; E. MASCHERONI, The Rearing of Donkeys and Their Crosses with Horses in Italy and Her Colonies, R. Feb. 1920, pp. 129-138, figs. 16, and in the following articles reviewed: R. 1901, Nos. 1824, 2207, 2811; R. 1912, Nos. 321 and 684; R. 1913, Nos. 330, 702, 708, 709; R. 1914, Nos. 352, 357, 546; R. 1916, Nos. 357 and 927; R. 1917, Nos. 729 and 1325; R. 1918, Nos. 538, 647, 665, 777; R. 1919, Nos. 220, 224, 414, 490, 943, 953, 1182; R. 1920, Nos. 93, 277, 522, 779, 894; R. 1921, Nos. 180, 316, 318, 412, 536, 656, 658, 742, 743, 842, 935, 939, 947, 1029, 1103, 1143; R. 1922, Nos. 84 and 188.

threshers became common, so that fewer horses were needed on the farms for threshing, the pastures decreased and were turned into vineyards which did much injury to horse-breeding, and the industry rapidly declined. It no longer paid the breeder to reserve his finest colt for a stallion, so that he applied for the services of the stallions kept at the Government Stations. These animals were chosen without any unity of aim. On the other hand, breeders having no well-bred stallion continued breeding the local race which is very strong, but soon began to show signs of degeneration. The English and Arab stallions however proved excellent sires provided sufficient care was given to the foals. The author much regrets that the want of a clear aim in breeding has resulted in mixing the different races. He is of opinion that the breeder of the Apulian horse should set two objects before him : 1) the production of a farm-horse of the Breton type ; 2) the production of a riding and a light draught animal suitable for military purposes.

**SHEEP.** — Travelling sheep-breeding was formerly much developed and the flocks coming down from the Abruzzi occupied at least 200 000 hectares, or two-thirds of the "Tavoliere". Subsequently the animals were greatly improved both by repeated crossing with Merinoes and by the fact, that being transported by rail, they were spared the fatigue of long journeys on foot. When the breeders had succeeded in obtaining wool of greatly superior quality, they had to face severe competition from the Australian and the Argentine ; this dealt a great blow to Apulian sheep-breeding and in a few years many of the animals had to be slaughtered and much of the pasture-land was ploughed. Sheep are however still reared in large numbers in the Province of Lecce, near Tarento, in the Province of Bari, in the neighbourhood of Matera, and in Basilicata near Altamura. In each of these provinces a different variety of sheep is raised, but the distinguishing characters are of slight importance. The animals are somewhat larger than merinoes and have a long, fine fleece parted down the middle. Their meat is a more vivid pink colour than that of other breeds and the fat is a transparent white.

The author believes that sheep-breeding might again become an important industry in Apulia ; large flocks of merinoes, known locally as "gentile" or "spagnola", should however not be kept. The sheep to choose is the "long-wooled" or "soft-wooled" animal that does not need to migrate to the higher land, being resistant to the summer heat of the "Tavoliere". Each farmer should keep a small flock of these sheep to graze on his fallow land and by the road-sides.

**PIGS.** — The pigs of Gargano are white, have little hair, a slightly arched back, long snout, and short legs ; they often weigh 2 quintals or more. Their meat is of fine quality and marbled, the fat is white and firm.

Over 10 000 animals are reared annually on the promontory whence the breed takes its name. From November to early June the pigs feed on the Gargano pastures and then descend to the plains, where they are turned out into the barley, wheat, and bean stubble fields ; in September

they are driven into the oak woods of Mt. Gargano to feed on the acorns. If the crop is scanty the animals are put into sties and given beans and then maize until they are ready for the butcher.

F. D.

971 - **The Development of Stock-Breeding in Sardinia.** — VALLISNERI, A., in *L'Italia Agricola*, Vol. 59, No. 6, pp. 194-200, figs. 5. Piacenza, July 15, 1922.

**CATTIE.** — Two methods have been adopted in Sardinia with a view to improving the cattle-breeding industry of the island: 1) crossing the dual purpose animals chiefly found in the north of Sardinia with a Swiss bull, in order to obtain good beef and dairy cattle; 2) crossing the native cattle with the Modica breed so as to obtain draught animals. The pure native cattle are reared only in the centre of the island or on the east and north coasts, in poor districts where they cannot be replaced by better stock. The cattle are used for ploughing and when they can no longer work are sent to the butcher.

The Modica breed is gradually being superseded by the Swiss for the improvement of native cattle. Swiss cattle, if bred pure, in Sardinia lose many of their good qualities and become inferior to their hybrids. The latter, according to a series of measurements of adult cows taken by the author are 127 to 139 cm. in height at the top of the withers; their conformation is good. The cows yield from 20 to 25 litres of milk daily, but only during four months in the year, dating from the calving time at the end of the winter until the pastures become dried up.

Throughout the summer only a few grammes of milk are produced, but the suckling calves keep the teats active so that should rain fall in September, which is of rare occurrence, there is also an autumnal lactation period. The characters of these cross-bred cows are quite fixed and as the latter are triple purpose animals and very adaptable, they are now imported to improve the native breeds of Sicily and the Italian peninsula. Many have been introduced to replace the stock in the invaded provinces where they give entire satisfaction.

**SHEEP AND GOATS.** — Sheep are bred throughout the island, fixed flocks being kept in the coast districts, and travelling flocks in the central region. Milk is their chief product. The Sardinian sheep is a small animal about 60 to 70 cm. in height and the mountain breed weighs about 20 kg. and the plain breed 30 kg. It is thrifty, a good walker and excellent grazer. The fleece is light (weighing 600 to 700 gm.), the wool is coarse and unequal, dry and scanty. The meat of the adult sheep is inferior in quality, but that of the lambs is excellent. Lactation lasts from about 6 to 8 months with an annual average milk yield of about a quintal, which is a large quantity if the poor pastures and lack of care and shelter are taken into account. From 18 to 25 p. c. of cheese, according to the kind, can be produced from the milk and "Ricetto" is also made. The ewes' milk is made into butter of fairly good quality.

"Pecorino sardo" is the type of cheese usually manufactured. It found a rival in the "tipo pecorino", a cheese made from cows' milk, but this in its turn has been replaced by Roquefort with its larger out-

put, as the latter cheese is manufactured in Sardinia by several French Societies.

Sardinian sheep should be selected and not crossed with other breeds.

In the steepest parts of the islands goats do better than sheep, and they yield milk at a season when it cannot be obtained from any other animals. The flesh of the kids is excellent.

Pigs. — The herds of swine are decreasing in proportion as the work of deforestation continues. The Sardinian pig greatly resembles the wild swine; its coat is grey, or more rarely black, fawn, or pied. It is small (40 to 65 kg.), short and fattens easily if fed on both grass and acorns. Pigs fattened at home may weigh as much as 150 kg. when 2 years old. Large cheese factories have recently been started in the island and an attempt has been made to utilise their waste products by pig-breeding. Several foreign breeds such as Yorkshires, Berkshires and Casentaux have been introduced to improve the native animals.

A series of experiments and tests is still in progress (1) F. D.

972 — **Stock-Breeding in Greece.** — *L'Economiste d'Athènes*, Year 1, No 23, pp 356-357 Athens, April 15, 1922

The stock-breeding industry is well developed in Greece. Sheep and goats are the animals reared in the largest numbers as they find a plentiful supply of food in the extensive mountain pastures.

At the end of the War the number of sheep and goats had decreased 30 %. This was due partly to the unusual amount of meat consumed by the troops of the Greeks and the Allies, as well as by the hundreds of thousands of Greek and Serbian refugees, and partly to the fact that the civil population were obliged to eat meat owing to the short supply of bread during the period of hostilities.

There are also fewer horses and mules in the country as many were commandeered for the Army.

The live-stock reared in Greece had always been sufficient to meet the requirements of the inhabitants. The value of the stock and farm products imported before the War was never higher than 4 to 6 % of the value of the home production. On the other hand, Greece used to export hides, wool and cheese to the value of several million francs a year.

(1) As regards stock breeding in Sardinia and especially the rearing of horses, mules and donkeys, see R Feb 1919, No 224, R Mar 1921, No 316; R Sept 1921, No 935; R Nov 1921, No 1142, R Dec 1921, No 1250.

The volume of *L'Italia agricola* under discussion is entirely dedicated to Sardinia and in addition to the article summarised above contains the following papers: F. BLANDINI, One of the Agricultural Troubles of Sardinia, Dust Covered Land — G. HINCK, La Nurra: Roads and Drainage — F. BLANDINI, The Varieties of Wheat Cultivated in the Province of Cagliari, trigu moru (summarised in R Aug 1922, No 826) — O. GERVASO, Drainage and Irrigation in the Campidano d'Oristan — B. VANZI, Horse breeding in Sardinia — LIUZZI C., Viticulture in Sardinia during the last fifty years — G. SANNIO, Cheese Manufacture in Sardinia, A Model Cooperative Dairy — MANCONI, Cork Growing and the Cork Industry Sardinia. — B. ORRU, Small Agricultural Industries in Sardinia. (Ed.)

Although poultry-keeping is much dearer, transport is more expensive and the general cost of living has risen, Greece is still able to satisfy all internal demands for live-stock produce, the gradual decrease in the beef supply being counterbalanced by an increased amount of pork.

In 1920, the value of the live-stock produce imported from abroad was 5 % of the value of the native production.

On the whole therefore Greece can keep its own meat market well supplied. F. S.

973 - **A Study of the Argentina Cattle Crisis.** — LIGNIÈRES, J., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. 8, No. 20, pp. 570-574. Paris, 1922

The Argentina breeders are much concerned at the present crisis in the cattle trade which is characterised not by a rise in prices, but by a general stagnation of business. The causes of the crisis are several: 1) the necessity for economy which has caused all nations to increase their own production and deal with their own Colonies rather than import from abroad; 2) the unfavourable condition of the exchange rendering it difficult to purchase Argentine produce; 3) the accumulation during the War of enormous reserve stocks that have often greatly deteriorated and have in any case fallen in price; 4) the competition of Australia, New Zealand, Canada, Uruguay and Brazil

The result is that South American Frozen Meat Companies are obliged to reduce their purchases and the breeder is left with his stock on his hands. After having thus stated the causes of the crisis, the author discusses the remedies which have been suggested, some of which are of a local character, whereas others would be more radical and far-reaching. In this latter category come the opening up of new markets, propaganda, and the sale of the reserve stocks. F. S.

974 - **The Future of the Grazing Industry in Brazil and its Present Crisis.** — MORAES BARROS, P. (DE) in *Revista da Sociedade Rural Brasileira*, No. XXIV, pp. 324-328, São Paulo, June 1922.

The present crisis through which the grazing industry is passing must be attributed to three causes; 1) the replenishing of the depleted European flocks and herds; 2) the existence of large army stocks of tinned and frozen meat left on the continent at the end of the War; 3) the restriction of meat consumption imposed upon the people by the Governments of the belligerent nations.

This crisis can however be only of a transitory character, for the demand for meat and all the other necessities of life naturally tends to increase and it is easy to foresee that when once equilibrium has been restored in the congested supply market the sales will constantly and progressively rise as they did before the War.

The author, who is President of the *Sociedade Rural Brasileira*, has dedicated his paper to the President and Members of the Government of the State of Matto Grosso. He is convinced that Brazil will play a great part in this trade revival, for whereas stockbreeding shows signs of decline in the largest American States (the United States and Argentina) owing to the wide tracts of pasture lands that have been ploughed up for

intensive farming, the most favourable conditions for the rapid development of stock-rearing are to be found in Brazil, especially in the State of Matto Grosso. In order to be able to benefit from this privileged position at the right moment it is however necessary to take certain preliminary steps during the present crisis.

In the first place, all the factors must be eliminated that hindered local production before the War.

The native breed of cattle finds disfavour on the overseas markets owing to the large admixture of Zebu blood. This defect could be remedied within 5 years if the owners would set aside 10 % of the proceeds of their annual sales for the gradual replacing of their present bulls by Rio Grande animals, which are totally immune from red-water (*tristeza*). An active propaganda should be made in the centres of production.

Another obstacle that should be removed is the great burden of taxation. Brazilian meat is taxed to such an extent before it reaches the market, that it must of necessity be sold at a price which prevents competition with foreign products.

The author gives statistical data to support his views and draws the attention of the Federal Government and the Governments of the different States to the paramount importance of reducing these taxes in the interest of national trade.

In order to derive full benefit from the favourable cattle-breeding conditions in Matto Grosso, the means of communication between that State, São Paulo and Rio Grande do Sul must be improved. São Paulo is the centre of important industrial undertakings and of the movement of capital, whereas the latter State possesses breeding stock belonging to the best European races.

E. F.

#### HORSES

975 — **The Horses of the French Sudan.** — WILBERT, J., in *Revue de Zootechnie*, No. 9, pp. 843-859, with illustrations. Paris, June 1922.

In the colonies of Upper Senegal, the Niger and Upper Volta which form part of French West Africa, there are some 70 000 horses. The breeding of these animals has been left almost entirely in the hands of the natives and has suffered from their carelessness and ignorance. The few and inadequate attempts made by the local Breeding Service to improve the breed have met with relatively little success, but good results could be obtained if the animals were liberally fed and some general hygienic precautions taken. The native breeds of horses are of various types owing to unsystematic crossing, neglect and the effects of environment. The author has however been able by means of a thorough investigation based on accurate measurements to distinguish the 4 characteristic types.

1) Rectilinear, forehead flat, eumetric and medio-linear corresponding to the *Arab breed*. Its sole representative in the French Sudan is the Air horse which probably came from Judea and Syria.

2) Convexilinear, forehead convex, eumetric and mediolateral corresponding to the type of the *Mongolian breed*. This horse came from the Mediterranean region and was introduced by the Berbers. The type in-

cludes the subraces of Hoah, Sahel; Beledougou Kaminiandougou, Guenickalari, Minianka, Guidimaka and Kasso, viz., the greater number of the horses of the Western part of the Colony. From the practical standpoint the most important is the Hoah sub-race.

3) Convexilinear, hypermetric and longilinear corresponding to the *Dongolawi* race and including numerous subraces with characters in common (Djerma, Gondo, Liptako, Songhai, Yatenga, Boulssa, Boussomma, Torodi, Yagha, Bobo-Oule, Nounougou, and Boussangha). The horses of this type are excellent draught animals and can do heavy work, but have become apathetic and wanting in resistance as a result of the damp warm weather that occurs during the greater part of the year.

With the exception of the Mechdonf, Mavka, and Peuhl Moors of the Sahel and Gourma, no other native tribes breed horses which is now a matter of little importance, as since the pacification of the country the cavalry corps has been supplied.

4) Concavilinear, forehead dished, ellipometric and mediolinear. This breed is very similar to the Siginni race and to the Coto-coli pony as found on the borders of Dahomey at the extreme south of the Colony.

The author gives a short description of each of the above-mentioned races. Their habitat and zone of distribution are shown on a special map prepared for the purpose.

For this reason, it would be necessary to limit the work of selection to the improvement of a few breeds, and owing to the nature of the inhabitants and the conditions of the country, breeding centres should again be established, or only approved and licensed stallions allowed to be employed. In the latter case, more prizes ought to be offered to breeders who should be allowed the opportunity to buy selected animals from Stations where the horses become naturally acclimatised. Service Stations under veterinary supervision and managed by European, or native, experts, should be established in each breeding district.

The improvement of the Sudanese horses was actually begun as long ago as 1896, but met with little success. A second attempt led to the establishment of the Kowlikoro Station, which was first started for horses of Arab-Berber origin from the east of the Colony, and to measures being taken for the protection of the Mongolian breeds which supply the stallions entrusted to the local Authorities. Another attempt was made on a larger scale, but was abandoned in 1910, for although a certain amount had been accomplished, the methods adopted were not satisfactory. The results obtained however are useful to anyone wishing to profit by a horse-breeding experiment in French West Africa.

976 - **Improvement of Breeds of Horses in Italy.** — I. CELLA, R. (Direttore della Stazione di mont. equina di Pisino, Venezia Giulia), Il cavallo di Brioni come miglioratore dell'allevamento equino istriano, *Il moderno zootatro*, parte scientifica, Series V, Year XI, No. 1, pp. 46-47. Bologna, January 1922. — II. BAZZOCCHI, A., La produzione equina in Romagna (1), *Allevamenti*, Year III, Part. 4, pp. 105-107, figs. 3. Palermo, April 1922.

The author is of opinion that the best horses for Istria, whether for agricultural purposes, riding, or driving, are to be obtained from the Is-

lands of Brioni. These animals belong to the Hoflinger breed, which is reared in the Tyrol and was formerly improved by crossing with Arab sires. The native Istrian mares especially those resulting from Eastern or Lipizan (1) crosses, when mated with a Hoflinger stallion, produce excellent hybrids that resemble the paternal type more than the maternal and possess large, strong hoofs. On recrossing these hybrids with a Hoflinger stallion, an animal is obtained which fulfils all the requirements of the Istrian peasant and makes a good army horse. The Hoflinger horse and its crosses mature early, the former reaching maturity at 3 years of age.

II.— A short time ago horse-breeding in Romagna was rather a pastime than an industry. The Pineda breed of Ravenna alone was to some extent fixed and homogeneous. Bosnian and Croatian horses were subsequently introduced and later so-called Hungarian horses. The general confusion was also increased by the lack of unity of aim in the selection of stallions for the Government Stud Stations.

During the War however a very successful experiment was made in introducing the Sardinian horse, and breeders began to turn their attention to rearing trotters and, to a less extent, heavy draught animals. Some good Belgian stallions have been imported for the production of heavy weights, but there are no brood-mares. The offspring of the small local mares are loose-limbed. The present brood-mares, especially those of Sardinian blood, are more suited for the production of trotters. The author gives an account and the pedigrees of some of the imported stallions and race-horses. He recommends the importation of animals to increase the stock of brood mares and considers that if his programme were carried out, Romagna (Province of Ravenna and of Forlì), might become a very important centre for breeding light cart and carriage horses. F. D.

977 - **The Murmur in the Uterine Arteries of the Mare.** — RICHTER, J. (Director des Instituts für Tierzucht und Geburtshilfe der tierärztlichen Hochschule in Dresden), in *Berliner tierärztliche Wochenschrift*, Year XXXVIII, No. 10, pp. 109-111, bibliography of 13 works. Berlin, March 8, 1922.

During the last twenty years, the diagnostic characters of pregnancy, especially in the case of cows, has been the subject of much research. Clinical methods of examining the vagina and rectum have superseded ABDERHALDEN'S system which has proved of little practical use.

The technique employed in these examinations is now fixed and generally practised in the case of cows but hitherto no sufficient data have been available as regards horses.

The method advised by ALBRECHT (2), viz. local auscultation from the outside of the body, gives no practical results, but the method suggested by the author and based on internal manual examination is very successful. It is well-known that on introducing the hand into the rectum of a pregnant cow and placing the finger-tips upon the median artery of

(1) See foot note to No. 961 of this Review. (Ed.)

(2) No. VII, Part II of *Handb. d. tierärztlichen Chir. u. Geburtshilfe*, 1913, p. 230. (Author's note).

the uterus, a vibration of the arterial wall is clearly felt and a murmur resembling *ssst — ssst — ssst* — heard, which is an almost infallible sign that the animal is in calf.

By adapting this technique to the differences in the structure and position of the uterine blood-vessels in the mare, the author has been able to hear a similar murmur emitted by the artery of the uterus. It differs slightly in character from that heard in the case of the cow, bearing more resemblance to the sounds *sss — ss — s — sss — ss — s* etc. The author states that this vibration is of great use in the diagnosis of pregnancy and quickly ceases after the mare has foaled. E. F.

978 — **Mule-Breeding in Lower Poitou.** — GRAU, A., in *Revue de Zootechnie*, No. 10, pp. 1-11, illustrated, Paris, July 1922

There are large mule-breeding stations in Lower Poitou, the district including the *arrondissements* of Fontenay-le-Comte, Niort and Melle.

The author describes the ass and the mare used in the cross, and also the adult mule.

The sires are asses of the large Poitou breed. These animals are from 1.30 m. to 1.50 m. in height, having very large heads and very thick legs, and long open ears fringed with curly hair. The hair of the coat is long and shaggy, dark-chestnut in colour (lighter on the abdomen), and forms a kind of fleece which entirely covers the body giving these donkeys a characteristic appearance. An ashen-grey band encircles the head a little above the muzzle.

The great height of this breed appears to be due to the very calcareous soil, for the Poitou donkey only develops properly on the Jurassic plains in the district and on the recent alluvium of the marshy areas of La Vendée.

During the first month the foal is the object of the greatest and most constant care, and afterwards it accompanies its dam to grass and is not weaned before the age of 9 to 10 months. It is then given almost the same food as the adult animals, viz. lucerne, clover and lupin. The young donkeys are thrifty, for until the period of service, viz., the age of 2 or 3 years, they only eat 5 to 6 litres of oats a day. The service season is from February to July, and after each mating, the donkey is given an additional litre of oats.

Except during this period the adult animals are given no oats for they do no work and are always kept in the stable owing to their stubborn bad-tempered and sometimes dangerous dispositions; they are thus however predisposed to certain skin-diseases and to swelling of the feet. The author considers that a moderate amount of exercise and the observance of hygienic precautions would have a salutary effect upon the health of the donkeys. If each animal were turned out into a grassy enclosure communicating with the stable, the foot trouble would be avoided. It would however be necessary to surround the enclosures with walls high enough to prevent the donkeys seeing and attacking one another.

The horses used in breeding Poitou mules belong to the Friesian race introduced into the region at the beginning of the 17<sup>th</sup> century. They

are from 1.62 m. to 1.65 m. in height, their legs are powerful and covered with hair which is very thick at the lower extremity; the mane and tail are thick, the hoofs large and flat. Individuals with long head and ears, high withers and strong neck are preferred as they produce fine vigorous mares bearing strong mules. By means of continuous selection, the breeders have succeeded in obtaining a special type of mare particularly well-adapted for mating with the donkey. After they are served, the mares have no special treatment, until pregnancy is far advanced, when they are kept in the stable or left in the field and not obliged to work. As mating takes place in the spring, the mares foal the next year from April to June. After foaling, the mare is given grain, hay and warm drinks, which encourage lactation, and is afterwards put into the field together with the foal. Weaning takes place in November, the young mules of a year old, called locally *jetons* and *jetonnes*, are fed during the winter on artificial forages and carrots; with the return of spring they are turned out into the fields where they find clover and lupins. When 15 to 18 months old, the *doublons* or *doublonnes*, as they are termed, are harnessed to a cart in company with an old mare and do a moderate amount of work which develops and strengthens their muscles. Mules that have reached the age of 3 to 4 years are kept in the stable, given every care and fed liberally to make them put on flesh rapidly; at the end of the year they are sold at the fairs.

A full-grown mule is from 1.45 m. to 1.60 m. in height and weighs from 300 to 600 kg., it can do as much work as a horse, especially in damp, warm climates such as are very injurious to horses.

Over 20 000 mares are served annually by donkeys and of these about one half are fertilised; thus the number of mules born in the district every year may be estimated at from 10 000 to 12 000. In 1884, a Stud Book was started and a Breeding Syndicate was founded in 1902. E. F.

#### CATTLE

979 - **The Saint-Tropez (France) Breed of Cattle.** — GOUIN, R., in *Revue de Zootechnie*, No. 10, pp. 59-64. With illustrations. Paris, July 1922.

Saint Tropez is the ancient capital of a part of the territory of the Côte d'Azur situated between the mouth of the Argens (near Fréjus), and the Gulf of Giens. It possesses a special breed of cattle similar to that of the Camargue marshes, which is in the opinion of the author of African origin and not descended from the Italian Podolian race as has been maintained in other quarters.

The Saint-Tropez cattle are small (1.30 m. to 1.50 m. in height), they have a glossy coat generally black, but sometimes brown, and sometimes spotted with white. The mucous membranes are black and the horns and hoofs very hard. The horns are inclined slightly upwards, the loins are straight, the hocks rather close together, and the rump is sometimes higher than the withers. The cows have small, brown udders and yield only sufficient milk for suckling their calves.

This breed is used solely for work. The animals are not docile, but a special method of yoking is employed and they are controlled by the

voice. Local changes in cultivation and the disappearance of pastures have led to the practical extinction of the race. Reintroduction is not worth attempting, for even if the initial difficulty of obtaining sufficient breeding stock could be overcome, the conditions to which the Saint Tropez cattle were specially adapted have undergone such changes that it would be more advantageous to replace them by a dual purpose breed suited to the altered environment. E. F.

980 — **The different Thicknesses of the Skin in certain Breeds of Cattle.** — IMBODEN, J. G., in *The Breeder's Gazette*, Vol. LXXXI, No. 22, pp 726-727. Chicago, June 1, 1922

Certain breeders consider that the lack of resistance shown by Shorthorns to both cold and wind is due to their thin skins, for Hereford and Aberdeen-Angus cattle which have very thick hides are even able to graze during a storm without experiencing any ill effects. The author resolved to test this statement and collected data showing that the absolute hide yield is greatest in the case of the Herefords, the Aberdeen-Angus and Shorthorns following in decreasing order; the percentage is higher for bulls than for calves, and for one-year old calves than for two-year old animals.

Given equal quantities, the hide percentage of a thin calf exceeds that of a fattened calf of the same age. Climate and geographical position also have a considerable effect upon the hide yield, for cattle reared in southern regions where the heat is intense have thicker skins than those bred in the north, although the northern cattle have longer and more shaggy coats.

This difference is explained by breeders on the assumption that the thick skin of the southern cattle protects them from the rays of the sun and from insect attack, whereas a shaggy coat would be of little use. In the north and northwest, where there are fewer external parasites, the cattle do not need a thick hide, but require a heavy coat to enable them to defy the winter cold. The quality of the leather does not necessarily depend directly upon the general condition of the animal and therefore a very good yield of hides can be obtained from cattle that have received but little attention. There is no practical difference between the commercial value of the hides of thin or of fattened calves. E. F.

981 — **Experiments on the Industrial Crossing of Southdown Ram × Limousin Goat.** — VOITELIER, CH. and DEGOIS, E. in *Revue de Zootechnie*, No. 8, pp. 731-747, with Tables and Illustrations Paris, May 1922

The increasing demand that has arisen during the last twenty years for the meat of young lambs (*agneaux gris*), ready for the butcher at the age of 5 to 8 months has induced breeders to substitute for pure-bred animals, early maturing hybrids ready for the market when scarcely 5 months old, the product of an industrial cross between a Southdown ram and a Limousin goat. Only a first generation cross is made, the hybrids never being mated.

These animals are chosen as parents because large numbers of Limousin

SHEEP

or Berichon goats can easily be obtained in the region south of the Loire, while the Southdown ram is noted for its prepotency and transmits to its progeny the characters of early maturity, good conformation and excellent meat production. The characters of the parents are inherited in such a manner that the hybrids can be easily distinguished and identified. They always have the mouse-coloured head and legs peculiar to the Southdown, and although the extent of the pigmentation varies greatly in different cases, it is regarded as a dominant.

The Southdown limousin cross is very common but the technique involved still remains a matter for discussion. For instance some breeders recommend that the rams should be left entire, while others affirm that castration is necessary.

Another question in dispute is the age at which the hybrids should be sold, some experts being in favour of selling while very young while others advise keeping the animals till they reached a certain age, when they can command higher prices as the meat is of better quality.

One of the authors being a member of the Organising Committee of the Vaulx-de-Cernay Stock Breeding Experiment Centre, proposed that comparative crossing experiments should be made in order to determine the technique to be adopted and to show the effects of castration.

Experiments were accordingly carried out upon the hybrid offspring of a herd of 96 Limousin goats that had all been served by the same Southdown ram, Knight No 583. This ram was quite pure-bred, as was proved by the measurements taken by the author.

The goats were also pure-bred, for although they did not show the homogeneity characteristic of animals that have been selected by the same breeder and repeatedly inbred, they came from a country where the herds are free from any admixture of foreign blood.

The hybrids of the  $F_1$  generation were born from January 15 to March 6, 1921. All the males born within 24 hours of one another were compared during their growth period and at the time they were slaughtered, one of them being kept as a control, while the others were castrated directly they were 15 days old. The number of animals thus compared was 29: 11 entire and 18 castrated individuals out of the 120 hybrids (63 males and 57 females) produced by the 96 goats. All the animals were weighed separately every fortnight. They were suckled by their dams for 3 months and then fed liberal and varied rations, as well as given free access to the pasture.

The castrated individuals were divided into two groups, the first consisting of 11 head (these were compared from their birth with the same number of entire animals), while the second was composed of seven individuals which were kept to make good the losses in the first lot. These were born and slaughtered on the same day as the hybrids of lot 1.

The average age for slaughtering the animals was 6 months. The castrated hybrids were found to weigh from 4 to 4.2 kg. less than the entire. Thus castration has an injurious effect upon animals sent to the butchers at the age of 6 months. This conclusion has also been confirmed by ob-

servations made on the dressing-yield, 2 kg. more meat being obtained on an average from entire hybrids than from those that had been castrated.

E. F.

982 — **Goat-Breeding Congress at Ruremonde (Dutch Limburg).** — CREPIN, J., in *Revue d'Histoire naturelle appliquée* (Part I), Vol. III, No. 2, pp. 56-62. Paris, February 1922,

GOATS

In August 1921, a Congress of Goat-Breeders was held at Ruremonde (Holland); it was attended by 200 official representatives of seven countries.

The author gives a brief account of the subjects discussed at the meetings. A summary of the most interesting and less generally known facts brought forward is contained in the following paragraphs.

1) **THE GENETIC IMPROVEMENT OF THE DUTCH GOAT.** — This was a much debated question. The many Alpine goats imported from Switzerland during the last thirty years have not given satisfactory results chiefly owing to the difficulty of acclimatisation. The members of the Congress advocated a return to the local breeds.

The author considers that the goat-breeders of the Netherlands are working in the wrong direction and will never improve their herds until they try to recognise the true characters of the different breeds, as well as the peculiarities of each race, and cease basing their selection of individuals upon the absence of horns and lack of hair pigmentation, two characters that are not only very variable, but also mark degeneracy.

The German members of the Congress made some very interesting observations. Dr. DETTWEILER of Rostock agrees with the author that the qualities of a breed of goats do not depend upon coat colour and want of horns. He does not admit that the goat is so sensitive to climatic conditions as to be unable to thrive except in its original mountains, for, though from the form of its feet and its love of steep slopes it is clearly a mountain animal, the maximum returns are obtained from stall-fed herds.

2) **THE TREATMENT OF MILCH GOATS.** — TAPP (stock-breeding Inspector) of Münster, has discovered from a study of the milk yield of goats at all seasons, that the heat period under natural conditions occurs in the autumn, so that the young are born at a time when there is plenty of fresh, tender mountain grass. He advises that: a) goats should be allowed to kid every two years; b) they should be milked dry up to the time of kidding; c) such an arrangement of the date of service as will allow that the last females served may be still in milk when those first mated are running dry to prepare for the next lactation. It is clear that these measures are only applicable to a breed with a high milk yield such as the pure-bred goats native to the Alps.

**GOATS' MILK AS A FOOD FOR INVALIDS, ETC.** — Dr. POL DEMADE of Brussels has studied the effect of goats' milk in the nourishment of invalids and found that its use reduces the cases of infant gastro-enteritis by 50%. He considers this milk to be an excellent article for adolescent girls suffering from chlorosis or anaemia, as well as for tuberculous patients, although it can have no special power of destroying the Koch bacillus.

983 - Gloucestershire Old Spot Pigs. — SPENCER, S., in *The Journal of the Ministry of Agriculture*, Vol. XXVIII, No. 12, pp. 1105-1109, figs. 2. London, March 1922.

The standard for a typical Gloucestershire Old Spot pig is as follows: head, medium length and wide between the ears, nose slightly dished, ears rather long and drooping; chest wide and deep; shoulders well developed, but not projecting, in line with ribs; back long and level; loin very broad; sides very deep and presenting straight bottom line; belly and flank full and thick; quarters, long, wide and not drooping; tail set high, of moderate size, yet fairly strong and carrying long brush; hams large, not flat, and well filled to the hocks; legs, short, straight and strong. The skin, light or dark, must not show coloured splotches otherwise than beneath the spots of the coat which should be full and fairly thick, hair long and silky, but not curly, with an absence of mane bristles. Colour, white spots on black ground, or black spots on white ground. Such spots should be of medium size.

Bad points: narrow, head face and nose dished; ears thick, coarse or elevated; coat, coarse or curly; colour, slate or sandy; skewbald or saddle-back markings; wrinkles are also a highly objectionable feature.

The boars of the Gloucestershire Old Spots breed are very persistent in impressing their peculiar markings on their progeny, even from sows of other breeds and colour. This appears to prove that the breed is actually original and not the result of chance or of crossing two or more breeds within recent times.

Although nothing is known with certainty as to the origin and cause of the markings in this or in any other spotted breed, the causes of the present form, size and quality of the Gloucestershire Old Spots appear to be much more easily discovered and to consist essentially in the requirements of the pig-breeders and consumers. The animals are much in demand in the County of Gloucestershire on account of: a) the upland situation of many of the farms and the consequent need of a pig of robust nature, b) the large milk production, especially in the valleys, necessitating a considerable number of strong healthy pigs for the consumption of the skin milk, butter milk and whey: c) the need of bacon for the summer supply of animal food for the numerous farmers and their large families.

The Gloucestershire Old Spots pig, which is a hardy prolific and quick-growing animal most suitable for the manufacture of large, heavy, thick sides of bacon, fulfils all these requirements admirably.

In view of the great difficulty in retaining certain points in other breeds, it may be asked why these qualities seem likely to persist under changed conditions. One possible answer is that these particular characters are more or less inherent in the Gloucester Old Spots breed, whereas the special points which it is desired to retain in other breeds are fancy characters, to a certain extent the result of chance and therefore not natural to the animal and of little or no practical value.

Another proof of the many good qualities of this Gloucestershire pig is furnished by the phenomenal success of the Society established some 8 or 9 years ago. The first volume of the Herdbook, published in 1915, con-

tained the pedigrees of 39 boars and 242 sows, giving a total of 256, whereas the seventh volume published in 1921, contained the entries of 1407 boars and 5382 sows or a total of 6,789.

984 — **The Presence and Significance of numerous Bacterial Spores in the Body of the Silkworm Moth.** — LOMBARDI, L., in *Bollettino della R. Stazione Sperimentale di Sericoltura*, Year I. No. 3, pp. 87-96. Ascoli Piceno, July 1, 1922.

SERICULTURE

The presence in the silkworm moth of any microorganism other than the pathogenetic agent of pebrine has hitherto been regarded as a matter of no practical importance. This opinion has now been somewhat modified by the researches of the author who at the request of a firm supplying silkworm eggs examined the bodies of certain affected moths in order to determine whether the eggs laid by them could safely be used. The bodies of the insects were covered with innumerable pustules, the trunk became shrunken and the legs and wings dropped off, so that the diseased insects could be recognised in the compartments.

The author began by determining whether the pustules which under the highest powers of the microscope had the appearance of crystalline dust and were resistant to chemical agents, consisted of accumulations of vibriion spores whose development was promoted by moisture.

Silkworms fed on leaves dusted over with spores did not contract the infection and their cocoon yield was about the same as that of the control lot, though the control group produced longer-lived moths.

The author's researches show that the spore masses may arise in two ways; either the moth is infested by the microorganisms when it leaves the cocoon, or the bacteria find favourable conditions for exceptional development in the excessive dampness of the environment due to a lack of ventilation in the storage rooms.

If only a few diseased moths are found in one part of the store-house, the question may be regarded as of little importance; should however the percentage of affected insects be high it is a bad sign for the quality of the eggs, except in the case of small and very active breeding establishments.

F. D.

985 — **The Value of the Fifth Quarter in the Meat Trade.** — DECHAMBRE, P. and DEGORS, E., in *Revue de Zootechnie*, No. 7, pp. 634-645. Paris April 15, 1922

VARIOUS

The weight of a slaughtered animal is calculated from that of the 4 quarters of meat. Not only the net meat, but all the other parts are of value. The head, viscera, glands, fat and hide make up what is known as the fifth quarter, and it is an old tradition in the meat trade that the yield of this fifth quarter considerably diminishes the purchase price of the pound of meat. Since the War, in the estimates of butchers anxious to fix their prices, this reduction has varied round about 50 centimes per pound of net meat. The author thought it would be of some importance to discover the causes of these variations. These have been determined sufficiently accurately from weighings made of all parts of the animals slaughtered at the Perray abattoir connected with the Vaulx-de-Cernay Stock-Breeding Centre. In order to fix prices, it was necessary as far as pos-

sible to know the weight of the different kinds of offal. For this purpose, the author collected the results of the weighings of 82 cattle of different breeds and ages and of both sexes, compared the figures thus obtained, and struck averages to which could be applied the prices now asked. The figures obtained at the Stock-Breeding Centre were tested by a certain number of results published by CORNEVIN, LAWES and GILBERT, and WOLFF. The weight of the offal is expressed as a percentage of the live-weight of the animal at the time it is killed. The author examined in turn the feet, tongue, cheeks, brain, heart, liver, viscera, hide and suet. The results are given in the following list.

feet . . . .	1	%	price of kilogramme	1	fr.
tongue. . . .	0.4	$\frac{0}{10}$	» » »	9.50	»

After finding the weight of each of these kinds of offal, it was only necessary to know the retail prices asked in each district in order to ascertain the value of the fifth quarter. If we take the yield as 50 %, the total amount paid for the offal is to be distributed over 1000 lbs of meat. Then 0.50 represents the reduction in one pound of meat due to the fifth quarter. This figure is higher if the yield of the animal is below 50 % and lower if it exceeds 50 %. From the results obtained it may be calculated that the money value of the fifth quarter regularly reduces by one franc the price of the kilogramme of net meat bought standing.

## FARM ENGINEERING.

### AGRICULTURAL MACHINERY

986 - **A New Plough-Share.** — CLAROU, CH, in *Revue Agricole de l'Afrique du Nord*, Year 20, No. 155, pp. 463-464, fig. 1. Algiers July 21, 1922.

In order to insure the plough-share penetrating deeply, especially into dry soils, DE CONINCK has hit upon the plan of providing it with several recurved points distributed along its width, in place of the usual single awl-shaped point.

Three points are affixed to this share, one at either end and the third in the middle and make the share cut the ground better and assure the horizontal section of the furrow, afterwards turned by the mould-board. The portion of the share between the points is not sharpened.

The author has tried mounting this share on a double two-way plough by attaching to the second body an ordinary share. The points cause the plough to cut more deeply into the soil with the expenditure of

less traction force. The DE CONINCK share can be mounted on any plough-body, but is especially suitable for heavy types such as the double two-way plough.

## RURAL ECONOMY

987 — **The Production of large and of small Farms in Sweden.** — HÖIJER, R., in *Recherches de la production des grandes et petites fermes en Suède*, pp. 1-16. Stockholm, 1919 (1).

The author divides the agricultural farms into 4 classes :

- 1) farms with a maximum of 2 hectares under cultivation
- 2) " " 2 to 10 hectares under cultivation
- 3) " " 10 to 50 " " "
- 4) " " over 55 " " "

He emphasises the great difficulty of determining the effect of a single factor — in this case, the size of the farm — upon the yield of the land. In this work, he confines his attention to the quantitative production of the land, and deals with certain districts of Sweden that are similar in character.

The districts are treated separately and are as follows: 1) the plain in the Government of Malmöhus; 2) the plain of Kristianstad; 3) the uplands of south Sweden; 4) the plain of Vestergötland; 5) the plain of Östergötland; 6) the valley of Lake Mälär. In the case of each of these districts, the author studies its importance from the agricultural standpoint, the climate, length of the growing season, annual rainfall, nature of the soil, percentage of the surface under cultivation, crops grown, state of the drainage, facilities for communication and percentage of the population engaged in agriculture. He also gives three graphic Tables showing, for each class of farm, the standard of cultivation, the crop yield and the condition of stock-breeding.

The reader's attention is drawn to the fact that as regards crop returns, the large farms are far superior to the smaller, although the cultivation intensity index of the large farms is lower. This is due to the fact that the figures taken do not represent the total intensity, but only the labour intensity. The latter is always higher in small farms, whereas the cultivation intensity is greater in large farms. If the total figures were available, there would probably be a change in favour of the large farms, and the intensity figures would correspond to the crop yield.

*Conclusions.* — The best size of farm depends upon the district; where agriculture is well developed large farms are more satisfactory, and from the point of view of the utilisation of the crops and their nutritive value, they are superior to small farms, but large farms are always more

(1) From a report made by A. LEKANDER and laid before the Agricultural Academy of Sweden.

easily affected than medium, or small, holdings by changes in the general economic condition of the country.

On the other hand, in districts where the natural advantages are not great, small and average farms can always compete successfully with large farms, although their prosperity is only relative, for they are unable to adopt the methods of cultivation, or profit by the progress of technique to the same extent as similar holdings in more favoured regions, where larger farms are paramount.

## AGRICULTURAL INDUSTRIES

### OENOLOGY

988 — **Composition of Bulgarian Grapes, Must and Wines.** — DIMITROFF, CHR. in *Описание на земеделските изпитателски институти в България за природонаучни и стопански изследвания из областта на земеделието.* (*Review of the Agricultural Research Institutes in Bulgaria*), Year II, Nos. 3-4, pp. 137-163 (French, summary pp. 164-166 Sofia, 1922.

The author refers to the importance of the vine-growing industry in Bulgaria, the spread of phylloxera, the necessity for reconstructing the vineyards in Bulgaria with American vines, the physiological processes involved in the ripening of grapes and the chemical changes accompanying it. Four tables are given at the end of the paper setting out the results of the analyses of : 1) some varieties of grapes gathered in 1911, in the neighbourhood of Pleven (school of Viticulture and Station of Viticulture and oenology ; 2) 55 different samples of the same vintage sent by vine-growers ; 3) 110 samples of musts. They also contain the results of the complete analyses of 27 white and 63 red wines from the various provinces of Bulgaria :

The general averages, minima, and maxima are as follows.

Table I : berries : 91.7 — 84.9 — 96.8 % ; stalks : 6.9 — 3.2 — 15.1 % ; must : 72.9 — 55.9 — 51.2 % ; pomace : 20.9 — 13.4 — 29.5 ; grape-skin : 18.6 — 10.2 — 26.9 % ; pips : 2.3 — 1.1 — 4.8 % ; sugar in must : 13.4 — 10.6 — 15.6 % ; total acidity : 0.45 — 0.30 — 0.70 % ; dry extracts : 5.15 — 3.81 — 7.98 %.

Table II : must : 77.4 — 65.5 — 86.5 % ; pomace : 22.8 — 14.9 — 31.5 % ; grape-skin : 20.3 — 11.3 — 32.5 % ; pips : 2.5 — 1.2 — 5.9 % ; sugar : 14.6 — 11.9 — 18.0 % ; total acidity : 0.49 — 0.32 — 0.80 %.

The general averages of Table III are : sugar 16.79 % ; density : 1.0791 ; acidity % (expressed as tartaric acid) : 0.7980.

The general averages of Table IV are : for the white wines : density : 0.9903 ; alcohol : 10.00 % ; extract : 1.9029 ; total acidity : 0.5818 ; volatile acidity : 0.1662 ; fixed acidity : 0.3714 ; tannin : 0.0084 ; sugar : 0.4719 ; glycerine : 0.6042 ; ash : 0.1691 ; phosphates ( $P_2O_5$ ) : 0.0181 ; sulphates ( $SO_3$ ) : 0.0147 ; potassium sulphate : 0.0319 ; alkalinity of ash (deci-normal solution of sodium hydrates) : 13.75 ; for red wines respectively : 0.9942 — 8.14 — 2.1750 — 0.7610 — 0.1665 — 0.5529 — 0.0474 ; minimum quantities : 0.5006 — 0.2191 — 0.0210 — 0.0281 — 0.0612 — 15.03.

F. D.

989 - **Figs as Raw Material for Alcohol Manufacture and as a Stock Feed.** — BENAVENT, J. in *Agr. culture*, Year VI, No. 3, pp. 354-356. Barcelona, July 5, 1922.

One of the products used in the manufacture of alcohol is the fruit of the fig-tree, *Ficus carica*.

A single tree bears a considerable number of figs ; in the province of Murcia, over 150 kg. of dried figs are obtained from each tree. BAYER, states that on soils of average quality 50 kg. of dried fruit are produced per tree and 4500 kg. per hectare.

The actual alcohol yield of ripe figs is almost equal to that of plums : 15 to 20 kg. of 90° alcohol or 30 to 33 litres of 54° alcohol is given by 100 kg. of dried figs. One hectare of fig trees produces 800 to 900 litres of 90° alcohol.

For obtaining alcohol either fresh or dried fruit can be used. In the first case, the figs are gathered when ripe and crushed in cylindrical presses ; tepid water is then added to the mass to be fermented, although extraction by maceration is preferable. Great care should be taken not to allow the density of the must to fall below 5° B. The vat with the fermenting mixture is then covered and a constant temperature of 20° C. maintained. When the fermentation process is complete, the fermented liquid is drawn off and the vat left open for 10 to 12 days, in order to obtain the best and most homogeneous product.

When dried figs are used, they are left to soak in water having a temperature of 50 to 60° C. After two days, they are subjected to the treatment described above.

*Nutritive value of figs before fermentation.* — According to the analyses made by RAVENTOS (Barcelona), figs contain : 4.3 % protein ; 0.3 % fat ; 71.2 % sugars ; 3047 calories, whereas the analysis of wheat gives : 10.7 % protein ; 2.1 % fat ; 74.7 % of sugars and 3519 calories. These figures explain the value of this food for the rapid and effective fattening of pigs.

*Nutritive value of figs after fermentation.* — An analysis made of samples from Majorca at the Laboratory of the Catalanian Service of Agriculture shows that the fermentation residuum contains : 85.71 % moisture at a temperature of 160° C ; 1.08 ash ; 1.75 % protein substances ; 0.27 % fats ; 3.37 % crude fibre, 7.82 % nitrogen-free extracts. These results show that figs after fermentation make a good stock feed ; they are very suitable for fattening cattle, though should not be fed to dairy cows.

E. C.

990 - **Sulphite Alcohol.** — DU BOISTESSELIN, H (Professeur à l'Institut Chimique de Rouen) in *Le Moniteur Scientifique Quesneville*, Series V, Vol. 12, No. 962, pp. 97-105. Paris, May 1922.

In the calcium bisulphite process adopted in the manufacture of cellulose, the decorticated wood, after being reduced to fragments, is put into an autoclave and subjected to the action of steam. A lye is added to the calcium sulphite and the temperature maintained at from 125-140° C for 15 or 20 hours. As the digestion proceeds, the lye becomes dark as a result of the organic substances, (amongst which are certain sugars,

produced in the alcohol by fermentation. This alcohol is called sulphite spirit to indicate its origin.

Over 2 million tons of cellulose are now made by the bisulphite process and therefore about 1 million hectolitres of alcohol, reckoned as absolute alcohol, could be obtained.

WALLIN and EKSTRÖM, two Scandinavian engineers took out almost at the same time a patent for the industrial manufacture of alcohol by the sulphite process which is in more general use than any other. Sweden became the home of this new industry which developed rapidly: between 1909 and 1920, the output of sulphite alcohol rose from 19 000 litres to 20 000 000 litres. At the present time, there are 22 factories in Sweden and 2 more in Norway. During the War, the sulphite alcohol process was prescribed by the Government in Germany. The United States and Canada are considering its introduction. In France, nothing has so far been done, although 60 000 tons of cellulose are manufactured which might correspond to the output of 24 000 hectolitres of 100° alcohol; 200 000 tons of cellulose pulp are also imported. This pulp, as has been pointed out by BIELET, could well be made in the country from imported wood, especially if alcohol were manufactured as a by-product.

The amount of alcohol thus obtained would be small as compared with the quantity required, being barely 4 % of the total out-put in France, but at the same time of a certain value.

The author examines the technical side of the problem. He shows that the sugars of the residual lyes left after the manufacture of cellulose are only derived to a small extent from the cellulose; they come mostly from the gums, and vary according to the quality of the wood, glyucose and mannose being obtained from the wood of gymnosperms, and glyucose and xylose from the wood of angiosperms. The maximum amount is obtained by the digestion of the wood for 15 hours at 128-138° C under pressure of about 4 atmospheres. He describes the various industrial methods which come under the two following heads, the Swedish process which has already been tested, and the American which is still on trial. In the first, the sulphurous anhydride that always accompanies the sulphite and checks alcoholic fermentation is neutralised by spent lime, which is afterwards removed by decantation; this is the WALLIN and EKSTRÖM method. A modification introduced by LANDMARK consists in the addition of whey which obviates the necessity of accustoming the fermentation micro-organisms to the new medium. In the second method, the sulphurous anhydride is removed by boiling and by a vacuum (MACKEE), or else by a current of air (MARCHAND). It should be noted that boiling alone is not sufficient, for while it drives off the sulphurous acid present, it also causes a partial decomposition of the sulphite.

The alcohol produced has been chemically examined with varying results; according to MORVER's analysis in 1912, it would appear to be purer than the alcohol made from cereals, but VON SCHEEL considered these data inaccurate, and gives the results of a very careful analysis, showing that this alcohol contains a perceptible amount of impurities, for

instance 3.4 % of methyl alcohol. The methods of production have since been improved, and the author is now in a position to give comparative analyses of potato alcohol, cereal alcohol and sulphite alcohol which show the remarkable superiority of the sulphite alcohol and it can now be used in the preparation of alcoholic beverages.

For industrial production large plants capable of turning out 30 000 tons of cellulose paste are to be recommended, but small plants such as exist in France, having an output of from 10 000 to 12 000 tons are also very profitable.

991 - **North African Barley and Malting.** — See No. 952 of this *Review*

VARIOUS  
INDUSTRIES

992 - **Milling and Baking Value of Saskatchewan Wheats.** — See No. 948 of this *Review*.

993 - **Desiccation of Fruits.** — CRUESS, V W and CHRISTIE, A W (College of Agriculture, Agricultural Experiment Station, Berkeley, California) in *University of California Publications, Bulletin* No. 330, pp. 47-77, 2 figs. Berkeley, September 1921

The authors were induced to make these experiments by the great development of fruit-growing in California, for though the dried fruit industry is already very flourishing, it will have to be further increased in order to be able to deal with all the produce of the orchards and fruit-gardens, so many new trees having been recently planted.

When the industry was first started some thirty years ago, the fruit was dried by artificial heat; later it was dried in the sun. The fruit thus prepared acquired a great reputation so that it would be difficult to substitute the artificially dried products, although new markets could easily be found where they would have a ready sale.

By desiccated fruit, the authors mean fruit dried by artificial means with as little alteration as possible in its physical and organoleptic properties. For this purpose are employed: currents of air, creosote and slightly raised temperatures. When so treated, the fruit has the same qualities as sun-dried fruit, sometimes indeed it is even superior, as in the case of grapes.

The advantages of desiccation over sun-drying are: greater rapidity and ease in the operation which can be carried out even in over-cast or rainy weather, whereas fruit dried in the air easily spoils. The artificial product is sound and its qualities — or defects — are quickly recognised.

By means of a grant from the State of California and the assistance of various firms, the authors have been able to make numerous experiments on a large scale. They use a machine, the air-blast tunnel dehydrator, which supplies a current of air and should maintain a moderate temperature. The machine is however rather small, which increased the unit expenses by giving too much draught (150 to 300 m. per second) and an excessive raising of the temperature to about 99° C at the beginning and about 77° C at the end. Even when the machine is well loaded,

*Process recommended for the Desiccation of fruit*

Kind or fruit	Weighting per c m	Hours of sulphuring	Max. Temp at end of process	Moisture required at the end of the process	Duration with the counter current system	Notes

Strawberries	5.5-7.5	1 1/2	71	10-25	24	Stalks removed

the fruit dries rapidly, but if the temperature is too high, its quality is much impaired. Different kinds of fruit can stand different maximum temperatures.

In certain cases, the authors peeled the fruits chemically by plunging them into boiling lye, then rinsing them in cold water and rubbing if necessary. Peaches were put into 5 % lye for 30 seconds; for pears a 10 % solution was required, the fruit being left in the solution for from 20 to 40 minutes according to the toughness of their skins.

Fruits thus peeled needed a less prolonged sulphur treatment, dried more rapidly and had a more attractive appearance, but they stained the wooden boards on which they were placed.

Frequently the authors found it advisable to alter the duration of the sulphuring according to the conditions of the experiment, for the sulphurous acid liberated corroded the wire-netting, and discoloured the fruit and also gave it a disagreeable flavour. These bad effects can however be prevented if the fruit is placed on planks of wood.

The principal results of the authors' experiments are given in the appended Table. They are still engaged in further experiments of which they hope soon to publish an account.

L. V.

994 - **The Amino-Acids in Cow's Milk.** — HIIJIKATA, I., in *The Journal of Biological Chemistry*, Vol. II, No. 1, pp. 165-170. Baltimore, 1922

DAIRYING

It is a well-known fact that a small part of the total nitrogen content of cow's milk is not formed of protein. So far only urea, uric acid, hypoxanthine, guanine, adenine etc. had been identified as constituting this fraction; the author has now added to the list the following amino-acids: lysine, arginine and histidine. Probably the mono-amine acids also enter into the physiological composition of cow's milk, but the author considers that further researches are necessary before this can be proved.

E. F.

995 - **Composition of Imitation "Pecorino Romano" Cheese.** — FASCETTI, G. in *Annali dell'Istituto sperimentale di Caseificio in Lodi*, Part 3, pp. 112-114. Lodi, 1922

The large exportation of "pecorino romano" cheese, which is made in Latium from ewes' milk, first led to the manufacture of an imitation product in Sardinia and South Italy from sheeps' milk and afterwards in North Italy from cows' milk, where no ewes' milk is available. In order to give this spurious cheese the characteristic commercial and organoleptic properties of true "pecorino", it is not enough to adopt the same methods in its preparation.

If however lambs' rennet diluted in sheeps' milk serum is used (serum is sent from the Campagna Romana for the purpose), a product is obtained which, after ripening for 6 months, acquires a slight smell of true "pecorino" which increases with further ripening. This imitation "pecorino" has also qualities of its own as the curd has a more delicate flav-

our; it is a distinct type and has its special patrons who prefer it to the genuine "pecorino" with its more pungent taste.

It is not difficult to distinguish real "pecorino" from the imitation by means of its smell; the author has however made a careful chemical study of the false "pecorino" to serve as a basis for its identification.

The chemical analysis of spurious "pecorino" gave the following percentages: water 31.50 — fats 26.60 — nitrogenous substances 30.51 — ash 11.39. The analysis of the degree of fermentation gives: total nitrogen 5.010 % — soluble nitrogen 1.275 % — albuminose nitrogen 0.225 % — peptone nitrogen 0.289 % — amide nitrogen 0.306 % — ammoniacal nitrogen 0.017 %. The Roman "pecorino" differs from its imitations in having a high proportion of fats and ammonia. According to SARTORI's analysis, its dry matter contains from 0.117 to 0.157 % of ammonia and between 41 and 45 % of fats (1).

## PLANT DISEASES

---

### DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

- 996 - **Researches on "Incappucciamento", a Disease of Red Clover** (1). — MANZONI, L., in *Le Stazioni sperimentali agrarie italiane*, Vol. LV, Parts 4-6, pp. 136-144, 2 pl. Modena, 1922

In the spring of 1920, some plants in a plot of *Tritolium pratense* on the estate belonging to the "Scuola di Viticoltura e d'Enologia" at Conegliano (Prov. of Treviso), were attacked by a typical form of "incappucciamento".

The root system of the plants was free from any signs of old or more recent attack by insects or other animals.

In every case however the wood vessels in the neighbourhood of the root-collar, or those at some distance below it, were obstructed by brown or sometimes black masses, some of which instead of being homogeneous, clear and almost transparent, were dense, opaque and finely granular, recalling a zoogloea. On examining these masses more carefully they were seen to be composed of hitherto unidentified bacteria, usually elongated, but sometimes elliptical and united in pairs. These micro-organisms were 1 to 2  $\mu$  long, and 0.5  $\mu$  or a little more in width. They were isolated, cultivated and inoculated into young, healthy plants.

It is probable that the bacteria find their way into the tissues of the host plant through very small wounds that afterwards heal over completely.

The root bacteriosis observed in clover plants suffering from "incappucciamento" is certainly not the cause of the disease; in any case it has never been shown to be responsible for it; on the other hand it cannot be definitely stated whether or not the form of bacterium isolated is the specific agent of the affection of the radicle system. G. T.

### DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

- 997 - **A Contribution to the Mycological Flora of Southern Italy.** — PARISI, R., in *Bollettino dell'Orto botanico della R. Università di Napoli*, Vol. VII, pp. 37-66 Naples, 1922.

This is a list of 205 species belonging to the mycological flora of south Italy. It has been compiled from the valuable material growing in the

---

PARASITIC  
DISEASES  
OF VARIOUS  
PLANTS

999 - *Claviceps purpurea* on Oats in Algeria. — DUCEILIER, L., in *Bulletin de la Société d'Histoire Naturelle de l'Algérie du Nord*, Vol XIII, No 4, pp 98-99 Algiers, 1922

*Claviceps purpurea* occurs in Algeria on many of the wild Gramineae (*Ampelodesmos*, *Festuca*, *Lolium* etc.), but the only cultivated species of the order so far attacked appears to be the oat

Since 1886, in which year ergot was especially noticed on oats coming from the valley of the Mekerra, the fungus has been seen in different regions of Algeria. The author has found it both in samples of oats sent to the Maison-Carrée Seed Station, as well as on standing oats in the neighbourhood of Bel-Abbès (1907-1908), in the Sahel of Algiers (1907-1908), in the valley of the Chéiff (1920-1921) and in the Department of Constantine (1908-1920-1921)

In Algeria, *C. purpurea* infests several species of oat, but is most frequently met with on the red African oat, a variety of *A. algeriensis* Trab., which is the kind most commonly grown

Ergot is also found on the Algerian black oat (another variety of *A. algeriensis*), in the Departments of Constantine and Oran, in Oran the fungus has been seen on the grey and the white oat (varieties of *A. sativa* L.) while at Bel-Abbès, it is reported as occurring on *A. fatua* L. var *glabrescens* Coss

The ergot of oats can be used in the same manner as rye ergot (1)  
G. T.

1000 - **Further Observations on Tomato Rot** (2). — CIFERRI, R., in *Le Stazioni sperimentali agrarie italiane*, Vol LV, Parts 4-6, pp 145-162. Modena, 1922

As a result of further study of the disease first noticed in 1921 near Alba (Province of Cuneo), and described under the name of tomato rot, the author considers that the Spherioides, *Phoma Ferrarisii* Ciferri, produces a typical form of dry rot in the green fruits of the tomato which entirely empties them of their contents.

If *Bacillus mesentericus* subsequently attacks the tomatoes, the disease assumes quite a different form called by the author "wet rot" (carie humide) to distinguish it from the first type.

The Mucedinea found on tomatoes already attacked by the Spherioi-

(1) See R May-June 1922, No 550 (Ed)

(2) See R Oct 1921, No 1065

dea and at first called by the author *Ramularia* sp. has now been specifically identified.

It is here described by him under the name of *Ram. Ferrarisii* n. sp. The data at his disposal do not allow him to state with certainty that there is any metagenetic relation between the Mucedinea and *Ph. Ferrarisii* as was previously suggested.

In order to check the spread of the disease, it is advisable to destroy all the infected fruits.

G. T.

1001 - *Ganoderma sessile*, a Polyporea injurious to Fruit Trees and Forest Trees, in Argentina. — GIROLA, C. D., in *Boletín del Ministerio de Agricultura de la Nación*, 2 pp., 2 pl. Buenos-Ayres, 1922.

Although *Ganoderma sessile* Murrill is by no means a very common fungus in Argentina, it attacks many fruit and forest trees and often causes a considerable amount of damage. The infection spreads either by means of the under ground mycelium passing from the diseased to the healthy roots, or else is conveyed by spores falling on wounds or lesions in the superficial roots or lower portion of the trunk.

In a single plantation this Polyporea has been noted on *Prunus Armeniaca*, *P. domestica*, *Pirus communis*, *Ficus Carica*, *Punica Granatum*, *Robinia Pseudacacia*, *Gourliea decorticans*, *Casuarina stricta*, *Eucalyptus Globulus*, *Tipuana Tipa*, etc.

As regards the control measures recommended, care must be taken not to introduce into soil that is free from the fungus any infected plants or roots, and to avoid contaminating the ground with soil, manure or débris containing the mycelium. All plants suspected of disease must be isolated, and the roots of badly infested trees should be dug up and burnt; the fructifications of the fungus must be carefully collected and burnt. The infected parts of the host-plant ought to be cut off, and pure tar or tar mixed with resin applied to the surface of the wound thus produced. It is also useful to disinfect with 5 % formalin, sulphuric acid etc. Great efforts should be made to avoid causing wounds or lesions in the superficial roots and near the root collar of the tree. All pruning implements that have been in contact with the diseased trunks, branches or roots must be at once thoroughly disinfected before they are used for cutting the sound portions of the tree.

When making new plantations, no dung should be applied and all lesion or wounding of the young trees scrupulously avoided. If there is any suspicion of infection, it is necessary to treat the roots with a 1 % solution of corrosive sublimate, or a 5 % formalin solution. All the props used for young trees should be disinfected by scorching or by immersion in a solution of copper sulphate, or a 5 % solution of formalin. It is also recommended that the end of the stake should be dipped in hot tar before it is driven into the ground. Where the trees have died as a result of the fungus attack, they must not be replaced for three years.

Water should not be allowed to collect near the root-collar of the trees, for moisture encourages the growth and propagation of the parasite.

1002 — *Microstroma Tonellianum*, a Mucedinea Parasite on the Plum Tree in the Marche. — CIPERRI, R., in *Rivista di Patologia vegetale*, Year XII, Nos. 5-6, pp. 59-64. Pavie, August 1, 1922.

The author describes in this paper an affection of the leaves of the plum tree (Luther Burbank var.) which was observed at Macerata and is characterised by the occurrence on the upper surface of the lamina of irregular whitish spots, corresponding to very small, whitish, waxy, scattered, or confluent dots that make their appearance on the lower surface.

Microscopic examination showed this affection to be due to the Mucedinea, *Microstroma Tonellianum* Ferr, which was described as a very rare parasite of the leaves of *Prunus domestica* when found for the first time at Valsalice (Turin) in July 1912.

All the infected leaves should be collected and burnt and spraying with Bordeaux mixture is the best prophylactic measure to adopt. G. T.

## WEEDS AND PARASITIC FLOWERING PLANTS

1003 — The Spread of *Panicum Phyllogon* and *P. erectum* in the Italian Rice Fields (1). — NOVELLI, N., in *Cronaca Agricola*, Year XXVII, No. 16, p. 4. Turin, August 31, 1922

Some years ago, owing to the use of impure seed of foreign origin, *Panicum phyllogon* and *P. erectum* were accidentally introduced into certain Italian rice fields that had been successfully freed from these pests by careful hoeing and weeding. Both these weeds, but especially *P. erectum*, having once established themselves, continued to spread in many of the rice-growing districts and seem to be still gaining ground.

In the author's opinion the only really effective means of controlling these weeds is to transplant the rice in the most infested plots. If this is not done, the greatest care must be taken to clean the ground, and hoeing should be carried out very late in badly attacked fields. The grain used for sowing must be free from all admixture of *Panicum* seed and the soil always worked to a considerable depth.  
G. T.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS

### GENERAL

1004 — The Coccid *Icerya purchasi* reported in Spain. — GARCIA MERCET, R., in *Boletín de la Real Sociedad Española de Historia Natural*, Vol. XXII, Nos. 1-2, pp. 136-141, figs. 4. Madrid, 1922.

No breeding centre of the Coccid *Icerya purchasi* had been known to exist in Spain until recently, when a colony was found on a *Citrus* shrub in the garden of the " Instituto general y técnico " at Badajoz.

As however the parasite has been reported from Portugal ever since

(1) See R. Dec. 1912, No. 1688 and R. March 1919, No. 279. (Ed).

1896, it is most probable that other breeding centres are to be discovered on the Spanish-Portuguese frontier.

1005 - Experiments in Controlling the Macrolepidopteron, *Operophtera (Chelmatobia) brumata*, in France (1). — PAILLOT, A., in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VIII, No. 27, pp. 745-748. Paris 1922.

MEANS  
OF  
CONTROL

It was found at Charly, in 1921, on examining the apricot trees of the 1920 experiment field that where the trunks had been protected by a band of viscous substances, many fewer adult individuals of *Operophtera (Chelmatobia) brumata* were present as compared with former years, and that the emergence period of the perfect insects was also much prolonged. Although the number of trunks treated was the same, there was a great difference in the number of insects caught each year. In 1920 and the two preceding years, many more adult males than females were taken, and as the sexes were captured in practically the same proportions in 1920 and 1921, it would seem probable that the males normally out-number the females. Although the males are provided with well developed wings, they too no less than the females, seem to reach the upper portions of the tree by way of the trunk.

The principal cause of the retarded emergence of the adult insects in 1919 was probably the peculiar meteorological conditions obtaining throughout the year, and especially in October, when the mean temperature was much higher than usual.

From observations made at Mouthiers in the Valley of the Loue, which is considerably colder than the Lyons district, it was found that the adult forms of *Op. brumata* emerge earliest when the average temperature is lowest. This fact must be taken into account in order that the most favourable moment for the application of the viscous bands may be chosen.

Comparative experiments have been made with Tanglefoot and other viscous mixture. One of them which is manufactured by C. W. COLLINS and CLIFFORD E. HOOD, of the Melrose Laboratory (United States) is very similar in composition to "Raupenleim", a substance widely used in Germany and Switzerland. Like Tanglefoot it can be applied directly to the bark of the trees and has the further merit of being very cheap. An attempt has been made at the Lyons Gas Works to compound a similar mixture with a basis of French products, as the process is well known and the raw material plentiful. The first results obtained were not satisfactory, but the author hopes that it will soon be possible to manufacture the mixture in France on a large scale.

G. T.

1006 - *Megastes pucialis*, a Microlepidopteron injurious to the Sweet Potato in the State of Bahia, Brazil. — BONDAR, G., in *Chacaras e Quintas*, Vol. XXV, No. 6, pp. 473-474, figs. 2. São Paulo, June 15, 1922.

INSECTS, ETC  
INJURIOUS  
TO VARIOUS  
CROPS

The Microlepidopteron, *Megastes pucialis* Saell. (fam. *Pyrilidae*) is one of the most formidable enemies of the sweet potato in the State of Bahia. The insect propagates throughout the year, but does most damage

(1) See also R. May 1921, No. 584. (Ed.)

during the winter from May to August. The larvae excavate large galleries in the stalks of the host plant, thus causing hypertrophy in the plant and also in the root system. When the larvae attack the tubers, the injury is still more serious.

The presence of the caterpillars is betrayed by little heaps of excrement that accumulate round the base of the plant and by the severe wilting or even sudden death of stems exposed to the rays of the sun.

The insect does most damage in June and August, the time at which planting is begun; more than half the sweet potatoes are attacked at a very early stage by the larvae which appear in large numbers, at this period, so that it is often necessary to replace the young plants two or three times.

The following methods of control are recommended: 1) The removal of all other *Convolvulaceae* that may be growing in the neighbourhood and serve as hosts to the Microlepidopteron passing thence to the sweet potato; 2) the planting of the sweet potato from January to April, so as to obtain strong vigorous plants by the time *Megastis pucialis* begins to make its appearance.

Owing to the habits of the caterpillar, insecticides are not to be advised. A visit should be paid to the field during the hours of sunshine and when any wilted plants or heaps of excrement are found, an attempt must be made to remove the parasite from the stem and destroy it.

G. T.

1907 - Notes on *Dinapate wrighti*, a Beetle living on the *Washingtonia filifera* Palm in California. — TOMPKINS DE CARNETT, R., in *Bulletin de la Société entomologique de France*, No 9, pp 119-121, 1 pl Paris, 1922

The Bostrichid, *Dinapate wrighti* Horn lives in South California on *Washingtonia filifera* H. Wendl., a palm that is becoming increasingly scarce

According to HUBBARD's statement (1899), this insect never deposits its eggs upon living plants; the author has however frequently found the holes by which it had made its exit on large and medium-sized palms which were not only alive, but appeared to have suffered no harm from the presence of the parasite. It is thus seen that the attacks of *D. wrighti* are not always fatal although they weaken the tree and frequently cause it to fall. In May 1917, the author examined in the Palm Cañon alone (South California) nineteen fallen trees, the victims of this parasite.

HUBBARD has stated that the insect never deposits its eggs in palm trunks which have long lain on the ground, but here again the author is of contrary opinion, for he obtained 133 adult beetles, 27 pupae and 17 larvae from the trunk of a palm that had been dead for several years as was clearly proved by its blackened extremities.

In the case of living palms, the holes by which the adult individuals of *D. wrighti* make their escape are usually situated at the base of the trunk, rarely near the top, but dead trees lying on the ground are perforated indiscriminately throughout their length.

G. T.

1008 - *Teracotona submacula*, a Macrolepidopteron injurious to several Plants in the Union of South Africa. — GUNN, D., in *Union of South Africa, Journal of the Department of Agriculture*, Vol. IV, No. 6, pp. 542-547, 1 pl. Pretoria, June 1921.

In 1919-1920 the kitchen gardens of Port Elizabeth and the neighbourhood were found to be infested by the Macrolepidopteron *Teracotona submacula* Walker (fam. *Arctiidae*) to an extent surpassing all records for the past fifty years.

The insect is a native species that is very common throughout the Union of South Africa and has been collected by the author at Pretoria, Johannesburg, Uitenhage and Bathurst. In the South African Museum there are specimens from Grahamstown, Port-Shepstone, Durban, Potchefstroom, Potgietersrust, Damaraland and Salisbury in Rhodesia. The larva of this insect, which is popularly known as the woolly caterpillar, is omnivorous, its favourite hosts however appear to be the cabbage, bean, beetroot and lettuce.

The youngest caterpillars as soon as they hatch out of the eggs deposited in small heaps on the stems and branches, devour the leaves, only the veins remaining intact. When half-grown, the caterpillars eat the whole leaf. They were sometimes so numerous in the private kitchen gardens and the market gardens of Port Elizabeth and its vicinity that all the beds of beans, beetroots, cabbages and lettuces were completely destroyed; the insects then passed on to the carrot beds and attacked them in the same way. *Ter. submacula* also causes great damage to flowering plants as the larvae devour the leaves and tender shoots and strip the stems quite bare.

The author gives in his paper a detailed description of the life-history and habits of the Macrolepidopteron. Its complete cycle of evolution lasts from a hundred and seventy-five days to a hundred and eighty-one days and there are two generations in the year.

The eggs of *E. submacula* are much parasitised by Chalcids; the larvae are effectively controlled by a Braconid and two parasitic Tachnids. A native bird, the cape robin (*Gossypha caffra*) lives on the caterpillars.

If the infested area is not very extensive, the larvae can be collected by hand early in the morning or in the late afternoon and destroyed by crushing or throwing into vessels containing water and petroleum or a soapy emulsion of petroleum or carbolic acid.

If the caterpillars are very numerous and the kitchen garden large, it is better to spray with aceto-arsenite of copper, or with lead arsenate in the form of a paste or powder. The application of these sprays is more effective if delayed until the larvae begin their attacks.

In order to make the liquid insecticide adhere better to the cabbage leaves an experiment has been made of adding a mucilaginous substance extracted from the branches of the Barbary fig. This mixture has to be used fresh. Instead of spraying the cabbages, they can be dusted over in the early morning with aceto-arsenite of copper and lime. For these plants however spraying with liquids having a lead arsenate basis, or com-

posed of aceto-arsenite of copper and lime has proved more efficacious than the application of powders.

In the case of flowering plants, or delicate specimens, spraying with lead arsenate, prepared preferably from the powdered form rather than the paste, is better than spraying with aceto-arsenite of copper.

As the adult caterpillars make their cocoons in the ground near the plants which provide them with food, the soil should be thoroughly worked in order to destroy any chrysalids that may be present. This was done with very satisfactory results during the summer of 1919-1920, when there were large numbers of cocoons. G. A.

1009 - *Phenacoccus hirsutus*, a Coccid injurious to various Plants in Egypt. —

HALL, W. I., in *Bulletin de la Société entomologique d'Égypte*, Year XIV (1921), pp. 17-29  
Cairo, 1922

It is highly probable that the coccid known popularly as the Hibiscus mealy bug was introduced into Egypt from India. It was first regarded as a new species for which the name *Pseudococcus hibisci* was proposed, though no description was published, but has since been identified as *Phenacoccus hirsutus* Green (1). This coccid was first reported from Mataria in 1912, but very likely it has existed at Abbassia since 1908. In any case, it is practically certain that Mataria was the first centre of infection whence the parasite spread throughout the district of Cairo. In 1915 the Mataria zone suffered severely, but it was not until the second half of 1918, that Cairo was infested to any considerable extent. The following year the coccid made its appearance in still greater numbers and destroyed many trees including not a few splendid specimens of *Albizia Lebbeck* growing at Gizah.

The attack, which was at first confined to Cairo, subsequently spread southwards as far as Beni-Suef and the Fayoum; its northern limits seem however to have been the village of Shubra and Abon-Zaabal. The wind is the chief agent of the diffusion of *Phen hirsutus* and as the prevalent wind in Egypt blows from the north it is only to be expected that the infested area is most rapidly extended in a southern direction.

This coccid is more or less omnivorous, but prefers trees and shrubs, especially those that have been weakened by age or the attacks of other enemies. Some of the most important of its hosts are: *Hibiscus* spp., *Morus* spp., *Albizia Lebbeck*, *Bauhinia* sp., *Grevillea robusta*, *Erythrina* spp., *Zizyphus* spp., *Ceratonia siliqua*, *Psidium Guajava*, *Acacia arabica*, *Parkinsonia aculeata*, *Robinia Pseudacacia*, *Cajanus indicus*. Annuals generally escape without much injury, unless they happen to be in the immediate neighbourhood of a centre of serious infestation. This applies especially to the cotton-plant which is very susceptible to the attack of the insect and suffers very severely if infested at an early stage in its development.

The plants attacked are conspicuous owing to the fact that the growing points become knotted and shrivelled which renders them unsightly and

(1) See *R. July* 1922, No. 797. (Ed.)

hinders or arrests their further development. Although the growing points are always the centre of attack, the coccid may be found on nearly every part of the plant. At the end of the summer the adult females seek the most suitable places for oviposition, in order that their eggs may be well protected from the winter cold. Large number of ovisacs are to be found in the crevices of the cortex.

The author gives a detailed description of each stage in the development of the insect and a long account of its life-history.

Fumigation has proved a successful means of controlling *Phen hirsutus* but it is necessary to consider how far it is to be recommended from the economical standpoint. Fairly good results have been obtained by spraying with petroleum emulsion provided that the diseased portions of the plant were also removed. The nature of the injury caused by the insect is such that no amount of spraying can really give the desired result. It is also necessary to state that should the plants be again contaminated by other diseased individuals in their vicinity — which it is almost impossible to prevent in Cairo — the last condition of the pruned tree is worse than the first, because the larvae have at their disposal young tender shoots on which they thrive apace. Repeated sprayings are certainly of use in preventing attack, but they are not fatal to the insect. The only way to exterminate the pest is to substitute more resistant species for the most susceptible host plants.

No natural enemies of *Phen hirsutus* have been reared in sufficient quantities for it to be possible to expect any help in this direction, at all events for the present.

The enforcement of the different legislative measures passed of recent years has greatly decreased the danger of any extension of the infected areas, while the suppression of the trees most liable to the attack of the parasite will almost certainly result in its eventual extermination.

**Note on cocoa growing in the State of Bahia (Brazil)**

by

DR JOAQUIM WANDERLEY DE ARANJO PINHO

*Victoria, Brazil.*

In Brazil the cocoa tree is indigenous and grows in the shade of the forest which covers the banks of the river Amazon and of certain of its tributaries, where it has its natural habitat. Even to the present day, it is seen wild in Pará and Amazonas, the most northerly States of Brazil. The Spaniards after having learned from the Mexicans the use of chocolate and found it to their taste, commended the exportation of cocoa beans to Spain; this export has been the cause of much fighting and smuggling. The Portuguese, to whom nature had given so valuable a tree without need of cultivation, turned their eyes to its fruit. Cocoa began to be sent to Lisbon from Pará, at that time the chief town of Capitania, the administrative division of colonial Brazil, which controlled the whole of Amazonia. Only the fruit of wild trees found on the banks of the rivers was collected and restrictions were not made because of the savages who inhabited these countries.

In 1678 a "Carta Regia" (Royal decree) ordered regular cultivation and this preliminary regulation was followed by others granting bonuses and reductions of duty on cocoa produced on regular plantations. The production of the cocoa plantations and that of the wild trees reached fairly high figures for the period: in 1778, it was 902 tons and, in 1818, 1524 tons. In Bahia cultivation is said to have begun in 1746, from seed brought from Pará by the French planter Louis Frédéric WARNEAUX. This seed was sown at Cubiculo on the banks of the river Pardo, in Canavieiras, by Antonio Dias RIBEIRO. The Portuguese Government took an interest in the cultivation and by its agents, known under the title

of "Conservadores das Florestas" (Conservators of Forests), tried to assist production. Reference may be made to the speech of FERREIRA DA CAMARA, one of these Conservators, at the Academy of Sciences at Lisbon, in 1789, in which he started a propaganda in favour of the cultivation of cocoa in Bahia and stated its advantages and profits. It is even said that the introduction and plantation of cocoa trees in Bahia was due to his efforts. In 1779, there were cocoa trees at Rio de Contas and at Cayrú and in 1802 at Santarem the people cut down the trees "for they were of no use to them."

Von MARTIUS said in 1819 that the cultivation had had a successful beginning, but that at that time it was almost non-existent and that one could see at Camamú trees which proved that the region was favourable for them. It was only in 1820-1822 that it was introduced at Ilheos. Pierre WEYLL, and his companion SANARAKER having obtained a "Sesmaria" (land granted by the king in perpetuity) in 1818, brought in German planters on two occasions, to colonise this land. At that time people were interested in the cultivation of sugar cane and coffee, but the cocoa tree was also planted; old cocoa trees of this first plantation by the Germans are still shown at Provisão. That plantation was the nucleus of the cultivation at Ilheos. In 1778, the export of cocoa from Bahia was 900 kg.; cultivation developed slowly and in 1835 the export reached 26 805 kg. The statistics show the increase of exports which continue to grow yearly. It was not until after 1890 that the cultivation made a great advance owing to the high prices given for cocoa.

At that time the export from Bahia was 3 502 tons and that of Amazonia 3 387; in 1900, the export from Bahia had risen to 12 131 tons and that of Amazonia did not exceed 3 085 tons. Amazonia, which was the principal producing State, gave place to the State of Bahia, which at present yields 90 % of the Brazilian export and by itself occupies the second place in the world's statistics for countries producing cocoa. The growth of cocoa is the most valuable product in the State of Bahia and accounts for 25 % of the Budget receipts

\* \* \*

The cocoa plantations in Bahia occupy the southern part of the State, from the mouth of the river Jequiriçá to the boundaries of Espírito Santo. This area has an extent of over 500 km. along the coast and varies in width from some ten to more than 100 km., and possesses the conditions required for the crop.

In some parts planting is not possible and generally the land near the sea must be left out. In certain places planting is done near to the sea; in others it is necessary to go inland to avoid sandy soil and wind.

In this area plantations are not regularly distributed; they are grouped around centres, sometimes separated by long stretches of virgin forest, while others continue without interruption over large districts.

The producing centres may be divided into three groups:— the first

which stretches from the river Jequiriça to the river Una, in which are found some important centres such as Jequié, Rio de Contas and Ilheos, the largest of all the districts ; the second, which is situated on the banks of the rivers Jequitinhonha and Pardo ; the third formed of isolated plantations. A river and its tributaries always form the centre of radiation of plantations. In the first group, the plantations are made on the banks of the rivers and numerous streams, on the hills, on their slopes, in the intermediate valleys, in short wherever the cocoa tree seems able to live. In the second group, the plantations are made on the banks of the rivers, on the rich alluvial plains, often inundated by high floods, for which reason new plantations are made on higher ground. The third group shares the conditions of the first two. The difference between the first two groups is also shown by the quality of the produce. The cocoa coming from Belmonte and Cannavieiras, of the second group, is better prepared and of better quality, and in Jequitinhonha are found the best equipped and best cultivated plantations.

The first group on the contrary, although it produces good cocoa, and has good plantations, is divided up into small farms under numerous proprietors who cannot give the produce the necessary care. This group, in which are Ilheos, Rio de Contas, Jequié, Santarem, Camamú and Una, supplies almost 75 % of the total output of the State of Bahia. The centres of production are called after the names of the communes or the ports of shipment, as, for example, Ilheos, which controls the produce of two communes :— Ilheos and Itabuna. Except Jequié, which makes use of the Nazareth railway for transport, all the producing centres ship from the ports up to Bahia. There are as many as 24 communes in which the cocoa tree is planted, but some of them are unimportant, either because planting is decreasing and is being replaced by other crops or because planting is in the experimental stage.

\* \* \*

The characteristics of the region in which cocoa trees are planted are :— regular rains, even temperature, humid atmosphere, presence of tropical forest, soils rich in humus or fertilising matter. Over so large an area, these conditions certainly vary, but on the whole, they are not notably modified. There are no great mountains in the whole of the area occupied by planting, but only low hills not over 300 m. in altitude. The plantations do not reach to more than half this height.

The cocoa tree can give good results at greater altitudes, but the transport of the crop would be difficult and as there is plenty of land, hills of a certain height form the future reserves. The rainfall averages 1800 mm. and falls every month. No month can be said to be wetter than another, as the distribution varies each year ; but at Ilheos it may be said that the wettest months are from December to May and that the dampest and coldest months are from June to September. There was a great drought in 1920,

but the only consequence was a decrease in the crop of the following year, and the trees have not suffered.

The humidity of the atmosphere is great, and often, during the night and early hours of the day, fog covers the plains, the savannahs and even the hills. The average temperature is from 25 to 27° C., the maximum 33° and the minimum 14°. Temperatures of 33° are recorded on very sunny days, followed by a drop to 18° the next morning.

\* \* \*

The soils on which cocoa is planted are generally very good, rich in fertilising matter and covered by dense tropical forest. Analyses have not been made and the composition of these soils is not known, but analyses would show that they possess good qualities. On the banks of rivers, in the plains and in the deep valleys between the hills, soils are found with deep beds of decomposing vegetable matter. Sandy loams and clay soils are most common and are those on which most of the plantations are made. On the slopes of the hills, very fertile, clay soils are formed by the decomposition of the primitive rock. Granitic soils are also met with, on which the forest trees grow well: these soils are also very good for cocoa. The rock should not be compact, and should be in blocks with interstices through which the roots of the cocoa tree penetrate, and the subsoil should not be formed of horizontal strata. Plenty of plantations on such soils and giving a good yield can be seen at Ilheus. At Belmonte and Cannavieiras, the predominating soil is of the humus type on the banks of rivers in the alluvial plains of the basins of the rivers Jequitinhonha and Pardo. In the other producing centres, good alluvial soils are also found, but clay soils predominate.

With the exception of Cannavieiras and Belmonte where the soils are better chosen and prove more fertile, planting is done without much regard to the conditions of the soil. It is only on sandy soils, in places where compact rock is met with, or else hard clay-sandy soils, or places where water accumulates and forms permanent marshes that no planting is done. It is certain that with this procedure, good crops will not be obtained, that the average production will be much lowered and that soils of poor quality should not be chosen while there are good soils from which to select.

\* \* \*

Neither the number of trees nor the area cultivated are known but only estimated. According to such estimates, the area covered by plantations is 104 200 ha., on which are planted 103 300 000 trees. There are about 5 800 000 young trees not yet in bearing or bearing very little, and about 97 500 000 trees in full bearing, old trees yielding very little and trees temporarily useless because of disease or the effects of floods, etc. The trees which no longer bear fruit are not included.

These figures are approximations only and the author hopes to make a fresh investigation to verify them. If the parts be included which are still unplanted, where there is forest, pastures and other crops, the area may be doubled and the area occupied by cocoa cultivation will thus be found to be nearly 210 000 ha.

\* \* \*

Three kinds of cocoa trees are planted in Bahia, known under the local designations of Common Cocoa, Pará Cocoa and Maranhão Cocoa.

The Common Cocoa, which may be classed in the "Amellonado" type of Van HALL, has large, wrinkled fruits, almost cylindrical in the middle and narrowing at both ends. The tree grows more in height than in breadth and the leaves are of medium size, rounded at the base and undulate between the nerves. The beans are of good size and less flattened than those of other kinds. It requires more care in cultivation than the other varieties and only gives satisfactory results on soils of good quality and when sheltered from the wind. Under good conditions this species yields well and lives a long time, but is later before beginning to bear than the others.

The Pará Cocoa, which may be classed under Van HALL's "Callabacillo" type, has rounded fruit, with a smooth, thin shell. The beans are very flattened and the leaves are longer and thinner than those of the Common Cocoa. It does not require good soils and grows more rapidly than the other kinds and has a tendency to develop more in breadth than in height but is very sensitive to lack of moisture. It appears that this kind is the result of hybridisation between the Common Cocoa and the Maranhão Cocoa.

The Maranhão Cocoa resembles the Common Cocoa in having slightly longer and larger fruits than those of the Common Cocoa, the fruits are as wrinkled or even more so than the latter, and the tree grows more in breadth than in height. The beans are less flattened than those of the other two kinds. Its root system is more superficial, which makes it suitable for shallow soils.

Hence, it may be concluded that the Common Cocoa should be preferred for good deep soils and that the others should be planted on poorer quality soils. At Belmonte and Cannavieiras planters prefer to grow the Common Cocoa and at Ilheus the two other kinds.

With regard to yield, it appears that the Common Cocoa fruits more regularly and more abundantly; the other kinds have high yields, followed by a decrease, and do not maintain a steady production.

\* \* \*

The yield per tree and per hectare is very variable: planting is done at various spacings, from 625 up to 1000 trees per hectare. The kind planted and the quality of the soil cause variations in the yield per tree. At

Belmont and Cannavieiras, the average yield of a tree may be estimated at 750 grammes and at Ilheus at 650 grammes, figures which must be reduced for the other centres. The production per hectare may vary from 540 to 1200 kg. and yields of 2000 kg. per hectare and 4 kg. per tree have already been obtained.

\* \* \*

The cocoa tree is almost always planted in virgin soil in places previously under forest.

For this the forest is completely cut down, the felled timber is burnt and the ground is prepared by cleaning up the débris left by the fire. Generally planting is not done for some months after the cleaning, as felling is done in the dry season and planting when there is rain. The native vegetation of the ground is a guide to the planter as regards the quality of the soils, and the growth of certain trees is also a good indication. After the ground has been prepared the places where the cocoa beans are to be planted are marked by means of stakes 1.30 m. in height. Before planting the cocoa trees, temporary shade trees are planted, generally manioc or bananas, and a few months later the planting of cocoa trees is begun. The distance between the stakes, and consequently between the trees, varies from 3 m. to 4.25 m. in new plantations, while in the old plantations it was as little as 2 m. The kind of cocoa tree planted also determines the distance; for the Common Cocoa planting must be closer, as it grows more in height than in breadth.

The usual method is to plant three beans round the stake; as the young plants which spring up are allowed to grow there is often a group instead of a single tree. In Bahia shaded cultivation is not practised and for this reason trees are not planted for permanent shade; after the temporary shade is withdrawn, fast growing trees of the secondary forest which grows up after the old forest is felled, are used for the young cocoa trees. In course of time the trees cover the space with their branches, and shade the whole ground at which time it is said that the plantation has "closed up". The plantations are formed by means of clearings opened in the forest called "roças", having a variable number of cocoa trees (up to 5000). The "roças" are separated one from another by zones of trees of the original forest; a collection of "roças" forms a "fazenda", which is a variable number of small plantations separated by large trees. These trees serve as protection against wind and the sun.

These zones of trees are now being removed in order to join up the "roças" and large extents of cocoa trees without any shade may be seen. So long as the plantation has not "closed up", which happens in the fifth year, the cocoa plants must be freed from weeds and vegetation which grows vigorously; weeding is made 3 or 4 times a year. After the plantation has "closed up," it is only necessary to weed from time to time as the shade prevents weeds from growing.

The care given to cocoa trees is limited to cutting a few dead branches,

adventitious branches and to freeing them of parasitic plants. No regular pruning is done and almost all planters are against it. Many planters pay more attention to the trees, but nowhere can it be said that the culture is scientific and methodical, or that the attention necessary to obtain the highest yield is given owing to the fact that with present methods and current prices, good profits are obtained. The lack of experimental stations (which are non-existent) and of experts to give practical instruction and show the planters the advantages of intensive cultivation causes the planter to be guided by experience and tradition, and the cultivation to be maintained almost in its primitive state.

\* \*

The cocoa tree begins to bear fruit from the fourth year for the Pará and Maranhão kinds and from the sixth to the seventh year for the Common cocoa. The first fruits are few in number and scattered on the trees which should not enter into full bearing before the eighth year. However it bears some fruit, so that the plantation from the beginning gives a return to the planter for which reason the early fruiting species are usually grown.

The plantation is made either by the proprietor himself, or by labourers with whom he makes a contract. Under this procedure, the contractor takes possession of the ground, fells the forest, plants the cocoa trees, uses the land for his catch crops, and, at the end of the time arranged, receives in payment a sum previously agreed on for each tree planted. This is one of the reasons why cocoa cultivation is done with little capital or, more correctly, with the sole labour of the small planter.

\* \*

The cocoa tree bears fruit all the year round; the fruit ripens in May in small quantities, and the yield increases up to July, when production is almost suspended; the crop of the early months is called "temporã", this preliminary crop is followed by the regular crop, "safra", which lasts up to April, when it ends. The months of full bearing are generally from September to January, and in Bahia the crop years are counted from May to April.

\* \*

When the fruits turn yellow they should be gathered, which is done by means of bill hooks fitted on to long poles. The fruit which falls is collected into heaps and opened with large knives and the beans are extracted by hand. The cocoa beans are then taken to the fermentation houses. The methods of harvesting differ very little in the various countries.

\* \* \*

Fresh cocoa (called "soft cocoa"), when it reaches the fermenting house, is placed in depots called "cochos". These are wooden boxes measuring about 1 m. in height, 1 m. in width and 5 to 8 m. in length. Some planters use boxes with small holes bored in the bottom for the escape of liquor formed during fermentation, others prefer them quite water-tight. Good results are obtained with both systems. During fermentation the cocoa is covered with banana leaves, sacks, etc., and is turned over every day. Fermentation is more or less rapid according to the quality of the cocoa and the state of the weather and lasts from five to eight days.

Experience is necessary to judge when the fermentation process is ended.

\* \* \*

When fermentation is over, the cocoa is taken out of the "cochos" for drying. Drying is generally done in the sun on wooden floors which can be covered with a corrugated iron roof to protect them from rain. These drying places vary in dimensions according to the requirements of the plantation and are of two types:— 1) "Balcons", super-imposed moveable floors on rails at different levels, having a single common cover; 2) "Barcaças", formed of a single fixed floor, the cover running on rails. The first type is much used at Cannavieiras and Belmonte, and the latter at Ilheos. Drying places with artificial heat, called "estufas" are also used, they are constructed in different ways, but based on the same principle. These drying places consist of a structure, into which a truck with several drawers of perforated tin is run and a heated chamber. At Belmonte a dryer of the "Guardiolo" type is in use, and another type with mechanical movement is installed at Ilheos. These dryers all have defects and no agreement exists at present as to which is the best type. The best cocoa is obtained by drying in the sun. Drying lasts for three to eight days, and should be done slowly so that the cocoa may dry completely.

To give the cocoa a shining appearance, it is subjected in the dryers, while still moist, to "pisagem", an operation identical with "dancing" in Trinidad: barefooted men collect the cocoa in small heaps on the drying places and tread on the beans for about an hour; when it is over the cocoa continues to dry and, when quite dry, it has a polished shiny appearance.

\* \* \*

The cocoa when quite dry is taken to the warehouses where it is weighed and put into sacks. At Cannavieiras and Belmonte transport is by river in "canoas" (canoes) up to the shipping ports. In other centres donkeys are used forming "tropas" (collection of several donkeys under control of one or more men). To reach places where transport is easier, that is to

say either a navigable river or a railway station, the "tropas" travel by very rough paths. The dangers, accidents in crossing streams and marshes where the animals sink up to their necks and sometimes fail to get out, the passage through the forest and the descent of hills where the paths follow the slope directly, make transport difficult and reduce the quality of the cocoa. As soon as the cocoa reaches its destination or the shipping ports, it is classified under commercial types in the warehouses of the big merchants, and made up in large lots and mixed in order to render it more uniform. The cocoa is then packed in bags of 60 kg. and shipped either on sailing ships or small steamers which call at the various ports. Almost all the cocoa is sent to Bahia, whence it is despatched to foreign countries. During the war shipping was done at Ilheus for Rio de Janeiro, where transshipment was made to transatlantic vessels; it is for this reason that the statistics from 1914 to 1919 indicate a great increase in the export of cocoa from this port. At present small quantities are sent from Cannavieiras and Ilheus to Rio for local consumption. Bahia is the market and port of despatch for cocoa of the State of Bahia.

\* \* \*

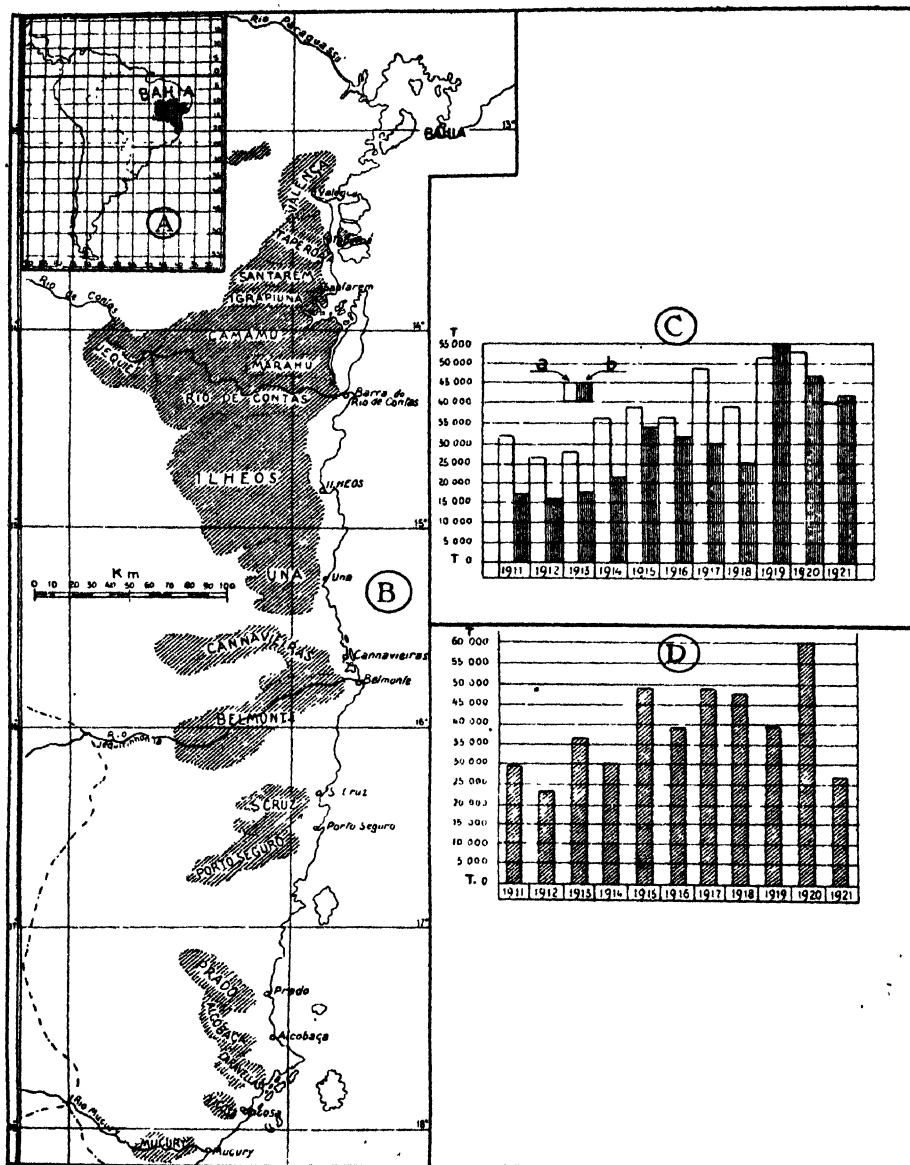

On the market, cocoa is classed under three kinds:—"Superior", "Good Fair" and "Fair". The "Superior" cocoa is shiny, dry and without external defects and has an odour like chocolate; when cut, not more than 2 to 4 % of internal defects are found. The "Good Fair" should have the same qualities on a smaller scale and not more than 8 % of internal defects. The "Fair" is badly prepared cocoa, of poor appearance and in which the defects are as high as 25 % or more. Local purchases are made per *arroba* of 15 kg. and, at Bahia the accounts of the brokers are passed for quantities of 10 kg. Exporters make their offers on the basis of 50 kg. but shipments are made in bags of 60 kg. net.

The difference in price between the kinds is variable and has reached as much as 2\$ (3 francs at the rate of exchange). The price in the Bahia market is also very variable, but the average, for the past few years, has not fallen belows 12\$ (12 *milreis*) for 15 kg., and the market depends on the prices in the New York market.

\* \* \*

The estimates of the net cost of a plantation are too long to be shown, but it may be said that a cocoa tree costs from 2\$500 to 3\$ (4 to 5 francs) everything included:—cost of land, staking out, planting and maintenance for five years. For plantations which have drying installations 4\$ per tree is calculated, the price 30 *contos* per 1000 *arrobas* of production (50 000 francs for a production of 15 000 kg.) is taken as a basis for the purchase of a plantation. The cost of harvesting, preparation and drying the cocoa is small and we may calculate 250 *reis* (40 centimes) per kg. or 2\$250 per 15 kg. at the plantation. If the calculation is made to include transport to the

warehouses of the buyers at ports of shipment the cost per 15 kg. (1 *arroba*) would be from 4 \$500 to 5 \$ (7 to 8 francs) an amount which, with the transport to Bahia, would amount to 6 \$500 — 7 \$. The present average price is 16 \$ per 15 kg. and it is evident that the planter has a margin to cover the cost of upkeep of the plantation, which is very small, and to pay interest on the invested capital. This capital, that is to say the capital invested in cocoa planting in Bahia, allowing that the value of a cocoa tree in 3 \$ and that the estimate of the number of trees is correct, is 310 000 *contos*, or, at present exchange, 516 000 000 francs.

\* \* \*

The State of Bahia imposes duties amounting to 19.5 % of the commercial value on cocoa exported either to foreign countries or to other States of Brazil. The average of the market prices during a fortnight is taken and this average is fixed as the value for the next fortnight. The Communes also tax the cocoa which crosses the limits of their territories to the extent of 250 to 200 *reis* per 15 kg. The State taxes are calculated at Bahia, where the cocoa arrives already burdened by the cost of transport, etc. and in consequence taxation exceeds 25 % of the value of the produce in the producing centres.

\* \* \*

The cocoa tree in Bahia has also its diseases, caused either by fungi or by animals, but they are neither very important nor serious in character. With cultural attention and supervision in the most infested countries the diseases will disappear. At Ilheus in 1919 trees were damaged in some districts and looked as if they had been burnt. A Commission studied the matter and ascertained the presence of *Thrips*, "mosquilla" and other injurious insects. Without any remedy other than the rain, which had previously been deficient, the trees regained their former appearance and bore well. It is always necessary to be on the look out, for the germs of disease are there and at any time there might be a serious outbreak. In principle, it may be said that diseases of the cocoa tree do not exist to such an extent as to endanger production and local conditions do not favour propagation of disease and that the trees are resistant to their pests, but care is always necessary (1).

\* \* \*

The cultivation of the cocoa tree is still progressing in Bahia; fresh plantations are made in the principal producing centres, but not to such an extent as to cause a great increase in production. As one gets away from the shipping centres and transport has to be done over considerable

(1) See R. April 1918, No. 493. (Ed.)

distances, by roads which are impracticable when it rains, the crop scarcely pays the cost of transport and does not give the planter a profit. Labour also is insufficient and the casual labourers who used to come from the north of the State no longer do so. These two factors, viz., difficult transport and want of labour, are the principal causes which prevent expansion. There are also the old plantations, trees attacked by disease, those which, owing to bad upkeep have become almost useless, those damaged by floods, and in short all the plantations which bear little or nothing and it will be seen that no great increase of production is to be expected. In the writer's opinion, during the next five years, crops exceeding an average of 850 000 to 900 000 bags of 60 kg. per annum cannot be counted on. Progress of the crop depends mainly on transport, the cost of which must correspond with the market prices of the product. The planter ought not to pay for transport almost the value of the product. If railways cannot be constructed, roads for transport animals would be sufficient, provided that they are well maintained. Localisation of labour would be a second requirement to do away with casual labour which is often lacking and hence causes wages to increase. Lastly Government measures are wanted for the protection of planting by laws giving prizes for good produce, prescribing the construction of roads, decreasing the export duties on cocoa, facilitating the acquisition of land and guaranteeing the rights of the first occupier, keeping good order and not permitting injustice, founding experimental Stations and instruction by agricultural officers in the producing centres to teach good methods, intensify rather than extend the cultivation, demonstrate the advantages of good product, in short to cause the cultivation to pass from the present primitive state to a state of scientific and methodical cultivation. Once these measures are taken, great progress may be expected in cocoa cultivation, and such measures are absolutely necessary to enable cocoa to withstand a fall in price which may be expected in view of the increase in the world's production, the protective measures taken by other countries and the rate of Brazilian exchange, at present very low but which may rise at any moment. It is certain that at the present time this planting gives good profits and remunerates in a fairly satisfactory manner the capital invested; and the writer strongly recommends the employment of capital in the purchase of plantations already in bearing. It is not reasonable that people should borrow capital at excessive rates of interest, and hope that the planting will provide for this interest, pay off the capital and in addition allow the planter a good income.

Cocoa-planting in Bahia offers excellent prospects for the investment of capital, provided that care is taken to select a plantation in good condition; with sound, economical management such a plantation would undoubtedly return a satisfactory income. The fall in the Brazilian exchange makes the present time very favourable for such investments.

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION

RURAL  
HYGIENE

1010 - **Action of Vitamines.** — MITCHELL, H. H. (College of Agriculture, University of Illinois) in *Science*, Vol. 56, No. 1437, pp. 34-37. Utica, N. Y., July 14, 1922.

The discovery that small amounts of certain substances of undefined chemical composition are necessary constituents of a complete diet has opened up a wide field of research. Experiments have been made with animals by supplying them with rations deficient in certain vitamins. The study of vitamin A has been made with rats, vitamin B with pigeons; vitamin C with guinea pigs and monkeys. The results are consequently not always applicable to other cases; for example foods deficient in vitamins A, B and C for the animals in the experiment may contain sufficient for the requirements of human beings and domestic animals.

Although large amounts of meat or meat extract will not adequately protect guinea pigs from scurvy, in the case of human beings, even a relatively low concentration of the vitamin in meats will prevent an out-break indefinitely. In the case of human requirements, therefore, fresh meats should not be considered deficient in vitamin C though such is the case with the guinea pig.

For this reason it is premature to generalise from the results so far obtained; for example, milk and butter have a high growth vitamin or liposoluble A content, which may be entirely lacking in the case of hydrogenated fats or vegetable oils and this fact is made use of in arguments against the employment of these oils. It is very doubtful, however, whether such foods are deficient in vitamins from the human standpoint to such an extent that it is necessary to replace them by others which are richer in these substances.

On the other hand probably the functions of the growth vitamin are confined to the period of active growth; adult rats have been maintained in good health for over a year on rations devoid of this vitamin.

At the Illinois Agricultural Experiment Station, 4 sows have successfully raised in less than one year, two litters of pigs each, although the

ration, according to the tests with rats, was nearly if not entirely deficient in vitamine A.

The theory of vitamines may also be exaggerated in other ways

The English Medical Research Committee for instance states in a recent report that a deficiency in vitamine may be responsible for ill-health, but such a statement is based on conjecture and probability and ought not to be accepted as a fact. The part played by vitamines is at present hypothetical and views respecting food requirements of human beings and animals which are merely based on hypotheses ought not to be accepted without due consideration.

1011 — Influence of the Weight and Size of Seeds on Yield. — DESPREZ, F., in *Journal d'Agriculture pratique*, Year 86, No. 7, pp. 141-143. Paris, Feb. 18, 1922.

AGRICULTURAL  
EXPERIMENTS

It has always been admitted that the largest and heaviest seeds gave the best cultural results.

VARRO, COLUMELLA, PLINY and in more recent times OLIVIER DE SERRES, P. JOIGNEAUX, SCHRIBAUX, etc. have recommended this mechanical selection for obtaining the most vigorous plants and the greatest yield. Some agriculturists however have attributed but slight importance to these characters of the seed. Thus, the Belgian agriculturist DE CALUWE published a pamphlet in 1908 in which he set out the results of experiments carried out at the "Jardin d'Essais" at Ghent with oats and barleys which were unfavourable to large seeds. Further, basing his conclusions on tests made by JANNESON, of the Glasterberry Station in Scotland, by TH. REMY, of the Agricultural College of Bonn-Poppeledorf in Germany, and others he came to the conclusion that the results of practical and carefully arranged experiments tended to negative the superiority of large heavy seeds.

The writer refers to some experiments made by him since 1896 at the Agricultural Experimental Station of Cappelle (Nord) with 5 varieties of wheat sown on 5 plots of an area of 20 ha. each; one half of each plot was sown with large seed and the other with small. The superiority of the large seeds, so far as the yield of grain calculated by weight was concerned, was evident and in some cases very marked. The difference was greatest in the case of a yellow bearded wheat for which the large seed gave a yield of 4800 kg. per ha. and the small seeds a yield of 3898 kg, a difference of 902 kg. per ha. For the other varieties, the difference, though less marked, was still considerable (kg. 125 — 275 — 282 — 367). The specific gravity of the grain (weight of 1 hl. expressed in kg.), was the same for two varieties and for the other three, that of the large grain was slightly greater than that of the small grain. There was no appreciable difference in the weight of the straw.

In 1922 fresh experiments were undertaken at the Cappelle Station with oats and barley so as to have them under conditions identical with those of DE CALUWE.

L. V.

## CROPS AND CULTIVATION

AGRICULTURAL  
METEOROLOGY

1912 - **Critical Period of Wheat as regards Rain.** — AZZI, G. (Director of the Department of Agricultural Ecology), in *Nuovi Annali del Ministero per l'Agricoltura*, Year 1, No. 2, pp. 299-307. Rome, Dec. 31, 1921.

In the development of cereals critical periods are encountered during which the plant feels most acutely the unfavourable effects of its environment, such as drought.

In the case of wheat the greatest need of moisture is felt : 1) during germination and the initial growth of the young plants ; 2) during growth ; 3) during the period of earing. The critical period for the formation of ears was previously determined by the writer by means of the formula of correlation and by making use of statistical, meteorological and phenological data ascertained for the Province of Girgenti. It follows that the period of about twenty days required to form ears is of capital importance ; if, during this period the total amount of atmospheric precipitation is less than the minimum compatible with the normal development of the plant, the harvest will be poor, even if rain falls during the remainder of the growth period. Wheat can give good crops even with a total rainfall of less than 300 mm. ; but as the minimum is approached the influence of the distribution of the rainfall prevails and becomes decisive during the critical period.

In this connection the writer has investigated experimentally 4 varieties of wheat : *Apulia* (Rieti × *Spelta*), *Cervaro*, *Carlotta Strampelli* (Rieti × *Massy*) and *Spelta*. The experiment was carried out at the Botanical Garden of the University of Rome during the agricultural year 1920-1921. The plants were grown in pots ; copiously watered from sowing on December 29 up to April 12, and from the 7<sup>th</sup> day after forming ears up to maturity ; during the interval, on the other hand, the plants were given a variable number of waterings : 0 — 1 — 2 — 5. The best selected varieties, of high specific productivity, *Spelta* and *Carlotta*, suffered most from the absence or slowness of the watering, the two other varieties were less exacting.

The harmful effect of insufficiency of water during the critical period is shown by : — the total production of grain expressed in weight — the average weight of the grains — the length of the stalks — the length of ears — the weight of straw — etc. There was also a delay in earing and reaching maturity, more noticeable for the selected varieties, especially *Carlotta Strampelli*. The length of the ears did not diminish correlatively with the length of the stalk ; on the contrary, in the variety *Apulia*, in spite of want of moisture they maintained an almost invariable length. This capacity of decreasing the length of stalk while maintaining the length of ear unchanged, may be interpreted as a character of adaptation to drought.

With the varieties *Spelta* and *Carlotta*, not even as many as 5 waterings

made in the conditions of the experiment were sufficient for them to reach the production of the two other varieties.

Production therefore depends on two factors : specific productivity and resistance to the unfavourable conditions of environment. In the 4 varieties studied, these two factors were more pronounced in the *more hardy* varieties. The variety *Cervaro* especially seems to unite in the best proportions the characters of specific productivity and resistance to drought ; it is well suited to a dry climate.

Adaptation to drought may arise : — 1) by advancing or retarding the formation of ears so as to alter the critical period ; 2) if the roots are deep ; 3) if the structure of the plant is such as to enable it to economise moisture. This last is true resistance to drought, and the real object of these experiments.

L. V.

1013 — **Plant Indicators of Soil Types.** — KELLEY, A. P., in *Soil Science*, Vol. XIII, No 6, pp. 411-423. New Brunswick, N. J., June 1922.

From ancient times, it has been observed that the presence of certain plants shows the condition of the soil on which they are growing ; CATO, PLINY and COLUMELLA noted the correlation between the soil and the flora. The idea was developed during the eighteenth century, and in the nineteenth century two schools of thought arose, one, represented by NAGELI, SCHIMPER and others attributed the chief importance to chemical conditions, and the other believed in the physical theory founded by THURMANN. Although many of the relations existing between soil and flora have been discovered, comparatively little work has been done in correlating plants with soil types.

The author has undertaken a series of researches with the object of determining whether a general hydrogen-ion concentration may be assigned to each of the soil types of southeastern Pennsylvania, and whether a definite relation exists between these soils and the flora growing upon them. He tested many soil types for acidity by the colorimetric method which is the most practical. Borings were made with an auger to the depth of 10 ft. in some cases. It was found that the carbon dioxide in the soil did not affect the reaction.

The acidity of a soil type is a variable quantity, but an average pH value may be assigned to each type. The values obtained represent surface soil conditions ; some borings were made with a soil auger, but not enough data are accumulated to formulate conclusions as to the acidity.

Soil acidity is governed in part by such factors as arrested leaf decay, and physiographical features of slope, degree of slope and relative elevation. Some types of soil seem to have a higher degree of acidity in late summer. Soil acidity influences flora to such an extent that certain plants may be assigned as indicators. The author gives a list of the characteristic species for 7 different types of soil. Thus *Quercus alba* is typical of rich neutral soil ; *Quercus stellata* is characteristic of poor soil with a high magnesium content ; *Quercus pinus* is the dominant tree of acid soil.

Soil acidity may perhaps induce variation in plant species.

A. de B.

[1012-1013]

SOIL PHYSICS  
CHEMISTRY,  
AND  
MICROBIOLOGY

1014 - **The Control of Soil Moisture by Means of Auto-Irrigators.** — DE PEÑALTA, F. (Department of Plant Physiology, College of Agriculture, Los Baños, Philippines), in *The Philippine Agriculturist*, Vol. X, No. 10, pp. 467-477, figs. 3, plates 1, bibliography of 4 works. Los Baños, Laguna, May 1922.

LIVINGSTON and KORETSU consider that a soil is satisfactory for plant growth if it can supply water to the root system as rapidly as required; otherwise growth is checked. With these points in mind, the author has investigated the relation of growth to different moisture contents when these are controlled by means of auto-irrigators or provision made for maintenance at the same level by means of a regular supply of water.

A modified LIVINGSTON auto-irrigator was employed. Three vertical cups (irrigators) connected by glass tubing provide the cultures in pots with moisture. A constant supply of water is afforded by means of a mercury control-tube, the free end of which is placed in a water reservoir. For each pot containing oven dry soil, 3 auto-irrigators were employed with a single reservoir. Three parts of pulverised loam to 1 part of coarse sand were used. The height of the mercury in the tubes varied from 40 — 20 — 10 — 5 cm., and zero. The soil moisture determinations gave respectively: 9.39 — 10.4 — 12.29 — 14.43 — 25.11. In the control pots, the moisture determinations were taken twice daily.

*Lactuca sativa* was used.

In both sets of experiments, there was an increase in dry weight in conjunction with the increase in soil moisture. A constant supply gave more satisfactory results than the periodic and variable supply. The difference was more marked for the high percentage moisture content than for the low content. For example, continued use of the auto-irrigator, and without the mercury medium, gave 5.66 gm. of dry matter. Curtailed use, namely 25.11 % moisture, gave 3.22 gm. or a gain of 75.8 %. A 40 % mercury medium gave 0.88 gm. and a 9.39 % moisture supply gave 0.83 gm., or an increase of only 6 % dry weight.

Comparative Graphs indicate the vegetative growth obtained. In this case also, the use of the auto-irrigator apparently has a beneficial effect when maintained regularly, and not discontinued, but this influence was more marked for the low moisture content than for the high, the gain in leaf area being 155 % to 16 %.

Atmometer experiments were also made, and the general results were as expected. The comparative data will serve in future experiments.

L. V.

1015 - **Factors influencing the Determination of Sulphate in Soil.** — HIRST, C. T. and GREAVES, J. E., in *Soil Science*, Vol. XIII, No. 4, pp. 231-239. New Brunswick, N. J., April 1922.

The methods for the determination of sulphates may be divided into two classes, namely, gravimetric and volumetric. The gravimetric method is not as simple and exact as was formerly supposed. In the presence of salts and acids which influence the result in various ways, such as by the occlusion of salts present in the precipitate, or to a less extent by the solubility of the precipitate, a serious error may be introduced, sometimes

even as much as 5 %. The volumetric method, which consists in titrating the excess of barium chloride used to form the precipitate with potassium chromate, followed by a titration with iodine, also causes considerable errors.

The authors have made a series of experiments in order to ascertain the causes which give rise to the errors in the two methods of soil analysis. Experiments with solutions of chloride of sodium, potassium, aluminium and iron showed that sodium chloride has a slightly depressing effect which is somewhat more marked with potassium chloride; the chlorides of aluminium and iron introduced a positive error with the gravimetric method and a negative error with the volumetric. The effect of nitrates is much more noticeable, the alkaline nitrates causing a positive, and the aluminium and iron a negative error. In the analysis of sulphates in samples of soil, it is obvious that clarifying agents such as alum or lime cannot be used and that the centrifuge or a filtration method must be employed. In the experiments which were carried out the soil was mixed with water in the proportion of 1 : 5, but this ratio could be varied considerably. In the case of chlorides and nitrates ten minutes shaking of the soil and water was sufficient, but at least forty minutes were necessary for sulphates.

The volumetric method with chromate always gave negative errors, small in the case of normal solutions, but much greater if the solutions were concentrated or diluted. This method is however to be preferred on account of its rapidity and simplicity; when a fair degree of accuracy is desired a correction must be made for presence of iron, aluminium and nitrates.

**1016 - Presence of Cobalt and Nickel in arable Soil.** — BERTRAND, G. and MOKRAGUATZ, in *Comptes rendus de l'Académie des Sciences*, Vol. CI, XXV, No. 2, pp. 112-114. Paris, July 1922.

The existence of cobalt and nickel has up to the present appeared to be very localised and deep lying. The writers have recently been able to determine the presence of these elements in arable soil, in small quantities. A sample of garden earth, from the Pasteur Institute, gave under analysis: — 0.0037 per 1000 of cobalt and 0.0174 per 1000 of nickel.

A. de B.

**1017 - Tests of Vesuvian Bacteriology.** — ROSSI, G., and RICCARDO, S. (Istituto di Batteriologia agraria della R. Scuola Superiore di Agricoltura di Portici), in *Nuovi Annali del Ministero per l'Agricoltura*, Year 1, No. 2, pp. 241-255. Rome, Dec. 31, 1921.

The writers offer a contribution to the study of the micro-biological processes which take place in the formation of soils, by determining in them the successive development of the active microbial flora. The Vesuvian zone is admirably suited for this form of research, as it contains large tracts of soils bacteriologically sterile which gradually become covered with vegetation either spontaneously or under the influence of cultivation. In this region sterility is periodically caused: —

1) by the flow of lava;

2) by the eruption of ashes which almost always accompanies the falling in of the cone ; the case of 1906 was striking as it produced layers with a depth of as much as 25 cm. ;

3) by the action of sulphuric and hydrochloric acids contained in the air in the form of vapours and smoke or carried down by rain. In cultivated soils the ashes may be buried in the ground and they then have a beneficial effect ; otherwise they cause sterility.

The succession of macroscopic and microscopic vegetable species in the sterile Vesuvian zone was previously studied by COMES, but a bacteriological examination was not made.

The writers have studied the various bacteriological processes which took place in the soil. In this preliminary test they indicate the results obtained as regards nitrogen fixers, cultivated in the ordinary way with samples of soil in a soil infusion containing  $1\frac{1}{2}\%$  of mannite. In all soils of the circum-Vesuvian plateau zone they found the *Bacillus amylobacter* (*Clostridium pasteurianum*) present in the four forms described by ROSSI in 1908 ; they also found *Azotobacter*. They were of various sizes and shapes, granular, hollow, etc. At altitudes of 310 and 878 m. nitrogen fixing agents were completely lacking, both those of the *Clostridium* and those of the *Azotobacter* type. An exception must however be made of the "Colle Umberto" which arose in 1895-1899 and in 1906 was covered with ashes which were subsequently carried away by wind and rain. The young student F. S. SAUVE found upon it a few forms of *Clostridium*.

The absence of these bacterian species from some soils throws some light on the difficulty which may be met with in reafforesting Vesuvius. Even if a possible relationship between the rooting of some leguminous plants, such as the robinia and the broom, and the root bacteria is excluded, it is not impossible that one of the reasons for the frequent want of success in the rooting of woody plants may be found in the absence of certain bacterian species, assuming that other known factors are admitted. The interest of the problem is evident in any case, the Vesuvian zone presenting conditions peculiarly favourable to its solution. L. V.

1018 - **The Influence of Moisture and soluble Salts on the bacterial Activities of the Soil.** — GREAVES, J. E., and CARTER, E. G., in *Soil Science*, No. 4, pp. 251-270. New Brunswick, N. J., April 1922.

The authors had formerly studied the influence of moisture on the bacterial activities of the soil and the object of their new work was to consider the effect of various soluble salts upon the water requirements of the ammonifying and nitrifying organisms. The soil used in their experiments was of a sedimentary type with a high lime content and a water-holding capacity of 45 %, and possessed a very interesting bacterial flora. Samples of 100 gm. were each mixed with 2 gm. of dried blood and different quantities of various salts and were put into sterilised pots which were covered and weighed ; water was added in amounts increasing from 10 to 45 %. The samples for ammonification were incubated for a few days at a temperature of 28°-30° C, and then analysed ; those for nitrification were incubated

for 21 days ; every seven days the water content was made up to the initial percentages. The maximum for ammonification was reached : a) with 30 % moisture in the case of untreated soil (14 mg. ammonia in 100 gm.) and of those to which the following salts had been added : sodium carbonate, potassium carbonate, potassium nitrate, calcium carbonate, calcium sulphate, calcium nitrate, magnesium chloride, magnesium carbonate ; b) with 35 % moisture in the case of soils to which had been added : sodium sulphate, sodium nitrate, potassium chloride, potassium sulphate.

The samples to which the sulphate or nitrate of magnesium had been added reached their maximum with 25 % moisture.

The relative toxicity of sodium chloride, sodium carbonate, potassium chloride, potassium carbonate and calcium carbonate diminished on increasing the moisture ; for example, the addition of chloride or carbonate of potassium to a sample containing 10 % moisture reduced ammonification by 50 %, whereas with 45 % moisture the first salt lowered the result slightly and the carbonate had the opposite effect. In these instances the toxicity was due entirely to osmotic pressure. In the case of other salts tested in the experiments, especially with those of calcium and magnesium, toxicity increased with the moisture content, which suggests the conclusion that the result was not due to physical changes in the soil, but to the physiological effect on the protoplasm of soil organisms.

The untreated soils and those to which had been added carbonate, sulphate or nitrate of sodium, chloride, carbonate, sulphate or nitrate of potassium, and chloride or carbonate of magnesium, reached the maximum for nitric nitrogen production when the soil contained 20 % moisture, whereas the soils containing potassium carbonate, calcium sulphate, calcium nitrate, calcium carbonate, magnesium nitrate and magnesium sulphate reached the maximum with 25 % moisture. When the water-content reached 35 % nitrification ceased in all the pots except in that treated with sodium chloride, where it continued to some extent before the maximum was reached, with 30 % moisture. The addition of water to soils containing small amounts of potassium chloride, potassium sulphate, magnesium nitrate or magnesium chloride changes the toxic medium to one which is favourable for nitrifying bacteria ; for example, chloride of potassium is toxic in soil containing 10 % of water but with 20 % there was double the production of nitrates. Nitrate of sodium was the only salt tested, which, even in the presence of a high percentage of water, reduced the production of nitrates, notwithstanding that the passage from a toxic to a stimulating medium by increased water content was very pronounced in the case of sulphates, especially those of potassium, magnesium and calcium.

1019 - **Influence of Hydrogen-ion on Growth of Azotobacter.** — GAINES, P. I., and BATCHELOR, H. W. (Department of Bacteriology, Kansas Agricultural Experiment Station), in *Science*, Vol. 56, No. 1437, pp. 49-50. Utica, July 14, 1922.

After isolation of several strains of *Azotobacter* from different soils and grown in dextrose media, the maximum hydrogen-ion concentration permitting growth was found to be pH 5.0-6.0 in every case. This

is appreciably lower than that reported (pH 6.6-6.8) for two strains by FRED, but agrees closely with previous work by GAINEV. As the hydrogen-ion concentration of the medium decreased, growth increased until pH 6.1-6.4 was reached.

No fixation of nitrogen took place in a concentration greater than pH 5.9, but at pH 6.3-6.5 fixation was as great as in lower concentrations. The growth of the organisms did not affect to any appreciable extent the concentration of the medium.

1020 - **The Carbon and Nitrogen Relations of the Nitrite Ferment.** — BONAZZI, A. (Laboratory of Soil Biology of the Ohio Agricultural Experiment Station, Wooster, Ohio) in *Journal of Bacteriology*, Vol. 6, No. 5, pp. 479-490, bibliography of 15 works. Baltimore, Sept. 1921.

WINOGRADSKY has demonstrated that nitrite fermentation organisms are capable of growing in a medium completely void of organic matter in presence of air, which oxidises the ammonium compounds; nitrite fermentation is followed by an increase in carbon content, which indicates that a source of carbon is found and utilised by the organism. GODLEWSKY as well as WINOGRADSKY and OMELIANSKY, found that cultures of nitrite- and nitrate-forming organisms lacking free or combined carbon dioxide could not develop. BEIJERINCK suggests that the carbon is fixed by the basic carbonate in the culture liquid, and not utilised and assimilated by the organisms; but if this were true it is difficult to explain why the ratio of nitrogen nitrified to carbon assimilated should be of constant value. It appears that an intimate connection exists between these two factors; hence the view advanced by LOEW that this is due to a single biochemical process.

After making several experiments, the author has identified the source of carbon fixed by nitrite organisms. It has been demonstrated that organisms from American soils which differ in form and life-cycle from organisms from Europe and Asia, are similar physiologically. Using the OMELIANSKY solution, it was found that when fermentation occurs and changes the sulphate of ammonia to nitrites, the organisms have recourse to the energy derived from this exothermic reaction to regulate chemosynthesis of carbon, in other words to remove the free carbon dioxide and encourage carbon assimilation as a result of fermentation. A limited quantity of nitrogen is also used as an organic source; the nitrites are derived from the waste products.

The effect of magnesium carbonate or nitrous acid on ammonium carbonate is responsible for the liberation of free carbon dioxide.

By a special process, free carbon dioxide was removed from the cultures and a potassium or sodium carbonate absorbent employed to lessen the tension of the atmosphere and disperse that in the solution. In such cases, development is hindered. If this depletion of carbon dioxide in the cultures reaches certain limits, the nitrite organisms are incapable of action, which proves the absolute necessity for free carbon dioxide. This is obtainable from the carbonate but the organisms are unable to assimilate from the carbonate direct.

Nitrite bacteria are therefore essentially autotrophic, dependent on the presence of free carbon dioxide which leads to the formation of nitrous acid and its salts. The functions of autotrophic carbon assimilation and nitrogen nutrition are intimately connected, and mutually interdependent.

1021 - **Effect of Tree Products on the bacterial Activities in Soil: Ammonification and Nitrification.** — GIBBS, W. M. and WEREMAN, C. II., in *Soil Science*, Vol. XIII, No. 4, pp. 303-322. New Brunswick, N. J., April 1922.

The greater part of the soil of northern Idaho consists of a silt loam. This area is covered with vast forests which are gradually being cleared by removing the timber *en masse* and burning the debris and each year there is an increase in the acreage of land available for agriculture. The first crop on this land is fairly good, but each successive crop is diminished for three or four years but after six or seven years better crops are obtained. This result is attributed to harmful substances left in the soil by the timber which disappear in six or seven years. The fairly good yield obtained from the first harvest can be explained by the small amounts of available plant food left in the soil, which are removed by the first crop.

The object of the author's investigations was to ascertain the effects of these harmful substances on soil bacteria.

FERNOW states that in a century the products formed from the leaves of a forest constitute 15 % of the soil ; in order to be well within the limit found in nature the authors used forest material in amounts varying from 1 to 3 %.

The samples were composed of saw-dust, bark and needles from different forest trees ; three types of soil were chosen for the experiment, forest, garden and field. Samples of soil weighing 100 gm. each were put into bottles of 500 cc. capacity, and 1 gm. of dried blood was added to each and the moisture content brought up to 25 %, and an additional 2 gm. of water for each gm. of wood or other tree product. The samples were incubated at a temperature of 28° C for a week, after which they were analysed for ammonia content. The samples for nitrification were prepared in the same manner except that the moisture content was made up to 20 %, and the incubation lasted four weeks ; the moisture lost by evaporation was restored each week.

The samples for denitrification were prepared in the same way as were those for ammonification, with the exception that sodium nitrate solution was added instead of blood.

All the substances which were tested reduced ammonification. In the forest soil, cedar (*Thuja plicata*) was the most harmful and reduced ammonia accumulation 78.9 %, the sugar maple coming next as regards toxicity. The white pine (*Pinus monticola*), the least toxic of the group, reduced it by 13.1 %. The results were very similar in the case of field soil. Cedar, maple and larch were the most toxic. Among the products other than sawdust *Thuja plicata* needles exerted the greatest inhibitory action, followed by those of *Pinus ponderosa*, *Pinus monticola* and *Abies grandis* ; larch needles had little effect.

All the substances tested proved to be inhibitory to nitrate formation from blood and ammonium sulphate. This effect is reduced but is not entirely removed by applications of 1 % of carbonate of lime.

Ash and maple sawdust in 3 % applications almost stopped nitrification. Cedar, maple, larch and Douglas fir sawdust caused the greatest reduction. Apart from sawdusts, applications of 3 % of white fir, yellow pine and cedar needles practically prevented nitrate formation. Notwithstanding the effect of the needles, white fir sawdust was but slightly detrimental. The forest residue which covered the soil also reduced both ammonification and nitrate formation. On the other hand, ferns, which abound on forest land, had little effect.

The denitrification experiments indicate that the reduction of nitrates is not due to the denitrifying group but to inhibition of the nitrifying organisms. With the exception perhaps of maple and ash none of the substances tested would serve as a source of energy for denitrifying organisms.

A. de B.

1022 - **Soil Fatigue.** — D'HUBERT, A., in *Journal d'Agriculture pratique*, Year 86, No. 7 pp. 136-138. Paris, Febr. 18, 1922

The writer defines the fertility of a soil as its capacity to produce vegetable matter, independently of its chemical composition. Decrease of fertility has been attributed to several causes:—

- 1) The most simple hypothesis is the soil's exhaustion in nutritive matter. Recent research has shown that this is not adequate, for the composition of soil solutions is, if not constant, at least almost invariable.
- 2) Another explanation of soil fatigue is furnished by RUSSELL and his collaborators who bring in *antagonism between the germs in the soil*, in which the injurious germs get the better of the useful germs. The former class is represented mainly by protozoa, which by phagocytosis would destroy the latter, represented chiefly by *Azotobacter*. The exhaustion of the fertility of the soil would be due to the rapid increase of the protozoa. This is perfectly correct when it is a matter of crops *in vitro*, but, in nature, protozoa and *Azotobacters* play a secondary part relatively to other living agents. Moreover this hypothesis does not explain why a particular crop e. g. lucerne, cannot be grown again on the same ground except after a certain period of repose.
- 3) *The injurious effect exercised by the organic residues left by the plant in the soil* is another suggested explanation. These residues may be either dead roots, or pellicles coming from the desquamation of the live roots. In this order of ideas, PRIANICHNIKOW and PÉRITOURINE have proved experimentally that the introduction of fragments of roots into a pot of screened soil reduces the yield. The writer has repeated this experiment under conditions permitting a more rigorous comparison. As soil is too complex a medium for it to be possible to study in it each of the factors which regulate vegetation, he preferred to make use of a sterilised nutritive liquid, in which he grew maize, following the method suggested

by MAZÉ. Three series of experiments were made :— one series grown in a liquid which had not yet borne any crop, one series in a liquid which had already borne a crop of maize, one series in a fresh liquid, but into which fragments of roots had been introduced.

The average lengths of stalk and roots showed marked increases from the 1<sup>st</sup> to the 2<sup>nd</sup> and from the 2<sup>nd</sup> to the 3<sup>rd</sup> series ; they were respectively 60 and 40 mm., 135 and 180 mm., 125 and 200 mm. It is therefore possible to conclude that, at least in the case of young plants, the presence of the dead roots of a plant is very favourable to and does not hinder growth.

4) There remains a fourth hypothesis, closely connected with the last, namely that the plant *elaborates waste products injurious* to itself, which check the development of plants of the same species, behaving like toxins. Although this hypothesis is still slightly inconsistent, it alone can explain several facts.

It is supported by WHITNEY, who quotes the following commonly observed fact : beneath the trees on a lawn there is no vegetation, and the grass disappears. This lack of vegetation is not due to shade for it would then be observed only under the north part of the tree, where the shade is more persistent ; but this is not the case, the lack of vegetation being uniform under the crown of the tree. This lack of vegetation is also not due to exhaustion of the soil by the roots of the tree, either in nutritive matter or in moisture, for, whatever amount of manure and water is given, the soil does not recover its fertility. This is therefore in all probability due to the excretion, by the leaves, of injurious substances which the rain carries down to the ground below. It must also be remembered that acid soils are infertile ; now acidity in itself, is not injurious ; in fact cultures in liquid media require an acid reaction ; nor can it be stated that acidity is injurious as checking the process of nitrification ; in fact the plant assimilates ammoniacal nitrogen as well as nitric nitrogen ; it follows that acidity is merely an indication of the presence of injurious substances.

APPLICATIONS. — This hypothesis has led to a practical application for ascertaining the nutritive value of a soil. The method recommended by WHITNEY consists of rapid comparative experiments of growth, made so as to shield the soil against the action of oxygen which would destroy the vegetable toxins, which are highly liable to oxidisation. With this object, the soil tests are made in metal pots steeped in melted paraffin ; the experiment lasts only 2 or 3 weeks ; the weights of the crops are then taken. By adding manures to the soil it can be ascertained which is the more suitable. The soil Bureau of the United States has used this method for more than 10 years ; it is not absolute, but, in practice, its results agree with those given by cultures in the field and chemical analyses do not always give such satisfactory results. It is desirable that further research should be made regarding the nature of the supposed toxic substances and the right means of destroying them. Up to the present time the use of carbon disulphide, toluen, calcium sulphide and heat have been tried empirically ; but a strict scientific study is required.

L. V.

1023 - **Irrigation in Tunisia.** — CHÉROT and CRUZET, in *Bulletin agricole de l'Algérie Tunisie Maroc*, Year XXVIII, No. 6, pp. 159-175. Algiers, June 1922.

In Tunisia, the work of the Government of the Protectorate for urban and rural water-supply and for agriculture and industry is most praiseworthy. At present there are only 135 places, with a total of 5 000 inhabitants, for which it has not been possible to provide a water supply.

The greater part of the expenditure of about 40 million francs which the Government has devoted to this work has been absorbed by the installations for carrying water to Sousse, to Sfax and to Tunis. These necessary canals are 120 km., 166 km. and 207 km. in length respectively.

The various irrigation undertakings of importance, found chiefly in the centre and south of this region have been grouped as follows for the purpose of Government assistance :—

1) Syndicates using natural spring water . . . . .	7
2)       "       " flood water . . . . .	2
3)       "       " artesian well water . . . . .	8
4)       "       " drainage water. . . . .	1
	•
Total . . . . .	18

Other similar associations are being formed.

After this preamble, the writer gives his personal opinions on the principal questions of drainage and irrigation, and suggests that in Tunisia where the greatest difficulties in the utilisation of local resources are to be found, the programme to be carried out should be —

- 1) Utilisation of permanent water courses ;
- 2)       "       " alluvial       "       "
- 3) Search for natural springs ;
- 4) Establishment of artificial sources ;
- 5) Development of underground springs and reserves ;
- 6) Drainage of marshy land and drying marshes ;
- 7) Storing water from the mountains in reservoirs ;
- 8) Scientific utilisation of natural reservoirs.

*Permanent water courses* are very scarce in Tunisia. There are however, to the south of the region numerous permanent springs which may sometimes attain a flow of 1200 litres per second.

At present all this wealth of water is more or less used by the local population for the irrigation of the neighbouring land and for motive power. On this subject, the writer gives some personal advice for the resolution of new and important problems of drainage.

**UTILISATION OF RUNNING WATER.** — As in Tunisia the hygrometrical state of the air undergoes considerable variations, sometimes a sudden change in temperature may precipitate an excessive amount of water which often causes in most of the streams actual flooding and consequently inundations of the neighbouring land which in this way are irrigated and fertilised by the mud and detritus carried by the floods.

Up to the present the natives make, at various chosen points on the streams, rudimentary irrigation works which regulate these inundations

to the best advantage. But these plants, owing to their poor construction and the power of the water flow, are easily carried away and destroyed. Consequently the writer emphasizes the necessity for constructing stable and complete plants which, while entailing heavy capital expenditure, would quickly pay their way through the increase in the local agricultural production.

**SEARCH FOR NATURAL SPRINGS.** — For this the writer advises the careful study of the geological structure of the land according to the method of Abbé PARAMELLE who, after a long practice of 25 years in 40 Departments of France, has seen his theories crowned with good results.

**ESTABLISHMENT OF ARTIFICIAL SOURCES.** — In many cases the establishment of artificial sources consists in sinking wells in the customary way, or else, when the sub-soil allows of it, and when the impervious layer is not deep, to bore a tube well.

The tube well can be sunk by NORTON'S method which consists in a steel tube driven through the impervious layer to reach the water-bearing zone, this tube being provided at one end with holes which act as a filter and at the other with a small hand pump for raising the water.

Other methods can also be used, for example those in use in Lombardy and the Northern parts of Italy for irrigating the plain of the Po. They consist of wooden cylinders driven into the ground to a depth of two or three metres through the impervious layer.

But such tube wells cannot be sunk unless the impervious layer is not thick and it is easy to reach the water-bearing stratum.

In conclusion the wells, whether sunk in the ordinary way or by the tube well method are always very useful for purposes of cultivation and irrigation and for all other human needs. Consequently the Inspectors of the Engineering Department should have experience of the means of discovering water-bearing zones so as to be able to give advice and information as to how to make use of these natural sources on request and in return for a suitable fee.

**ARTIFICIAL SOURCES.** --- Among these, in addition to the preceding, the most interesting are artesian wells. The Civil Engineering Department has constructed several in Tunisia which have given really remarkable results. Sometimes again the sub-terranean water is so arranged that after a careful study of the geological formation by means of levelling, excavation, etc. it may be made to rise to the surface level. This was done in 1918 by the Department at the Triba centre of colonisation, by excavating through strata of rocky and marble ground an approximately horizontal tunnel 150 m. long which gave access to a spring of which the minimum daily output is 500 cubic metres.

**DEVELOPING UNDERGROUND SPRINGS AND RESERVES.** — This development can be obtained by slowing down the flow of running water and thus encouraging infiltration through the soil.

This is not advisable unless the impermeable stratum is fairly shallow, since otherwise difficulties which may be insuperable will be encountered. The means which can be used to obtain the development of sub-

terranean water are many including :— earth dams, infiltration wells, etc.

But these experiments should not be made without a previous survey of the ground by opening up the soil and subsoil, levellings, soundings, etc. The writer noted, in the district of Béja, the unforeseen formation of a very large spring which arose in a badly watered property, after the clearing of a plot of ground hitherto neglected because of its want of fertility. Unintentionally the proprietor had helped to enrich the underground reserves of water with irrigation water by increasing with the clearing the coefficient of infiltration in the land.

**IMPROVEMENT OF MARSHY LAND AND DRAINAGE OF MARSHES.** — Although Tunisia is poor in water, the special conformation of the land in the Northern district is favourable to the accumulation of stagnant water and consequently of marshes, swamps, etc. The writer therefore emphasised the immediate steps to be taken for the benefit of the country by indicating the more important places where works of improvement should be carried out.

**RESERVOIRS WITH DAMS.**— The first work of this kind was constructed in Algeria between 1845 and 1849 at the mouth of the river Fig, in the plains. In the Oran district, where there is an annual rainfall of from 400 to 500 mm., there are 5 ; the Algiers district has 2 ; in the Department of Constantine, where several attempts have been made, there are none.

The writer says that after many years these works have shown their rather serious and peculiar drawbacks. Each year it is observed that the capacity of the reservoirs decreases in a marked degree. For example, the reservoir Djidionia, the initial capacity of which was about 2 200 000 cubic m. could not hold more than 200 000 cubic m. in 1912. Having ascertained this fact, the French engineers tried to lessen the mischief by getting rid of the accumulated detritus, and they did so by using the running water itself, that is to say by sacrificing a volume of water 8 to 10 times that of the mud removed.

Hence the chief difficulty which checks schemes of construction barrage and reservoir is the sense of uncertainty that the basin will not fill up so as to eliminate what are called the "aléas géologiques".

To solve this problem several commissions composed of experts have been formed. It has however not yet been possible to check the decrease in the capacity of these reservoirs under the effect of the accumulation of deposits brought down by the running water, which proves a serious disadvantage in Tunisia.

**CONDITIONS NECESSARY FOR THE SATISFACTORY USE OF RESERVOIRS WITH DAMS IN TUNISIA.** — According to the writer the best conditions will be realised if the actual volume of water from the rainfall does not exceed double the capacity of the reservoir, so that the half of the water which comes from the autumn rainfall can cleanse the reservoir, the other half, coming from the spring rainfall, only being used. For this reason :

1) A good number of probabilities which are derived *a priori* from topographical examination must be disregarded ;

2) A careful study must be made of the behaviour of the rains and the regulation of the streams of the district, which must be supplemented by geological examination, by soundings and other tests so as to ascertain the local stratification. It is only after these preliminaries that a detailed study of the scheme can properly be made.

UTILISATION OF WATER FROM BARRAGE RESERVOIRS — The greater part of this water is used both for agriculture and for town purposes.

In Tunisia the idea of replacing coal by electricity has always been popular. However as the most important consumers of electricity would be the railway and the mining companies, such substitution would be inexpedient, since the electrification of transport is not important in the country on account of the small number of trains.

NATURAL RESERVOIRS. — Up to the present these reservoirs have not been used by private industry, but they might offer certain advantages for the irrigation of cultivated land. Thus with that object the Sebka, El-Kourgiz and Garaa-El-Hamada could furnish several millions of cubic metres of water.

To sum up, little remains to be done in Tunisia as regards urban and rural water supply, but irrigation and similar schemes can make further use of local resources by utilising all the local supply, by improving and supplementing the plants which already exist with the co-operation of the local Government, which should encourage and help all good private initiative.

G. D.

1024 — **Production of Phosphoric Acid by the Method of Electric Condensation and Precipitation.** — SWANN, T, in *Industrial and Engineering Chemistry*, Vol. 14, No. 7, pp. 630-631. Washington, July 192.

MANURES  
AND  
MANURING

Up to the present phosphoric acid has generally been prepared by the treatment of mineral phosphates or bones with sulphuric acid. The new method by electric precipitation, is actually in use at Anniston (Alabama, U. S.), where three electric ovens are employed, which require a power of 10 000 H. P. and 44 000 volts.

This method consists in fusing in the electric oven (1) a mixture of crude phosphate, coke, sand and iron shavings. The phosphorus which by this means is set free combines partly with the iron and forms iron phosphide containing 25 % of phosphorus and part volatilises with other gases in the oven and is oxydised in the air; the phosphoric acid of 90-95 % concentration is collected in specially designed condensers, after which it is refined by special methods. The particular advantage of this process consists in the production of a highly concentrated acid which is almost free from iron, as all the iron contained in the phosphorite separates out in the form of phosphide. The acid is sent out in barrels or in transport-tanks lined on the inside with a special acid-resistant, wax compound. For pharmaceutical purposes it is necessary to recrystallise the acid, as by this means a purity of 90 % can be obtained for medicinal use or for making oxygenated water.

(1) See *R. May* 1919, No. 571. (Ed.)

This process has already been applied to the manufacture of fertilisers for which purpose a great expansion can be foreseen.

Fertilisers have already been produced containing ammonia, phosphoric acid and potash, with a fertilising power five times that of the ordinary product.

There should be some means of safeguarding the use of such a concentrated fertiliser, but the concentration will effect a great saving on freight, and it will also be possible to reduce the cost of the fertiliser. In order to fix ammonia, it will be an advantage to replace sulphuric acid by phosphoric acid and in this way to produce a fertiliser which will contain two of the three essential fertilising elements.

A. de B.

1025 - **Enriching Extract of Phosphoric Acid by means of successive Decompositions of Phosphorites.** — BOLKO, E. and SOKOLOVA, O., in *Zeitschrift für Angewandte Chemie*, Year 34, No. 88, pp. 548-550. Leipzig, Nov. 4, 1921.

There are two great difficulties in working Russian phosphorites (1), namely their small content of phosphoric acid and the great distance between their beds in the N. E. and the regions of Central Russia where they are required. Also the ordinary processes with sulphuric acid or bi-sulphate of soda do not dissolve more than 70 % of the acid contained.

The new process of Prof. PRIANICHNIKOV of Moscow, which not only makes it possible to dissolve all the phosphoric acid, but also gives a richer solution of the mineral, is therefore very important. In this method use is made as solvent not only of sulphuric acid, but also of the phosphoric acid previously extracted. To begin with sulphuric acid slightly in excess is allowed to act on the phosphorite, to which water is added in the proportion of 2 to 3 or of 2 to 4. It is mixed vigorously for half an hour and taken to the filter press. The precipitate is washed with water until it is quite free of phosphoric acid and the water used for washing is not concentrated but is used to dilute the sulphuric acid in the subsequent operations.

The following method is however perhaps preferable : — from the precipitate of the first operation two liquids from washings are obtained which are kept separate and used for washing the precipitate of a second operation. The precipitate is washed for a third time with pure water and three liquids from washings are thus obtained which are used to wash the precipitate in a third operation. This is again washed with pure water, and so on, so that each time an extra liquid from washing is obtained. The operation is repeated five times and at the end the first liquid from washing, which at the beginning contained 8 to 9 % of phosphoric acid, contains 28 % of phosphoric acid, without diminishing the quotient of purity. In fact the quantity of phosphoric acid dissolved does not depend on the quantity of acid used but only on its concentration.

- 1026 - **Experiments on the fertilising Value of "Supra" disintegrated Phosphate, in Belgium** (1). — GRAFTIAU, J., with the collaboration of GIELE, J. and HARDY, P., in *Bulletin de la Société Chimique de Belgique*, Vol. 31, pp. 22-23. Brussels, 1922.

Disintegrated phosphates are already produced in large quantities: they are obtained by calcining, in a rotary kiln, a mixture of calcareous phosphate with substances acting as a flux. The writer has tested "Supra" in pots of varnished wood fibre. Oats were the principal crop, forage cabbages the after crop. The pots were manured identically with 1.5 gm. of nitrogen in the form of nitrate of soda and 28 gm. of potash in the form of sulphate. The pots with phosphoric acid had 0.75 gm. of manure.

The writer describes in detail the course of the experiment from which he draws the following conclusions:

The test shows the high fertilising value of "Supra". The increased yields are much the same as with slag. This manure may be recommended when it is desired to use basic manures. It cannot be mixed either with manures having the power of setting free ammoniacal nitrogen or with superphosphates, exactly like slag. It is important to note that the manure should be kept dry and when spreading the workers should protect their respiratory organs.

- 1027 - **Assimilability of various Phosphate Manures.** — VON WRANGELL, M., in *Landwirtschaftliche Jahrbücher*, Vol. LVII, No. 1, pp. 1-77. Berlin, March 1922.

For a long time the effects of various phosphates on crops in different conditions of environment has been studied at the Experimental Station of Hohenheim (Germany). At first experiments were made with various crude phosphates in the form of oolite, Norwegian crystalline fluorapatite, and of phosphates containing carbonic acid, such as carbonatapatite, staffelite and Lahn's phosphorite. The conditions and the process of absorption in two special plants, mustard and maize, were studied by examining the various chemical reactions of the liquids in the soil. Phosphates of lime soluble with difficulty (crude phosphates or pure tricalcic phosphate) were used and quite different effects were obtained in the two plants, especially regarding the ratio of absorption between the molecule of lime and that of phosphoric acid. This molecular ratio is called the "lime-phosphoric acid factor". It at once seemed probable that from this ratio it would be possible to deduce the capacity of plants for using insoluble phosphates, and to find some explanation regarding the manner in which assimilation of phosphoric acid is caused.

The numerous experiments made show this theoretical supposition to be correct, and this factor may possess great importance. By examining the value of this factor in various plants it is found that the phosphates of lime are not well absorbed by cereals, especially by wheat, rye and barley (1.3); slightly better by oats (1.6) and by maize (3). The potato comes next, then leguminous plants such as beans, peas; clover absorbs well (12), turnips, sugar beet, mangolds and hemp absorb very well (23), tobacco and mustard also well (15). In the recent work of PFEIFFER and

(1) See R. May 1919, No. 572. (Ed.)

RIPPEL, "Behaviour of various plants under the action of phosphates soluble with difficulty" (*Journal für Landwirtschaft*, LXIX, p. 165), in which the "lime-phosphoric acid" factor is calculated, the important discovery is given prominence that with a progressively intensive manuring with phosphoric acid the "lime-phosphoric acid" factor decreases regularly.

The reaction of the soil has very great importance for the rate and degree of absorption of phosphoric acid; the acid reaction facilitates and increases its absorption. The absorption of phosphoric acid by a plant which grows in an acid soil is very great: on the other hand the alkaline reaction increases the absorption of lime. Special experiments made with oats and maize by applying to excess alkaline manuring (with silicate of potassium, nitrate of potassium, nitrate of ammonia and gypsum) and acid manuring (with sulphate of ammonia and sulphate of potassium) have plainly proved that the "lime-phosphoric acid" factor undergoes great variations. To ascertain to what extent plants withstand an acid or alkaline manuring, special experiments were made in cement boxes, made waterproof with a layer of paraffin, in which the reaction of the soil could be quantitatively controlled. In the case of maize the results were such that poisoning by alkaline reaction might be inferred whereas mustard consumed the insoluble phosphates even in the case of alkaline nitrogenous manuring. These experiments also prove a remarkable sensitiveness of mustard to chlorine. In fact the chloride of ammonia produces toxic effects on that plant. Further experiments are in progress in order to ascertain the function of chlorine. During growth a bright green coloration of the soil was also noticed, which may perhaps be explained by the presence of micro-organisms previously studied by REICHNOW, WOLLENWEBER, KNOP and LÖW. Growth was afterwards affected by some infection, as happened in the case of some experiments of comparative manuring with oolite and with carbonate of lime. Experiments were then made to determine what amount of lime is required to prevent the absorption of phosphoric acid. Some plants showed evidence of attempts to eliminate from their circulation the excess of lime which prevented that absorption: for example endogenetical production of oxalic acid, as the writer suggested in a previous work and as the researches of STALK confirm. To control the process sand was neutralised by a special treatment invented by the writer for cultures, by depriving them of all the carbonate of lime present. The sand was next manured and for each molecule of tricalcic phosphate 1 — 2 — 5 — 9 — 20 — 75 — 225 — 675 molecules of carbonate of lime were added progressively and respectively for each culture. Oats did well in the absence of carbonate of lime; the yield diminished by one half with one molecule of carbonate, by one third with two molecules; it was almost nil with larger quantities. On the other hand, maize continued to prosper in a satisfactory manner even with 5 — 9 — 20 molecules of carbonate.

Although in a less degree, the action of tricalcic phosphate can be noticed even in the presence of 225 and 675 molecules. The writer asserts that, the conditions of the soil being identical, there will never be an equal

reaction under the influence of tricalcic phosphate for two plants physiologically different. If plants of mustard and maize are grown in neutral soil to which has been added tricalcic phosphate the nutritive functions will be disturbed and the mustard will die for lack of lime and the maize for want of phosphoric acid, as can be proved by analysis of the ash. The writer attributes the greatest importance to the analysis of the ash. The researches of KRÜGER, EMMERLING and the recent experiments prove therefore that some plant species, although not all, utilise tricalcic phosphate in a satisfactory manner, even in the presence of lime.

The susceptibility of lupines with regard to lime, has been known for many years and has formed the subject of many publications, but hitherto with no definite result. On this subject the researches of PREIFFER, CREYDT, WALTER MEVIUS, KAPPEN, MERKENSCHLAGER, SCHULTZ-LUPITZ and other writers are worth noting; the experiments of BÜSGEN, according to the author, are contradictory. The writer thinks that the injuries caused by lime in lupines result from disturbances in the nutritive functions; easily soluble or physiologically alkaline salts of lime, such as the nitrate and carbonate especially, might, by their presence, prevent the absorption of phosphoric acid. This hypothesis, already expressed by the writer in a previous work, was recently confirmed conclusively.

The preceding observations lead to the establishment of a constant law of polarity between lime and phosphoric acid. Thus it has been ascertained that with manurings of phosphates of lime the absorption of phosphoric acid is very limited. The data of EMMERLING vary between 4 and 17 %, according to the nature of the soil. In experimental stations 30 % is not exceeded. The writer made experiments with tertiary phosphates of iron, aluminium and magnesium. Contrary to the general opinion, the results obtained with the first two were good and those with phosphate of magnesium were remarkable. The methods of manuring employed up to the present are therefore too exclusive in the sense that only phosphates of lime have been considered. The recent experiments have shown that, where the plant does not require lime, the other compounds of phosphoric acid should always be preferred. Regarding the specific case of phospho-magnesian manuring, the writer examines the two processes of assimilation which take place in the plant, namely that of absorption at the expense of ionic soil solutions and that of direct total absorption, without basic residue, of particles of phosphate of magnesium.

The writer next examines and controverts the theory of LOEW, according to which the two substances, calcium and magnesium, should be furnished to plants in a certain relative proportion in order that the best results should be obtained. The writer maintains on the contrary that the form of combination of the two elements is much more important than the quantitative proportion; for example, carbonate of magnesium is injurious, while the sulphate is favourable to growth. EHRENBURG'S law on the lime-potash stoichiometrical ratios, according to which the presence of lime prevents absorption of potash, enters this field of research, the numerical results of which do not always seem reliable.

The practical importance of this subject is worth consideration. In the first place it has been proved that the choice of the base in phosphoric compounds is far from being negligible.

The phosphate "Rhénania" and basic slag, the composition of which is still uncertain, have no great importance. More interesting is the problem whether nitrogen or phosphorus should be preferred. In LIEBIG'S time, mineral phosphates were undoubtedly preferred, but it is possible that since then the soils have changed under the action of a continued mineral manuring. At the present time it is incontestable that nitrogen gives better results than phosphoric acid. Furthermore the quite special conditions of Germany at present must be considered: nitrogenous manuring was already in deficit in many lands before the war, because of its high cost: the soils are on the average more sensitive to nitrogen than to phosphoric acid; then from an economical and national standpoint, nitrogen and potash are produced by German industry, while phosphates have to be imported from abroad. In conclusion the use of other compounds of phosphoric acid in replacement of those hitherto used as artificial manures seems to allow a good result by making possible the disposal of reserves of phosphoric acid. The writer next describes the experimental part of his researches, analysing in detail and chronologically the results given by each experiment, considering in a special way the conditions of soil, irrigation and the manuring.

The description of the experiments is supplemented by 23 large tables in which are grouped the numerical data relative to them, and by 2 photographic plates.

A. d. B.

1028 - **The Supply of Nitrogen for Agriculture in Germany.** -- *Wirtschaft und Statistik*, Year 11, No. 3, pp. 72-73, 2 figs Berlin, Feb. 1922

From 1913 to 1922 the German production of nitrogen has been the following:—

1913/14 . . . . .	110 000 tons	1920/21 . . . . .	242 000 tons
1918/19 . . . . .	115 000 »	1921/22 . . . . .	290 000 »
1919/20 . . . . .	159 000 »		

Half the production consists of sulphate of ammonia and the other half of nitrate and cyanamide of calcium.

TABLE I. — *Quantities (in tons) of fertilising matter consumed in German agriculture from 1913 to 1920.*

Year of manuring	Nitrogen	Phosphoric acid	Potash
1913. . . . .	210 000	630 000	557 000
1918. . . . .	115 500	231 000	670 000
1919. . . . .	159 200	137 800	756 000
1920. . . . .	212 000	268 000	578 000

The figures in Table I are represented graphically (in thousands of tons) in the annexed diagram.

For the year 1921-22 the use of 290 000 tons of nitrogen is estimated and it is expected that the whole of this amount can be supplied by national production. Besides artificial fertilisers must also be reckoned food stuffs, the residues of which (farmyard manure) supply the soil with nutritive principles. This is shown in Table II.

TABLE II. — *Differences in the use of various manures in time of peace and in time of war (in tons)*

Products	1913 Excess of imports (+ = excess of exports)	1920 Excess of imports (+ = excess of exports)
Cattle foods . . . . .	6 282 000	540 000
Crude feeding matter . . . . .	1 734 000	329 000
Manures :		
Crude phosphates . . . . .	297 000	116 000
Nitrogenous manures . . . . .	710 000	(+ 14 000)
Organic manures . . . . .	99 000	1 000
Potash salts . . . . .	(+ 1 676 000)	(+ 843 000)

TABLE III. — *Yields per hectare of the principal crops, in qrs.*

Products	1913	Average of the years 1904-1913	1921
Rye . . . . .	19.2	17.2	15.9
Wheat . . . . .	24.1	20.7	20.4
Barley . . . . .	22.0	19.8	17.1
Oats . . . . .	22.0	19.0	15.1
Potatoes . . . . .	157.1	135.1	98.8
Sugar beet . . . . .	—	287.8	204.9
Hay . . . . .	49.1	43.0	31.5

TABLE IV. — *Price obtained for nitrogen (in marks per kg.)*

Date	Sulphate of ammonia	Nitrate of Soda	Cyanamide of Calcium
1914 . . . . .	1.35	1.40	1.15
11 January 1916 . . . . .	1.48	—	1.74
13 March 1919 . . . . .	2.60	3.55	2.40
1 October 1919 . . . . .	5.40	6.50	5.40
1 March 1920 . . . . .	12.00	15.00	10.70
1 June 1921 . . . . .	14.50	17.50	12.90
7 October 1921 . . . . .	17.40	24.00	15.50
3 December 1921 . . . . .	25.80	31.20	23.00
<i>Increase in price at the end of 1921 (in proportion to the pre-war price equal to 1)</i>	19.1	22.3	20.0

The cessation of the importation of Chili saltpetre and the great decrease in the importation of cattle foods and crude feeding matter are of special importance. Concentrated foods admittedly supply annually 100 000 tons of nitrogen to German agriculture. The effect of the decrease in manuring is shown by the decreased yield per hectare of the principal crops (see Table III page 1203).

*Diagram representing the quantities (in thousands of tons) of fertilising matter consumed in German agriculture from 1913 to 1920.*

EXPLANATION :

- A = Potash ( $K_2O$ )
- B = Phosphoric acid ( $P_2O_5$ )
- C = Nitrogen (N)
- K = Nitrogen contained in Chili saltpetre.

The value of the nitrogen estimated to be used for the year 1921-22, according to the present price, is 7 milliards of marks. Taking the dollar at 180 marks, Chili saltpetre costs double the price of nitrate of soda produced in Germany.

A. d. B.

1029 - **Fixation of Atmospheric Nitrogen, and the Fabrication of Nitrogenous Manures in Egypt.** — HUGHES, F., in *Ministry of Agriculture, Egypt. Technical and Scientific Series, Bulletin No. 20*. Cairo, 1922.

After a general survey of the question of the fixation of atmospheric nitrogen, the author deals more especially with the problem of nitrogenous manures in Egypt in relation to soil conditions.

Before the war, Egypt spent some £15,600,000 annually on fertilisers, chiefly nitrate of soda and sulphate of ammonia. So far experiments have not been worked out to any large extent for Egyptian soils, but it may be concluded *a priori* that nitrate of lime is more useful than nitrate of soda. One of the chief drawbacks in Egyptian farming is the presence in the soil of small quantities of sodium salts, usually chloride, sulphate and bicarbonate and rarely carbonate, which is the most troublesome of all. Now as sodium is not one of the essential elements for plant growth the nitrogen from the nitrate of soda may be taken up in the form of nitrate of potash or nitrate of lime and the soda residuum will increase the amount of salts already present in the soil.

Pot experiments have been made with soil from the Nile bank to which various manures were added. Nitrate of lime proved the most effective. Taking the increase brought about by nitrate of soda (average) as 100 the following results are obtained for other fertilisers:— nitrate of lime 104; sulphate of ammonia 92; nitrate of ammonia 98; cyanamide 59. The slowness of the action of organic manures appears to be due to a failure to change the latter to nitrate, but the shortness of the time factor is no doubt of importance in this connection.

As regards the industrial aspect of the question the author states that at Assouan power is available of well over 250,000 HP which would serve to supply some 750,000 tons of nitrate of lime for six months, that is, more than the pre-war demand of the country.

Transport costs are very high in Egypt and hence the preference for concentrated fertilisers such as urea, superphosphates with 40% phosphoric acid content etc.

On the assumption that 100,000 tons of fertilisers were utilized annually, the increased wheat production is estimated at 6 million bushels (17%), which would give a total crop amounting to about 35 millions bushels.

A. d. B.

1030 - **Fertilisers for Beans.** — See No. 1050 of this *Review*.

1031 - **Seeds and Plants introduced by the Agricultural Department of the United States.** — *Inventory of Seeds and Plants imported by the Office of Foreign Seed and Plant Introduction during the Periods from: January 1 to March 31, 1917; April 1 to June 30, 1917, July 1 to September 1917; No. 30, 83 pp.; No. 51, 100 pp.; No. 52, 55 pp.* Washington, 1922.

In the first three parts of the inventory of imported plants (which also gives the places where the plants were collected, their description, and the uses to which they could be applied, etc.), FAIRCHILD, Agricultural Explorer in charge, mentions the following:

AGRICULTURAL  
BOTANY,  
CHEMISTRY  
AND  
PHYSIOLOGY  
OF PLANTS

**CEREALS.** — A variety of maize (*Zea Mays*) with bitter leaves coming from Rosario (Argentina). Although its yield is somewhat low, and it is liable to attack from grasshoppers, this species of maize can be cultivated advantageously in districts infested with these insects which only eat its leaves when there is absolutely nothing else to be found, as they dislike the bitter taste. This maize could perhaps be employed in crossing experiments undertaken with the view of obtaining forms resistant to disease and to insect attack.

**FORAGE PLANTS.** — Tussock Grass (*Poa flabellata*) a native of the Falkland Isles, where it grows on the peaty soil near the sea. It makes a good forage and the roots are edible and have a pleasant flavour.

Four forage Gramineae known as "Satintop" viz., *Andropogon erianthoides*, *A. intermedius*, *Chaetochloa barbata* and *Panicum decompositum*, imported from New South Wales are noted for their hardiness and heavy yield.

A collection of 11 species of *Poa* from the Belgian Congo sent by the Leverville Agrostological Garden.

*Panicum serratum* giving pasturage for sheep at an altitude of 2000 m. near Pretoria (South Africa) is worth trying on the mountain pastures of the Pacific slopes.

Meadow rice grass (*Microlaena stipoides*) from Australia and New Zealand, where it carries large numbers of stock, also merits a trial.

Three selected kinds of Red Clover (*Trifolium pratense*), sent by the Royal Danish Agricultural Society: Tystofte No. 71, early; Tystofte No. 87, late; Hersnap late; the last is the best, and is already grown on a large scale in Denmark.

**KITCHEN GARDEN PLANTS.** — A wild tomato from Cristobal (Panama Canal region), *Lycopersicon esculentum* resistant to wilt (*Bacillus Solanacearum*).

Manhattan melon (*Citrullus vulgaris*) from Natal.

The fruits can be kept for 6 months; they are much used in South Africa for preserves and are very suitable for this purpose owing to their thick rind which has a high pectin content.

*Allium triquetrum*, the form bred by TRABUT with very delicately flavoured bulbs.

Pepino (*Solanum muricatum*) from Ecuador, where there are two varieties, one white and the other red, that produce almost seedless fruits making excellent salad.

*Gnetum gnemon* from the Botanic Garden of Buitenzorg (Java), a shrub growing from the Khasi Mts (British India) to Singapore. It has edible fruits, the leaves can be eaten like spinach and the bark furnishes a stout fibre.

Lorocco vine, an undetermined Apocynaea coming from Tegucicalpa, Honduras. It is a perennial climber with deciduous leaves and thrives in temperate climates: the flowers and floral buds are used as a condiment.

A collection of excellent varieties of "pai t'sai" (*Brassica pechi-*

*nensis*), collected in the Provinces of Shantung and Hankow (China). Some kinds can be sown in April-May, August, and September.

ORNAMENTAL PLANTS. — Several strong, beautiful species of *Cotoneaster* suitable for flower gardens. Species of *Cotoneaster* are widely grown in England, but the English forms when introduced into the United States proved too delicate to be generally cultivated.

From Guatemala have been imported : the Monkey-flower tree (*Phyllocarpus septentrionalis*), which bears brilliant red flowers in January — *Lignum vitae* (*Guaiacum guatemalense*), an ever-green shrub with conspicuous purple flowers ; this plant was already grown in Florida. — *Salvia Hempssteadiana*, with fine clusters of blue flowers ; could be used as a substitute for *S. patens*, a handsome, but delicate plant.

"Pacayito" (*Chamaedorea* sp.), one of the few dwarf palms that can be grown in small pots in dwelling-rooms.

A collection of *Berberis* has been obtained from Columbia, Chili, Tierra del Fuego (Argentina), the Caucasus, Himalaya, Thibet and China. All the varieties are very hardy ; some are evergreen, some bear edible fruits while others are seedless. An evergreen type producing large seedless fruits suitable for jelly-making could easily be obtained by crossing the various types.

A collection of different species of *Styrax* purchased by a Paris firm.

*Ficus pseudopalma* from Corregidor (Philippines), with a crown of leaves which are about 1 m. in length.

*Casuarina stricta* and *C. Cunninghamiana* natives of Australia. It is hoped that they will prove hardier than *C. equisetifolia* which grows in millions on the road-sides of South Florida.

"Kadoesji" (*Cephalocereus sanguinosus*), a cactus with fine edible fruits.

*Butia capitata* (1) a hardy palm bearing eatable fruit. A native of Argentina.

PLANTS YIELDING OILS, TANNINS AND GUMS. — "Olivo tafahi" (*Olea europaea*), a native of the Fayum desert (Egypt). It owes its name, which signifies apple-olive, to the unusual size of the fruits ; these are 4.5 cm. in length and have a short diameter of 3 cm.

Soft lumbang tree (*Aleurites trisperma*) yields a drying-oil similar to the "tung oil" of China (2)

*Tamarix aphylla* ; the seeds were sent from Algiers by TRABUT. The plant is a native of the Sahara. A mite, *Eriophyes tlaiae* produces on the leaves galls containing 45 % of pyrogallin tannin largely used for tanning purposes by the natives. This plant, which has been tested in the Coachella Valley (United States), has grown to a greater size than any other arborescent species, the girth of shrubs aged 2 ½ years is 90 cm. at 30 cm. from the ground.

(1) See R. July 1921, No. 716. (Ed.)

(2) See R. February 1920, No. 254. (Ed.)

Two African gum acacias from Khartoum (Sudan) *Acacia albida* and *A. Segal* (1).

VARIOUS PLANTS. — A species of *Amaranthus* (*A. paniculatus*) from Cashmere with farinaceous seeds forming the staple food of the mountain tribes of several parts of India. In these regions, the plant is called "raiigira".

The "Pacaya palm" (*Chamaedorea* sp.) of Guatemala, where it is much grown for its inflorescences which are eaten as salad.

*Calycophyllum brevipes*, a Venezuelan *Cucurbitacea* with orange-yellow fruits having a sweet pulp and containing (perhaps in the loculi or seeds) a substance more pungent than is found in the capsicum. It is called "parcha de culetra" or the serpent's passionflower. Perhaps it is the "coco de mono" to which is attributed depilatory properties.

Kafir orange (*Strychnos spinosa*), a Loganiaceae from British East Africa imported from Nairobi. The inner part of the bark of this shrub appears to be an antidote to snake-bites. The fruit is edible and resembles an orange: *Strychnos spinosa* grows well in South Florida.

Seeds of *Bambostulda* from Dehra Dun, India. This species is easily cultivated in Panama and at Porto Rico. Its stems make excellent fishingrods.

*Cudrania* (*Machera*) *tricuspidata* (2) a Moraceae that has become acclimatized at Augusta, Georgia (United States) and gives a heavy yield. Silkworms fed on the leaves of this tree produce a silk different from the silk obtained from silkworms fed on mulberry leaves, and better-toned strings for musical instruments can be made from it. As silk is a typical protein, any change in its characters may be of importance for the study of alterations in other proteins.

A new annual Leguminosae (*Aeschynomene* sp.) for green manure. This plant is very well provided with root-nodules and could perhaps be used as a forage plant. It comes from Costa Rica.

Two Rubiaceae sent from Buitenzorg (Java): *Pavetta indica* and *Psychotria bacteriophila*; the latter has also been brought from the Comoro Islands, Madagascar, where it is indigenous: the first named grows throughout India and Malaysia. Both these plants are remarkable for their leaf nodules which resemble the root nodules of leguminosae and, like them, possess the power of fixing atmospheric nitrogen. Their capacity in this respect will be tested in Florida.

VINES. — *Vitis tiliacifolia*, a native of Guatemala, where its fruit is much used for making jellies. It grows well in South Florida, and would make a good stock for American and European vines.

"Callulos" (*Vitis* sp.), from the Mexican valleys; the berries are large and do not fall off when ripe, as in the case of most tropical vines. It is therefore suited to tropical countries and can be cultivated in Florida.

FRUIT TREES, SHRUBS AND BUSHES. — A collection of new varieties

(1) See R. 1921, Nos. 292 and 630. (Ed.)

(2) See R. March 1916, No. 338. (Ed.)

of apple trees raised from seed and sent by the Central Experimental Farm, Ottawa (Canada). Five of them belonging to the Wealthy variety are remarkable for hardiness, resistance to cold and the the flavour of their fruit.

Sixteen different species or hybrids, of the genus *Pyrus* (*P. amygdali-formis* — *P. betulaeifolia* — *P. Bretschneideri* — *P. Calleryana* — *P. phaeocarpa globosa* — *P. heterophylla* — *P. Korshinskyi* — *P. malifolia* — *P. Michauxii* — *P. oblongifolia* — *P. ussuriensis* Maxim — *P. ussuriensis ovoidea* Rehder — *P. Pashia* — *P. salicifolia* — *P. serotina* — *P. serrulata*) are worth trying as stocks for grafting. This is a matter of special interest at the present time as an effort is being made to eliminate all European fruit trees as stocks and to substitute for them trees with a more uniform root system.

Several collections of species and varieties of pear tree from the Province of Chihli (China) amongst which are the "pai li" and other cultivated varieties of *Pyrus ussuriensis* with edible fruit; another pear-tree possibly new to science and used as a stock by Chinese fruit-growers; cultivated varieties of *P. Lindleyi* etc. The cultivated varieties of *P. ussuriensis* and *P. Lindleyi* that are resistant to the blight or necrosis of the branches of the apple and pear-tree (*Bacillus amylovorus* [Burril] Trev) may prove of great value in crossing experiments aiming at producing forms that are resistant to this parasite.

The nearly-related genus *Docynia*, of which the species *D. Delavayi* has been imported from West Szechwan and the Yunnan, may also prove useful in the same direction. The lastnamed is also a very vigorous stock for grafting.

Collections of Chinese varieties of peach (*Amygdalus* spp.) from the Province of Kiangsu (China).

"Yacarati-à" or "papaya" (*Carica dodecaphylla*), indigenous in the Provinces of Misiones and Carrantes (Argentina), has been the object of interesting comparative trials with *C. Papaya*, and of crossing experiments. Crosses have already been obtained between *C. caudamarcensis* and *C. Papaya*.

Seeds of *Castanea mollissima* from Nankin (China) useful in crossing for the purpose of obtaining orchard chestnut-trees resistant to bark disease (*Endothia parasitica*).

Seeds of *Castanopsis sclerophylla* from Nankin probably useful for the same purpose.

*Ziziphus mauritiana*, cultivated in India (the best varieties being grown at Kandahar); its fruits are eaten fresh or dried. *Z. mucronata* from Kandahar. These tropical species are to be added to the already rich collection of varieties of *Ziziphus* with large and delicious fruits which have already been introduced from China into the United States where they are grafted on the common varieties and will soon be generally cultivated.

The Kansu virburnum (*V. kansuense*), of which the fruit is employed in preserve-making, could perhaps be used for the improvement of the native North American species (*V. americanum*).

From Canada, France, England, Italy and Java, several collections of red, black and yellow currants have been imported. Currants are little grown in the United States, but would probably do well in the Northern States of the Union.

*Rubus racemosus* from the Nilgin Mts. (British India).

Several collections of avocado (*Persea americana*), made in Guatemala by POPENHOE, and containing the following varieties: "panchoy", early — "benik", midseason — "tumin", exceptionally prolific — "kekci", early with small fruits that ripen slowly — "mayapan", one of the best in the collection, in the opinion of POPENHOE — "cabual" with special hazel-nut flavour — "candel" a very small seeded variety — "pankay" found at the altitude of 1500 m. (i. e. higher than for tropical countries) — "tertoh" bearing fruits that weigh 1800 gm. — a hitherto undescribed kind of *Persea* with fleshy persistent calix — "coyo", or "schukte" (*Persea Schiedeana*) a very rare species, also collected by POPENHOE in Guatemala, which is worth introducing into all tropical countries. This plant in the wild state bears fruit which are as good for the table as those produced by *P. americana*; it does not seem to be cultivated in any of the Botanical Gardens of the world. One form has a fine fruit weighing about 2 lb.

Other fruit-bearing species collected by POPENHOE in Guatemala are: the Tortoise-shell custard-apple (*Anona testudinea*), with rather tough-skinned fruits containing large seeds and with pulp free of stone-cells — "cereza", or "capul", the mountain wild cherry-tree (*Prunus salicifolia*), bearing bunches of large fruits (some 18 mm. in diameter) and with a taste similar to that of the ordinary cherry etc.

*Mangifera caesia*, resembling the mango, worth testing as a grafting stock and in crossing experiments.

*Garcinia multiflora* of Kiayingchow, near Swatow (China) produces small fruits of delicious flavour resembling that of the mangostan. As this tree can resist a temperature of  $-3^{\circ}\text{C}$  it could probably be grown in other than tropical countries, while its similarity to the true mangostan might render it useful in selection work.

A hitherto undescribed species of *Rollinia* coming from the valleys of North Columbia, and bearing edible fruit with orange-coloured skin and pulp, and the biribâ (*Rollinia mucosa*), imported from Brazil, form another group of Anonaceae to be added to the collection that is being made for crossing experiments at Miami, Florida.

"Cuatemoya", a hybrid between the "atemoya" (*Anona cherimola*  $\times$  *A. squamosa*) which produces delicious fruit, and the "custard apple", or basket anona (*A. reticulata*), have been obtained by WESTER from the Lamas Experiment Station (Philippines).

Guabioba (*Compomanesia Fenzliana*), a native of Lavras (Minas Geraes, Brazil), a Myrtacea with delicious flavour similar to that of the guava. In the Plant Introduction Garden of Miami, Florida, it has proved resistant to frosts and would probably bear excellent fruit wherever it was cultivated. *Nephelium bassacense* from Cochin China comparable to *N. lappaceum* from Java, which produces a delicious fruit.

*Litoco* (*Calamus* sp.), from Kaingan (Luçon du Nord, Philippines), with bunches of small, slightly acid fruits with a pleasant taste and keeping well.

Tree tomato (*Cyphomandra betacea*), a Solanacea cultivated for its fruit in British East Africa.

FOREST TREES. — A new species of *Picea* (*P. Meyeri*), of large size coming from Shing-hung-sham, in the province of Chihli (China).

Ash from Chinese Turkestan (*Fraxinus potamophila*). This species proved perfectly resistant at Fallon (Nevada), and will be a valuable tree for the poor land of the district.

A black, tropical walnut from Porto-Rico (*Juglans portoricensis*) which attains the height of 20-25 m. and produces fruits 3-5 cm. in length. Useful for the proposed hybridisation trials with the object of obtaining quickly-growing timber walnut trees.

*Prunus serrulata sachalinensis*, which is probably the best wood-producing cherry-tree. It grows to the height of 20 m. Several varieties of a collection of cherry-trees imported from Japan have shown every sign of possible acclimatisation on the Atlantic sea-board of the United States.

"Tzu" (*Catalpa Bungei*), imported from Chekiang (China), a tree of rapid growth. It attains the height of 30 m. and furnishes a very valuable wood for the fancy turnery trade. Much recommended for planting along the ditches and irrigation canals of the semi-arid regions of the United States.

1032 — **New and Noteworthy Philippine Plants** (1). — MERRILL, F. D. (Director and Botanist, Bureau of Science, Manila), in *The Philippine Journal of Science*, Vol. 20, No. 4, pp. 367-476 Manila, April 1922

The 17th of a series of studies published by the author. In the present paper 106 new species are described. Amongst these is included a further description of *Ficus argentea* Blanco, previously known only from BLANCO'S imperfect description. *Polychroa* Loureiro is accepted as the proper generic name for the group long known as *Pellonia* Gandichaud. The few Philippine forms formerly placed in *Polytrema* are now transferred to *Hallieracantha*. Three genera are reported for the first time viz. *Pyrenaria*, *Pleiocarpidia* and *Cowiea*, the latter a recently described genus, previously known by a single species in British North Borneo. A few notes on nomenclature are included, which involve some changes in specific names.

L. V.

1033 — **Nickel and Cobalt in living Organisms.** VERNADSKY, W. J., in *Comptes rendus de l'Académie des Sciences*, Vol. 175, No. 8, p. 382-285 Paris, Aug. 21, 1922

Nickel and cobalt belong by geochemical reactions, by the primary and partly secondary minerals and by their behaviour in the organisms, to the *isomorphous series of magnesium*. The elements which form this series give rise to similar chemical phenomena and to compounds which have similar functions in both the inorganic and organic spheres.

(1) See R. July 1922, No. 697. (Ed.)

In biochemistry, five elements of the series, iron, copper, manganese magnesium and zinc perform similar functions and replace each other. They form an integral part in many complex proteinic pigments which are fundamental in the physiological processes of the animal and vegetable kingdoms :— chlorophyll, hemoglobin, hemocyanin, hemosycotypin, pin-naglobin, etc. Certain physiological phenomena suggest the same chemical facts. It is to be inferred that other elements of the group will also show similar behaviour. These elements are *nickel*, *cobalt*, *cadmium* and possibly also *indium*. The last two have not yet been found in living organisms.

In 1854, J. FORCHHAMMER recognised the presence of nickel and cobalt in marine algae and in the ash of oak ; they have also been casually noted, but hitherto there has been no systematic experimentation.

In these conditions the writer in 1918-19 started experiments at Kief with the co-operation of the Academy of Sciences of the Ukraine, but difficulties were caused by the civil war. However the two elements were found in all the organisms on which experiment was made with L. TSCHOU-GAJEFF'S reagent. In plants, the presence of nickel and cobalt can be determined quantitatively.

The presence of nickel and cobalt was recognised in all the mosses examined from the neighbourhood of Kief. M<sup>me</sup> M. J. BEZSMERTNY, the writer's assistant, found them in the following plants in the district :— *Plantago media* — *Ficaria ranunculoides* — *Salix pratensis* — *Taraxacum officinale* — *Avena pubescens* — *Lamium purpureum* — *Capsella Bursa-pastoris* — *Stratiotes aloides* — *Lysimachia thyrsoflora*. Prof. W. SADIKOV, of the Radium Institute at the Russian Academy of Sciences at Petrograd, found cobalt in *Echium vulgare* L. at Salgnirka, Crimea.

The experiments made by M<sup>me</sup> I. C. STARYNKEWITCH have disclosed the presence of traces of nickel in house mice. L. V.

1034 — Chemical analysis of the Gramineae, *Panicum Maximum*, *P. jumentorum* and *P. barbinode*. — See No. 1053 of this Review.

1035 — Action of soluble Salts of Lead on Plants. — BONNET, F., in *Comptes rendus de l'Académie des Sciences*, Vol. 174, No 7, pp. 488-491. Paris, Feb. 12, 1922.

With the object of determining the action of soluble salts of lead, numerous tests were made in 1914 on Bordeaux wheat, buckwheat, lupin, lentil, cabbage, etc. The seeds, disinfected in alcohol, were set to germinate in distilled water, and the young plants were placed in solutions of various salts of lead of different degrees of strength. The results were as follows :—

1) The plants subjected to a strong dose of salt (decinormal solutions) absorbed the lead, which was only found again in the bark of the roots.

2) The lead taken out of the solutions was found in its entirety in the ash of the roots of the plant tested, and no traces were found in the ashes of the stalks and leaves.

3) Decinormal solutions of acetate or nitrate of lead are toxic for wheat (killed in 20 days), buckwheat (in 7 days), lupin (in 4 days),

balsamine (in 2 days), lentils (in 1 day) and cabbage. At the strengths used, the salts of potassium, magnesium and calcium did not appear to be antidotes of the lead.

4) Acetate and nitrate of lead gave identical results with wheat and cress. The younger the plant when subjected to the test, the more sensitive is it to the poison.

5) The more concentrated the solution of the salt, the more active is its absorption.

6) The transpiration of plants subjected to the action of lead was markedly decreased in comparison with plants which were grown in pure water.

Further experiments made by the writer in 1921 have fully confirmed these results. They have further shown that the salts of lead cause important modifications in the external morphology of the roots. In pure water roots are long and much branched, thin and unfurnished with absorbent hairs; in solutions of lead they are, on the contrary, short, thick and provided with numerous absorbent hairs. When the growth of the stalk is arrested by the lead salts, the growth of the roots is continued, though more slowly, in the same proportions as in normal conditions.

1036 - **The Role of Manganese in Plants.** — MC HARGUE, J. S., in *The Journal of the American Chemical Society*, Vol. 44, No. 7, pp. 1592-1598. Washington, July 1922

The presence of manganese in the soil and in the ash of plants was first detected by SCHEELÉ in 1774, but during the nineteenth century few researches were made as to the function of this element. Mention should be made of the work of BERTRAND (1897) and of BRENCLEY (1914) who concluded that manganese is an element essential to the economy of plant life. During the last 20 years, considerable attention has been given to the agricultural problem of manganese and the author knows of as many as 150 investigations on the subject.

While engaged on botanical research work necessitating a test for manganese, the author found that the latter is present in the seeds of many plants, and especially in the seed-coats, the integument of wheat containing approximately 0.02 % of its dry weight of manganese. This induced him to make investigations for the purpose of determining the functions of manganese by growing seedlings in PFEIFFER'S nutrient solution after carefully removing all trace of manganese from the compounds used in its preparation. This precaution was necessary as in previous experiments the calcium, magnesium and iron salts used as plant nutrients were found to have contained the small percentage of manganese required by the seedlings. Several lots of wheat were grown, some with and others without manganese. No difference between them was noticed for the first 6 or 8 weeks, but a little later the plants deprived of manganese behaved very differently from the others; their leaves, owing to lack of chlorophyll, became yellowish-green instead of deep green. The differences between the two sets of plants increased as they approached maturity,

those without manganese made a stunted growth and produced no seed. The dry weight of the plants given manganese exceeded by 135 % that of those deprived the element.

Other experiments were made with Alaska peas with very similar results. When analysed, the plants that had received manganese were found to contain 0.179 % of this element, whereas those to which no manganese had been added showed only traces derived probably from the seeds. The importance of manganese to plant development was also proved by growing several different species on sand ; at the present time, there are 20 different series of experiments in progress on the subject.

It may be assumed that the small quantity of manganese always present in the seed is sufficient to maintain a normal metabolic process during the first few weeks of growth ; afterwards the manganese is used up in the formation of new tissues and plants that do not receive a further supply of this necessary element become chlorotic. The first change to be noted is a lack in the development of chlorophyll in the lately formed tissues and the growing parts ; finally the tips of the branches die back, and the plant almost ceases to develop further.

It appears that leguminous plants are more sensitive to want of manganese than non-legumes ; this suggests that the element is concerned in nitrogen assimilation and the synthesis of proteins. Manganese apparently plays the part of a necessary catalyst in plant metabolism, and together with iron, functions in the synthesis of chlorophyll. A. de B.

1037 - **Influence of Lime on Germination.** — MAQUENNE, L. and CERIGHELLI, R., in *Comptes rendus de l'Académie des Sciences*, Vol. 171, No. 20, pp. 1270-1272. Paris, May 15, 1922.

MAQUENNE in collaboration with DEMOUSSY, has shown that lime is indispensable to germination ; even in very small quantities it triples the length of the roots of peas in 6 days when compared with pure water cultures (1).

The writers have examined the question again and made weight, tests independently of tests by length, and extended their experiments to various kinds of seeds, namely : peas, wheat, lentil, cabbage, cabbage lettuce, radish, buckwheat and maize. The seeds were washed in sterilised water for 24 hours and the maize seeds were sterilised with a 2 per 1000 solution of sublimate. They were then made to germinate in sand soaked in pure distilled water. After 2 or 3 days they were treated partly with pure distilled water and partly with a 1 millionth solution of sulphate of lime in very weak proportions, similar to those obtained by heating pure water in a burnt clay beaker, which corresponds to about  $\frac{1}{25}$  of the lime contained in Paris spring water. The growth took place partly in water or in a calcic solution, partly in sand soaked in water or solution. The temperature was maintained at about 20° C. and the experiments were made in the dark. They were continued as long

(1) See R. 1917, No. 813 (Ed)

as growth of the young plants in the calcic solution lasted, while the growth of the plants in pure water ceased much earlier.

The favourable action of lime on growth was confirmed for all the seeds, both as regards length and weight. The action was more marked in the roots than in the stalks. At the same time there was a total loss of dry matter, without doubt caused by the fact that respiration had become more active in the calcic solution owing to the larger growth of the young plant and was not compensated by photosynthesis, as growth took place in the dark. Maize alone seemed to be an exception, perhaps on account of the abundance of its reserves. The reserves were used in unequal proportions, both absolutely and in proportion to final weight, which is in agreement with the earlier observations of MAZÉ. In the seeds of cabbage, buckwheat and radish, the reserves diminished to a slightly less degree than in the control; consequently the writer suspects some errors in the experiments. In the others the diminution was more marked. In any case, lime exerts slight influence on the organisation of the reserves, which proves that it does not act of its own accord on respiration.

1038 - **Effect of Röntgen Rayson Cells of *Vicia faba*.** — KOMURO, H (Botanical Institute, College of Agriculture, Imperial University, Tokyo), in *The Botanical Magazine*, Vol. XXXVI, No. 424, pp 41-45 Tokyo, April 1922

Seeds of *Vicia Faba* (var. "Hyôgo") were steeped in water for 77 hours (until they had absorbed 57.87 % moisture), and exposed to rays at various intensities (20 H, 40 H and 50 H). and were then sown in sand. After 8 days, the tips of the radicles were fixed in FLEMING'S fluid together with controls (stained sections etc.). The most noticeable changes were seen with the radicles of specially irradiated seeds: enlargement of the cells of parenchymatous tissue sometimes to an unnatural size and of the nucleus; increase in the number of nucleoli; vacuolisation of nucleolus and cytoplasm, decrease of chromatic substance (karyolytic and occasional pycnotic conditions). Various physiological changes are evident (mitosis, asymmetrical mitosis, multinucleated cells etc.). There is an obvious effect on tissues as a whole. The modifications resulting from intense rays, are considered by the author to be partly due to lessened vitality of the cytoplasm (senescence), that is insufficient for normal division. The author believes the degenerative changes of tumour cells to be of a similar nature.

1039 - **The Effect of Iron and Aluminium Salts upon the Growth of Maize.** — ARNDT, C. H., in *American Journal of Botany*, Vol. 9, No. 2, pp. 47-71, 6 figs, 1 Table, bibliography of 46 works. Brooklyn, N. Y., February 1911.

The investigations of HOFFER and CARR on maize diseases have shown that a brown or brownish-purple discoloration of the lower portion of the nodal tissue is often associated with evidences of malnutrition and root-rot. Chemical analysis revealed the presence of considerable quantities of iron and aluminium in the discoloured areas. The injection of iron salts produced a similar change of colour, increased the ca-

talase and oxidase activities, and reduced the H-ion concentration. Aluminium salts produced no discoloration, but their effect upon the physiological activities were similar to those exerted by iron salts. Stalk and root-rot organisms were usually associated with the accumulation of iron and aluminium in the coloured area.

In 1915 BORDNAR reported a correlation between a high aluminium content of the sugar beet and its infection by bacterial organisms. His analyses showed that an accumulation of aluminium preceded infection, which indicates that it was related in some way to decreased resistance to infection.

The author gives a historical review of the many experiments that have been made on the subject of the toxic action upon plants of an excess of iron and aluminium (which is generally attributed to the increased acidity of the soil), and on the different effects of the various salts.

The object of the author's investigations was to determine the form and conditions of the toxic action of iron and aluminium salts upon maize and he gives a detailed account of the technique employed. Solution cultures were made in the main part of this experimental work, the results being checked with sand cultures. The solution chosen was the one employed satisfactorily by HARTWELL and PEMBER for studying the effect of aluminium sulphate on barley and rye. It contained: acid calcium phosphate, calcium nitrate, ammonium nitrate, potassium chloride, magnesium sulphate with traces of aluminium, manganese and zinc.

The author also tried a quite different and less complicated solution containing acid potassium phosphate, calcium nitrate and magnesium sulphate. This solution was recommended by the Committee on the Salt Requirements of Representative Agricultural Plants.

The iron phosphate behaved very differently in the two solutions.

In the first, the best results were obtained with 7 mg. per litre; with larger or smaller amounts the maize was less vigorous, whereas higher concentrations proved distinctly toxic.

In the second solution the same salt remained inactive, even when used in quantities 5 times as large as in that mentioned above.

The action of the various iron salts was different; thus optimum growth was obtained in the second solution with 0.0005 N. ferrous sulphate, whereas a 0.001 N., or 0.002 N. concentration of ferric nitrate produced a precipitation and the plants became chlorotic. Ferrous sulphate was almost twice as toxic as ferric sulphate, for the latter was more readily precipitated and its depressing effect was closely related to the H-ion concentration produced by its hydrolysis or precipitation.

Sulphuric, nitric and hydrochloric acids were about equally toxic when added to either solution in low concentration. Sulphuric acid is however the best tolerated, especially by the roots. The aluminium and iron salts of these acids behaved in the same manner, their effect depending upon the acid radical.

An initial H-ion concentration less than pH = 3.7 had little effect upon the rate of growth, for in most cases, the plant tended to shift the reac

tion towards neutrality. In this it was not however always successful; thus when ferrous sulphate and certain concentrations of the chlorides were added to the cultures, plant growth increased the initial H-ion concentration of the solution. The reaction was most readily shifted towards neutrality when the acidity was due to sulphuric acid which, as has been seen, had the least depressing action upon growth and therefore the change in the reaction was proportional to the size and activity of the plant.

In the first solution, the aluminium salts remained in solution and were directly toxic, in the second, they were readily precipitated and hence exerted an indirect toxic action due to the H-ion concentration produced. The nitrate seemed to be somewhat more toxic than the other aluminium salts and showed a greater tendency to produce chlorosis.

Both iron and aluminium salts collected in the lower portion of the nodal region, but only the first produced discoloration.

In sand, the toxicity of the acid and salts was much reduced, higher concentrations being needed to produce the same effects.

1040 - **Growth of Plants in Relation to Soil Humidity.** — See No. 1014 of this *Review*.

1041 - **Reaction in Fresh Water caused by Aquatic Plants.** — LAPICQUE, L., and KERGOMARD, Thérèse, in *Comptes rendus de la Société de Biologie*, Vol. LXXXVII, No. 26 pp. 512-515. Paris, July 15, 1922.

The writers have experimented on *Spirogyra* and *Elodea canadensis*; they could not make use of *Potamogeton* and Algae (*Mongeotia*?) taken from the Seine because these plants were too laden with bacteria and animalculae which exerted a disturbing action.

They arranged the plants in open vessels containing Seine water or spring water. These two waters had a concentration of hydrogen ions (pH) respectively equal to 7.3 and 7.6: leaving the former standing in the open air its alkalinity slowly increased until it reached pH = 7.8, evidently due to the escape of carbonic acid gas, produced by microorganisms in the pipes. Under the action of aquatic plants in the proportion of 1 gm. of green matter to 50-100 cubic cm. of water, the alkalinity decreased in the dark until a slight acidity was attained, that is to say that it was less than pH = 7, whereas in the light the alkalinity increased and in the sun could, in a few hours, exceed pH = 9 and even reach pH = 10. This action decreased when the sky was overcast.

It is evident that two opposite actions came into play, namely expiration of carbonic acid, which caused the acidity to increase, and chlorophyll assimilation, which caused it to decrease, a fact previously demonstrated by LOEB, by OSTERHOUT, who made use of it as a method for measuring chlorophyll activity and by WURMSER who made much use of that method. The experiments of these writers, made on marine algae had shown only relatively slight variations, not exceeding a logarithmic unit, while in the course of the above-mentioned experiments the variation reached three units.

L. V.

[1922-1941]

1042 - **Effect of Transpiration on Absorption of Salts by the Plant.** — MUENCHER, W. C., in *American Journal of Botany*, Vol 9, No. 6, pp. 311-329, bibliography of 22 works. Brooklyn, N. Y., June 1922.

Several contradictory reports have been issued in connection with this subject. Some men of science state that transpiration, and absorption of soil moisture regulate the absorption of mineral substances, whereas others do not admit this explanation.

In order to clear up these differences of opinion, the author carried out a series of methodical experiments. One of these tests was made with a pure line barley grown for 5 weeks in KNOP's solution, in both summer and winter. Transpiration was accelerated or retarded in three ways.

1) Variation in atmospheric moisture, by limiting air space and introducing moisture by means of atmometers (LIVINGSTON) and running water, or by absorption with calcium chloride.

2) Variation in light intensity, which accelerates or hinders physiological functions and also affects transpiration. The author exposed some plants to direct sunlight and others were grown in the shade.

3) Modification in concentration of the moisture necessary for plant nutrition in such a way as to assist or hinder the osmotic changes in the roots. With this end in view, the KNOP solution was diluted to half strength in some cases and in others the concentration was doubled.

In decreasing transpiration by means of the first method, viz. increasing atmospheric moisture when the concentration on the nutrient solution remains constant, no appreciable variation was noticeable in the amount of ash. If on the contrary, the shading method is employed, that is to say reducing the photosynthetic activity to almost half its usual strength, the quantity of ash is similarly decreased. Reduction of transpiration by means of increased concentration of nutrient solution causes decrease in ash.

As regards dry weight, the amount of ash varies very little even if transpiration is accelerated or hindered.

The results indicate that transpiration has no influence whatever on absorption of mineral salts. On the contrary, it is the quantity of organic matter produced by the plant which regulates absorption. As this increases considerably under the influence of sunlight, the quantity of ash also increases. Darkness has the opposite effect. To a limited extent, but always in an indirect manner the concentration of the nutrient solution surrounding the roots and atmospheric moisture surrounding the leaves behaves in a similar way. In every case the relation between the total weight and the quantity of ash remains constant.

The author has made several investigations in order to study the effect of different conditions on the root and shoot. The most important conclusion to be drawn from the results obtained was that, compared with the stem, the root develops more vigorously in the shade than in the sunlight, (determinations with dry matter). This deduction is not applicable in connection with the effect of light or darkness on transpiration. There is no appreciable difference in this respect, between plants grown under moist conditions and those grown under dry conditions. L. V.

1043 - **Process of Assimilation of Phosphoric Acid in Plants.** — See No. 1027 of this Review.

1044 - **On the Catalysis of Seeds.** — DE VILMORIN I., and CAZAUBON, in *Comptes rendus de l'Académie des Sciences*, Vol. 175, No. 1, pp 50-51. Paris, July 3, 1922.

SEEDS

A. NÉMEC and F. DUCHON had shown that the germinative faculty of seeds decreased parallel with the force of catalysis. The writers confirmed that result for some varieties of peas, and showed the relationship very clearly.

In this work they have taken up the enquiry for very slowly germinating seeds of trees, with the object of replacing, if possible, the determination of catalysis by germination tests. They experimented with varieties of pines and larches, but the relationship failed, probably because these seeds have an impermeable envelope.

There have also been cases in which the seeds, though obviously dead, still reacted strongly on oxygenated water producing a considerable liberation of oxygen. After heating for half an hour at 100° C the amount of gas liberated became insignificant.

1045 - **Weight and Size of Seeds as Factors influencing Yield.** — See No. 1011 of this Review.

1046 - **Hard Moroccan Wheats.** — MIÈGE, E., in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol VIII, No 17, pp. 522-527, May 10, 1922 and No 20, pp. 584-588, May 31, 1922. Paris.

CEREALS  
AND  
PULSE CROPS

Wheat cultivation covers an area of about 800 000 ha. in Morocco. The varieties grown are all of more or less impure. The different forms can however be isolated and may be grouped in classes corresponding to four essential types Zréa, Trikkia, Asker and Maizza. The Zréa group has generally straight elongated, pyramidal fairly compact ears tapering at the top, with long white or slightly pigmented awns and with solid or semi-solid straw. The grain is large, decidedly hard, non-symmetrical with concave base. In this class, the white Zréas and the red Zréas wheats are well known and much valued.

The Trikkia group is also very common ; it is characterised by a short, highly compact, oblong or triangular ear sometimes club shaped and curved, very broad in section ; the grain is non-symmetrical, with the base usually flat or even slightly convex and with the apex often crooked. The straw is solid or semi-solid and shorter than that of the Zréas. The wheats are divided into white and red varieties.

The Asker group is especially common in northern Morocco ; under this designation are classed the smooth eared varieties, yellow or white, with white awns and solid straw, hard grain, shorter and thicker than the preceding, more rounded and always of a dark colour. The ears are fairly long, semi-open, generally cylindrical and much narrower than the Trikkias and Zréas. This class is grown on poor soils.

The Maizza group includes all the blackeared wheats ; it is divided into smooth Maizza and hairy Maizza. It is a complex group directly

allied to the two principal classes of white wheats, the Zréas and the Trikkias.

A comparative study of these wheats has been made for a year. They were sown on the December 1, 1920 in a poor sandy soil, in lines 20 cm. apart, at a depth of 7 cm. and each grain was 5 cm. from the next. The rainfall for the year was rather above the average. The hard Moroccan wheats have shown themselves to be rather late, somewhat subject to rust but possess good agricultural qualities. The Zréas have given the best results, especially the white smooth kinds. The average weight of the ears exceeds 5 grammes. The Trikkias are placed second with an average weight of ears 4.37 gm.

The Maizzas, inferior to the former, are however better than the Askers.

Chemical analysis indicates a high percentage of nitrogenous matter sometimes exceeding 15 % and very little moisture.

In short, according to this preliminary test, the hard Moroccan wheats are wheats of excellent quality and value. P. C

1047 - **Is the Transplantation of Maize advantageous?** — MORETTINI, A. (R. Istituto Superiore Agrario Sperimentale, Perugia), in *L'Italia agricola*, Year 50, No. 8, pp. 259-263. Piacenza, Aug. 1922.

SCHREBER in France and ULPANI in Italy have suggested the transplanting of maize so that it may serve as a second crop after wheat. This method is not however employed in any of the countries where maize is cultivated. As no experimental data were available, the writer has tried this method several times at San Donà di Piave and on the estate of Casalina, attached to the Institute of Agricultural Experiments at Perugia and has made the following report:—

1) The growth of maize by transplanting is technically possible, as the plants take root again fairly easily and slight watering at the time of transplanting suffices to ensure that more than 90 % take root again in normal conditions.

2) As compared with plants from direct sowing, those which have been transplanted have greater root development owing to the greater number of internodes covered by the soil, and not less development of the part above ground; they ripen 10 to 15 days earlier and certainly give a higher yield. On the other hand there is the increased cost of labour, which, in ordinary circumstances makes the transplantation of maize generally undesirable, except in special conditions as for example to replace crops that have failed or blanks caused by insects or other agents in ordinary crops, or else as a second crop after wheat. F. D.

1048 - **Competition in Rice Transplanting in the Province of Novara (Italy) in 1921** (1). — NOVELLI, N., TOGNATO, L., and ROFFIA, A., in *L'Agricoltura pratica*, year XXVI, No. 2, pp. 24-31. Novara, 1922.

With the object of encouraging rice growers to adopt on a large scale the practice of transplanting, the "Comitato provinciale di Propaganda

(1) See R. Nov. 1921, No. 1113. (Ed.)

per le colture alimentari della provincia di Novara" in collaboration with the "R. Stazione Sperimentale di Riscoltura" of Vercelli and with the "Cattedra ambulante di Agricoltura" of the Province, held a prize competition for the agricultural year 1921. The prizes amounted to 22 000 lire and the total area of the competing rice fields measured 163.20 ha. The variety grown was in all cases but one (Onsen), the original Chinese rice. The present article was the Report of the examining Committee for the competition. Out of 27 transplanting experiments, 9 were made on a new ricefield, — 13 after rape for seed — 1 after colza for seed — 1 after rye for seed — 2 on fallow land — 1 on a 10 year old rice field. The production of rape and colza was 7.50 qx. to 13 qx. of seed per hectare, and that of the first crop of hay from 22 to 42 and up to 70 qx per ha.

Transplanting was limited to small portions of the rice field ; it was easy to make comparisons at any point between the transplanted rice and that grown in the ordinary way ; they showed that transplanting itself allowed very high average productions of 60 to 65 and up to 78 qx of paddy per hectare to be obtained.

In all these tests and to a more marked degree than in those of former years, thanks to the increasing improvement in method especially as regards the date of transplanting, the number of plants in each small bunch, the distance between the bunches, etc., the various and important advantages which are the result of the adoption of transplanting have been observed. They may be summed up as follows :—

- 1) a surplus production of from 8 to 10 qx of paddy per ha. ;
- 2) a secondary crop of rape, colza, forage, or in any case of good green manure ;
- 3) less impoverishment of the soil consequent on shorter submersion ;
- 4) better grown stalks, and consequently greater resistance to lodging ;
- 5) increased development of the panicles and the grain and greater purity of the seed.
- 6) better distribution and increased employment of manual labour.

1049 — **The Encouragement of the Growth of Lupins in Germany.** — SIMON, Prof. (Dresden), in *Deutsche Landwirtschaftliche Presse*, Year 49, No. 46, pp. 316-317, 2 figs. Berlin, June 10, 1922.

The growth of lupins is being developed in Germany and should be encouraged, as the seeds, when deprived of their bitterness by improved methods give an excellent food, rich in protein. The writer remarks that the plant grows not only on light soils, as is generally believed but also on sandy-loam and close granitic soils ; it is only necessary that the soil should not contain too much lime (1). Thanks to its vigorous and well developed root system, the lupin is able to find its food even in poor soils ; this observation is specially applicable to phosphorus. Further, like all the Leguminosæ, this plant enriches the soil with nitrogen, and is therefore an

(1) See R. May-June 1922, No. 551. (Ed.)

advantageous crop. In order to secure nitrogen fixation it is necessary to have recourse to inoculation. Although some species of lupins, including the yellow, have been grown in Germany for a long time, its general diffusion is still limited. For this reason the root-inhabiting bacteria of the lupin are either not common in soils in Germany or entirely absent. It is true that, in many places, similar plants are found such as the little *Ornithopus perpusillus* of sandy uncultivated soils, and certain perennial species of lupins native of North America, grown for ornamental purposes or found in woods; but the bacterial species which are special to them, when inoculated on lupins, only produce a feeble growth of nodules.

The Saxon Experimental Station of Vegetable Physiology at Dresden has made various experiments of inoculation of lupins with root-inhabiting bacteria of various other Leguminous plants. For the yellow lupin (*Lupinus luteus*) only the bacteria of serradella (*Ornithopus sativus*) hasten the growth of the plant in similar degrees to those of the bacteria of the yellow lupin itself; the bacteria of other Leguminous plants, such as beans, vetches, red clover, etc. are inert, and the growth of the plant takes place with difficulty, as with the uninoculated control. It is therefore desirable to make use of bacterial colonies taken from the lupins themselves. The inoculation of the soil with another soil is difficult, costly and uncertain and the inoculation of seeds with pure bacterial cultures is preferable. When the crop is already advanced, it may still be worth while to make a late inoculation.

Inoculation is indispensable in soils on which lupins are grown for the first time, but naturally this does not suffice in itself and for example the plants must have a certain amount of potash and phosphorus at their disposal.

For twenty years the bacterial cultures "Azotogen", supplied by the Dresden Experiment Station, have given excellent results. The growth of lupins has succeeded very well even in very poor, granitic soils cultivated for the first time: the inoculated lupins have made a vigorous growth, while those not inoculated have grown poorly.

Inoculation will prove very important for making large areas cultivable. In this connection the writer states that in Germany there are still 2 million hectares of non-marshy land uncultivated and a still greater area of marshy land.

1050 - **Action of various Manures on Beans.** — VAN HAUTEN, A. (Landw. Versuchsfelde der Universität Göttingen), in *Journal für Landwirtschaft*, Vol. 70, No. 1, pp. 1-7. Berlin, July 1922.

Autumn sowings were made in 8 plots, which had already been manured in previous years and in which the last crop had been barley; they contained average amounts of phosphates and lime. Spring manuring was given with 50 % potassic salt, sulphate of ammonia and basic slag variously compounded.

During growth the lack of potash was already revealed in the plots to which no potassic fertiliser had been applied: the plants did not flourish

and the leaves turned yellow, these differences becoming more marked after flowering. In the plots which were defective in potash, maturation was earlier, but the yield lower; on the other hand manuring with potash caused the yield to show a constant increase though to a less degree when manuring with potash was accompanied by manuring with phosphates. Nitrogenous fertilisers did not have any beneficial effect, which is to be explained by the fact that the beans are able to supply themselves with nitrogen. Phosphatic fertilisers were clearly injurious, evidently because the soil was already over supplied. The yield, in quintals per ha., was as follows: control 12.20 — with potassic fertiliser 16 — with phosphatic 11.40 — with nitrogenous 10 — with potassic and nitrogenous 16 — with potassic and phosphatic 13 — with phosphatic and nitrogenous 8 — with the three fertilisers combined 15.60.

At the same station, FEST had obtained, in 1908, a similar result with the same fertilisers. In estimating the yield in dry matter, the general results are not modified appreciably. The average size of the seeds was very nearly the same, their weights varied from 36.23 to 41.01 gm. per 100 seeds.

The percentage of crude protein was less in the seeds of the potash plots, because, in the latter stages of maturation, the non nitrogenous extracts are preferentially deposited in the seeds. In the potash plots, the maturation of the seeds and consequently the deposit of the non-nitrogenous substances, could be completely effected. Absolutely however, the amount of protein was greater in the potash plots.

Contrary results were given for starch and fats. On the other hand, the percentage of ash was greater in the potash plots, and potash in large quantities was found in the ash.

L. V.

1951 — **Brazilian Forage Plants** (1). — DE SOUZA BRITO, E. C. (Escola Superior de Agricultura e Medicina Veterinária), Apontamentos sobre as nossas principais forragens nativas e cultivadas, *Ministerio da Agricultura, Industria e Commercio, Serviço de Informaões*, Rio de Janeiro, 1918. — A. LAVOURA, *Boletim da Sociedade Nacional de Agricultura*, Year XXIV, Nos. 9 and 10, pp. 380-385; Nos. 11 and 12, pp. 425-432. Rio de Janeiro, Sept.-Dec. 1921.

**FORAGE CROPS,  
MEADOWS  
AND PASTURES**

Dr. DE SOUZA first considers the importance of the forage question for Brazil. He then quotes all that the Argentine has done to improve its pastures by replacing the hard native grasses by more tender grasses and especially by acclimatising leguminous plants from Europe. He then studies, from a practical standpoint, the principal Brazilian forage plants, indigenous and cultivated, at least such of them as have been determined botanically, analysed and tested in the "postos zootechnicos".

INDIGENOUS FORAGE GRASSES OR THOSE WHICH HAVE BECOME WILD.

— 1) "Capim gordura" or "Catingueiro" (*Melinis minutiflora*) (2). — This is one of the commonest forage plants in almost all the States of

(1) See R. 1915, No. 472; R. 1917, No. 1020; R. 1921, Nos. 386, 1116 and 117.

(2) Syn. *Panicum minutiflorum*. See R. 1915, No. 201; 1917, No. 18; 1921, No. 816. (Ed.)

Brazil. Under a temperate climate, it forms permanent pastures, sometimes very extensive, as in the numerous "fazendas" in the States of Rio de Janeiro, São Paulo, Goyaz, etc. It grows well with the Leguminosæ. According to the analyses which have been made at the "Posto Zootecnico Federal", it contains, before flowering, 12.8 % of digestible nutritive substances, with a nutritive ratio of 1 : 20, and after flowering, 21.9 % of digestible matter with a nutritive ratio of 1 : 11.4. The hay contains 49 % of digestible substances. This plant is chiefly suitable for milch cows. There are 3 varieties:— "gordura branco" (white var.) — "gordura roxo de hastes finas y longas" (red var. with long thin stalks) — "gordura roxo de hastes curtas" or "cabello de negro" (red var. with short stalks). The first does best on strong deep soils; the red "capim" prefers stiff soils. This grass is resistant to drought; but not to excessive moisture.

2) "Graminha" or "Capim de burro" (*Cynodon Dactylon*). — Couch-grass is common all over Brazil. The "carrapicho beijo de boi" (*Desmodium ascendens*) is one of the very few leguminous plants that can be associated with it. It resists drought and trampling very well. Before, during and after flowering it contains respectively 21.8 — 26.7 — 31.8 % of digestible nutritive matter, with the nutritive ratios 1 : 10 — 1 : 10.7 — 1 : 13.

3) *Chloris orthonoton*. — Perennial forage plant in high and low meadowland. It is one of the most hardy grasses; it is very tender and delicate and is easily propagated by seed and resists cold and drought. These qualities make it useful, although it has no great nutritive value. Dr. DE ANDRADE found in it 6.8 of nitrogenous matter per 100 of dry matter.

4) "Capim mimoso". — This name is given to several species of grasses, some of which are not yet classified and which grow on natural pastures in areas having a temperate climate. The "capim mimoso" of Matto Grosso and of Goyaz is *Eragrostis pelosa*, very rich in nitrogen (12.66 % of the dry matter) and, consequently, very much recommended for fattening cattle. The same species is called "panasco" in Ceará.

At Parana, this name is given to both *Andropogon tener* var. *Neesii* and *Paspalum marginatum*. The latter does not grow large, but it is well liked by cattle; it stands cold and drought and burning does not destroy it. The grass is common both in the State of Minas Geraes and on the ridges of the Lapa and Urubú.

*Andropogon tener* var. *Neesii* is one of the good forage plants of Parana; it is tender and stands cold, drought and trampling. It also grows in the States of Minas Geraes and São Paulo. On the fertile and cool soils of the States of São Paulo and Parana grow two other species which bear the name "capim mimoso": — *Panicum capillare* and *P. nitidum*. Their nutritive ratios are respectively 1 : 4.1 and 1 : 6.2

Another "Capim mimoso", *Eragrostis lugens* var. *glabrata*, grows on the most fertile soils of Minas and Goyaz up to Montevideo; it is much liked by animals.

5) "Graminha de Campinas" (*Chloris radiata*). — This has neither great growth nor is it hardy, but the grass might be used for making winter pasture. It contains, in the dry matter, 5.4 of nitrogenous matter, and has a nutritive ratio of 1 : 8. Like all species of *Chloris*, it flowers all the year round and produces much seed. Its propagation is easy and as a good forage plant it is worth growing. It is very common in the little frequented pastures of the States of São Paulo, Matto Grosso and Goyaz.

6) "Capim flor" "flecha" or "lanceta" (*Panicum echinolaena*). — Several species of the genera *Letochlopa* and *Tristachya* bear the same common names. *Panicum echinolaena* grows on the upland of Uberaba up to Goyaz, Minas, etc., where breeders think highly of it. Before flowering it is tender and then becomes slightly tough. According to an analysis made at the "Instituto Agronomico" of Campinas (*Boletim de Agricultura de São Paulo*, March 1914), the nutritive ratio is 1 : 6.5 ; its composition is therefore good. The grass has a creeping habit and prefers cool soils ; it withstands fires and forms a good constituent of winter pastures.

7) "Capim branco" (*Paspalum brasiliense*). — Very common in Uberaba, Parana, Goyaz, etc. It is slightly hairy, but tender and well liked by cattle.

8) "Capim do campo" (*Panicum cayennense*). — In Para it bears the name of "pennacho". It grows in the States of Parana, São Paulo, Minas, Goyaz, Pernambuco, etc. Cattle only eat the plant if better forage is lacking, because the blades are hairy and prickly. It stands drought and cold well.

9) "Grama commun" (*Paspalum notatum*). — It forms extensive pastures of good forages which grows all the year round. It contains 6.11 % of nitrogenous matter and has a nutritive ratio of 1 : 5.7.

10) "Grama das raças" or "grama comprida" (*Paspalum dilatatum*). — Indigenous and very common in southern Brazil ; cattle like it well ; of high nutritive value and contains 7.94 % of nitrogenous matter, and has a nutritive ratio of 1 : 4.5.

11) "Capim guiné legitimo" (*Panicum maximum*). — Although probably of African origin, is native on dry soils throughout Brazil. It is perennial, of fairly high food value, easily grown, stands drought and is well liked by cattle ; makes good hay and gives several crops a year. Eight varieties are known, all of good quality. The analysis of plants before flowering, made at the "Instituto agronomico" of Campinas, gave as composition of the dry matter :— Nitrogenous substances 9.25 % — fats 1.96 — organic matter 65.67 — non nitrogenous matter 32.26 — cellulose 22.2 — Nutritive ratio 1 : 3.8. It is the forage grass which is preferred in the Antilles, as it will support a large head of cattle. It is specially suited to rather sandy and humiferous soils.

12) "Capim Jaraguá" or "capim provisorio" (*Andropogon rufus*) (1). — In Matto Grosso the plant is termed "Sapé gigante" and "Capim vermelho" in Goyaz. It is native in the State of Goyaz, Matto Grosso and

(1) See R. 1917, No. 1154. (Ed.)

Planhy ; perennial ; tillers strongly and grows to a large size. Cattle are partial to it. Thrives on cool clay soils and makes good hay provided that it is cut before flowering. It requires annual burning (which can be replaced by heating) and, on fertile soils, a large head of cattle, which slows its growth and delays its hardening.

According to Dr. ATHANASSOF'S analyses, at the " Instituto Agronomico " of Campinas, its digestible nutritive constituents and nutritive ratio have respectively the following values :—*for green forage* :— before flowering :— 15.6 % ; 1 : 6.8 — during flowering period :— 18.9 % ; 1 : 20.2 — after flowering 20.33 % 1 : 25 — *for hay* :— made from grass before the flowering stage — 47.8 % ; 1 : 10.4 — made from grass after flowering 55.03 % ; 1 : 15.3. It forms excellent pastures by growing together with " capim gordura " and leguminous plants.

13) " Capim colônião " or " milhã roxo " (*Paspalum virgatum* var. *conspersum*). — It grows in low cool soils ; is easily propagated ; gives good hay, provided it is cut before flowering — Percentage composition (dry matter) :— Nitrogenous matter 6.07 — Fats 1.45 — Non-nitrogenous extracts 35.14 — Cellulose 5.14 — Organic matter 68.07 — Nutritive ratio 1 : 6.4. The name " milhã " is also given to the following allied species which have the same habitat and which, like the preceding grass, do not stand frost :— *P. griseum* (" milhã branco ") of Parana and São Paulo — *P. intermedium* (" milhã ") of São Paulo — *P. malacophyllum* (" milhã roxo ") — *P. aureum* (" milhã doirado ") of São Paulo Minas, etc. — *P. densum* (" milhã branco " or " milhã da Colonia ") — *P. conspersum* (" milhã do brejo ") — *P. altissimum* (" milhã colônião ") — *P. Cruz-Ardeae* (" milhã de campo ") — *P. laeve* " milhã do campo cultivado ").

14) " Pasto imperial " (*Paspalum scoparium*). — Indigenous from the Amazon up to Montevideo. There are 4 varieties :— 1) smooth ; 2) hairy ; 3) with small flowers ; 4) with narrow blades. The height exceeds 1 m. ; it is propagated by rhizomes and by seed ; is resistant to heat. Plants analysed after flowering contained in the dry matter :— 6.64 % nitrogenous matter ; 2.10 fat ; 37.33 nitrogen free extract ; 21.82 cellulose ; 67.89 organic matter ; nutritive ratio 1 : 6.4.

15) " Capim fino de folhas longas " (*Panicum oppresum*). — In Para the plant called " cannarana fina ". It grows on the low lands of the State of Rio de Janeiro and of northern Brazil and prefers clay soils and provides a good forage.

16) " Capim de planta " (*P. numidianum*). — Has little nutritive value, but on cool soils gives every year several heavy crops. Nutritive ratio from 1 : 10 to 1 : 13.2.

17) " Capim de Angola " (*Panicum spectabile*). — Introduced from Africa when colonisation commenced, it is grown in the low lands and is found wild on the banks of the Amazon and Guaporé rivers in the States of Pernambuco, Bahia, Ceará, as well as in the Guianas and the Lesser Antilles. Nutritive ratio 1 : 3.2.

18) " Barba de bode " (*Aristida pallens*). — Grows in São Paulo,

Rio Grande, etc. Cattle eat it so long as it is young and tender. Before flowering, its nutritive ratio is 1 : 4.2 ; after flowering 1 : 10.

Several other species, all of small nutritive value bear the same common name :— *Sporobolus argutus*, nutritive ratio 1 : 10.2 — *Andropogon condensatus*, nutritive ratio 1 : 9.36, of Rio Grande and Minas Geraes — *A. paniculatus*, *Ctenium cirrhosum*, of sterile lands of Minas Geraes and other States — *Eragrostis reptans* of the island of Marajó, characteristic of low clay soils, stands drought, and is useful for horses. There are still other forage plants of the same class :— “Capim limxo” (*Elionurus candidus*) of Rio Grande do Sul, frequent on the sand hills, bitter and, consequently, little liked by cattle — “Capim membeca” (*Andropogon virginicus*), which grows in several States — “Capim branco” or “pasto branco” or “Moroto” (*A. glaucescens*), very common in Minas, Goyaz and São Paulo — “Capim amargoso” (*Elionurus latiflorus*) gives good hay and animals only eat it dry ; it can therefore form reserve pastures for the summer (dry plants) or for winter (frozen plants).

19) “Capim bobo” (*Andropogon saccharoides*). — Abundant in Matto Grosso and in the State of São Paulo, on the edges of woods. It does not stand drought, has need of shade and is very nourishing. Nutritive ratio 1 : 4.1.

20) “Capim gigante” (*Tripsacum dactyloides*). — Is considered a good forage in the high lands of Marajó and Pará, but is much more common in Goyaz. The plants in flower reach a height of 3 metres.

21) “Capim burrão”, “grama de Jacobina” (*Chloris bahiensis*). — Excellent forage plant of the interior part of the State of Bahia, and also that of Pernambuco, Pará and some of the Southern States up to Montevideo. It contains in its dry matter :— Nitrogenous matter 10.32 % — Fats 1.18 — nitrogen-free extract 30.27 — Cellulose 19.43 — Organic matter 61.20 — Nutritive ratio 1 : 3.2. Requires cool fertile soils and is worth growing on a large scale on account of its high food value and its facility of adaptation to various zones of the country.

22) “Capim doido”, “capim comprido” (*Andropogon Minarum* Kunth. = *Sorghum Minarum* Hack). — Native and common in several zones of the States of Minas, Espírito Santo and São Paulo. It seems to prefer heavy soils. Perennial ; height about 1 metre ; has never, so far as is known, caused poisoning.

Another sorghum, *Sorghum halepense*, is grown in the State of São Paulo, which has shown itself very nourishing and stands trampling.

23) *Panicum cordatum*. — Grows only in the low lands of the State of Rio de Janeiro, where it is common on the banks of ditches. It is an excellent forage plant cut for use green and will probably make good hay..

24) “Pampuan” or “papuan” (*Ichnanthus caudicans*). — Breeders give this name to several forage plants much esteemed in the interior of Goyaz and of some other States, and which are well suited for fattening cattle. Six varieties of this species have been identified. In the States of Minas, Goyaz São, Paulo and Matto Grosso, the same common name is gi-

ven to a species of *Panicum*; in Pará and Rio Grande do Sul, *Paspalum jurcatum* is called "pancuan".

25) "Capim assú" (*Panicum megiston*). — Good forage plant of the island of Marajó; grows on sandy-argillaceous soils, is hardy and reaches a height of 10 metres. It can be mown.

In the interior of Minas, of São Paulo and on the low lands of Parana, the same common name is given to *Erianthus Trinii*, a good forage plant resistant to cold and drought. In the interior of the State of Bahia, this name is given to *Eragrostis brasiliensis* Nees = *E. bahiensis* Schultes, a perennial plant of about 1 metre in height, well liked by cattle. *Hemiarthria fasciculata*, a fairly good forage plant also bears the same name.

26) "Pé de gallinha". — Several forage grasses some of which have little nutritive value, bear this name:— *Eleusine indica*, common on the heavy soils throughout Brazil (it is called "capim de burro" in the north); it is tender and, under cultivation, gives an abundant production; nutritive ratio 1 : 3.3 — *Cynodon Dactylon*, more often called "graminha" — *Panicum sanguinale*, very common especially in Matto Grosso, São Paulo and Rio Grande do Sul; gives good hay if it is mown before flowering. — *P. Crus-Galli* — *Poa annua*, common in Rio Grande do Sul and São Paulo.

27) "Capim manexim" or "pé de papagaio" (*Eleusine coracana*). — Before flowering, this plant is very tender; the nutritive ratio is 1 : 3 and it makes good hay.

28) "Grama de Pernambuco" or "capim de Macahé" (*Paspalum mandiacanum*). — This plant grows abundantly on fertile soils. Before and after flowering the nutritive ratio is respectively, 1 : 5.6 and 1 : 3.9. When tender, cattle eat it, but only in the absence of other forage. It is indigenous in the Northern States. Owing to cultivation in the State of São Paulo the composition has been much improved; it contains 8.75 % of nitrogenous matter, with a nutritive ratio of 1 : 4.5. It gives from 4 to 7 abundant crops per year.

29) "Capim gordo" (*Paspalum conjugatum*). — In Pará it is called "capim de marreca". It is native on cool soils of Rio Grande, Parana, the island of Marajó and the South of Matto Grosso. Nutritive ratio 1 : 3.3 before flowering; 1 : 4.9 after flowering. The grass is non resistant to drought.

30) "Capim cocorobó", "capim batatal", "capim cebola", "graminha de Araraquara" (*Chloris distichophylla*). — Grows on sandy shaded soils in several parts of Brazil and Uruguay. Does not stand drought but its composition makes it one of the best forage grasses of Brazil; before flowering the nutritive ratio is 1 : 5.8; during the flowering period 1 : 4.5; the hay contains 7.09 % of protein.

31) "Grama mineira" (*Stenotaphrum glabrum*). — Grows on dry soils; stands drought, but not trampling; perennial; nutritive ratio 1 : 3.2; said to be of English origin, native in Matto Grosso, Minas, etc.

32) "Grama major Ignacio", "grama de S. Carlos" (*Paspalum laxum* Lam. = *Paspalum plantagineum* N. b. E.). — Very common species at S. Carlos do Pinhal (São Paulo), in Minas, Bahia, Rio de Janeiro.

When cultivated, it gives 6 to 7 crops a year, with a total yield of about 50 tons per ha. The nutritive ratio is narrow, namely 1 : 3.7 before flowering and 1 : 4.3 after.

33) "Capim Araguaya". — This is a still undetermined species of *Paspalum*, very common in the States of Goyaz and Matto Grosso, very much valued as a forage plant. Grows on damp soils and makes good hay.

34) "Cevadilha" (*Bromus unioloides*). — Indigenous in Parana; it is the "resene grass" of North America and the commonest forage plant of the Province of Buenos Aires. It is suitable for cultivation; when trampled by animals it becomes perennial. Nutritive ratio before flowering 1 : 3.6.

35) "Capim palmeira", "capim legue" (*Panicum sulcatum*). — Remarkable for its abundant production and its exceptional richness in nitrogenous matter; nutritive ratio 1 : 2.6 before flowering and 1 : 2.7 after.

The following species, for which the States where they are commonest are indicated, are considered good forage plants:—

36) "Capim setaria" (*Setaria brachiata*): — Ceará.

37) "Capim andrekiçé" (*Leersia Lexandra*): — Pará, Goyaz.

38) "Peua" (*Andropogon brevifolius*): — Pará, Goyaz, Amazonia.

39) "Capim zabo de rato" (*Panicum villoides*):— Pará and other States.

40) "Sentinella" (*Paspalum parviflorum*): — Pará, Goyaz, Espirito Santo.

41) "Grama do cerrado" (*P. obtusifolium*): — Paraná.

42) "Cannarana rasteira" (*P. repens*): — Pará, Matto Grosso.

43) "Cannarana de folha minda" (*Panicum amplexicaule*): — Pará etc.

44) "Cannarana roxa" (*P. zizanoides*):— Pará Matto Grosso, Bahia, Minas, Rio Grande.

45) "Capim mimoso do Piahy" (*Dactyloctenium aegyptiacum*):— Pará, Ceará, etc

46) "Forquilla" (*Paspalum papillosum*):— Pará, etc.

47) "Murukiá" (*Eragrostis VahlII*): — from Pará to Southern Brazil.

48) *Paspalum platycaulon*:— Rio Grande do Sul.

49) "Grama de ponta" (*Triticum repens*): — Rio Grande do Sul.

50) "Coqueirinho" (*Paspalum plicatum*):— Rio Grande do Sul.

51) "Capim arroz" (*Panicum oryzoides*):— Sao Paulo and other States.

52) "Capim gengibre" (*Paspalum falcatum*):— São Paulo, etc.

53) "Capim felpudo" (*Panicum* sp.).

54) "Capim de cheiro" (*Kyllingia odorata*):— Rio Grande do Sul and States in the north.

55) "Capim cevadinha" (*Bromus inermis*):— Considered to be an exotic; it is native in the State of São Paulo.

56) "Capim jaguaré" (*Panicum* sp.):— Rio Grande do Sul.

- 57) "*Grama lanceta*" (*Chloris* sp.): — Campos-Rio.  
 58) "*Capim marambaia*" (*Chloris* sp.): — littoral.  
 59) "*Capim camalote*" (*Rottboellia compressa* var. *fasciculata*): — on high dry lands of Matto Grosso; excellent forage; durable.

EXOTIC FORAGE GRASSES. — "*Capim de Rhodes*" (*Chloris Gayana*) and "*capim favorito*" or "*capim de Teneriffe*" (*Tricholaena rosea*) have been introduced into Brazil and grown with success.

INDIGENOUS OR ACCLIMATISED LEGUMINOUS FORAGE PLANTS: —

60) *Zornia diphylla*. — Common throughout Brazil; gives a good hay with 9 % of digestible protein and is well liked by cattle. Thirteen varieties have been identified.

61) *Galactea tenuiflora* var. *villosa*. — Common in Rio Grande do Sul. Perennial. The dry matter contains 19 % of nitrogenous matter.

62) "*Carrapicho beço de boi*" or "*amor de campo*" (*Desmodium ascendens*). — Grows all over South America and in the Lesser Antilles. Associates well with grasses, stands cold and drought and does well on all soils, but best on heavy soils; is easily propagated and is suitable for all kinds of domestic animals. Nutritive ratio 1:5.5.

63) "*Barbadinho*" or "*Carrapicinho*" (*Desmodium barbatum*). — Grows throughout South America; eaten by all domestic animals. Nutritive ratio before flowering 1:3.2. More than fifty species of this genus abound in Brazil; among them: — *D. albiflorum* — *D. asperum* — *D. axillare* — *D. cuneatum* — *D. pachyrhizum* — *D. uncinatum* — *D. incanum* — *D. bracteatum* — *D. molle* — *D. leiocarpum* ("marmellada de cavallo") (1) with a nutritive ratio of 1:2.5 before flowering and 1:2.8 for the hay — *D. cajaniifolium*, nutritive ratio before flowering 1:2.7 — *D. tortuosum* Welb. = *D. spirale* D. C. ("erva di mendigo", "trevo da Florida"); nutritive ratio 1:2.3 before flowering and 1:2.8 for the hay.

64) "*Capim bambú*" (*Cassia Langsdorffii*): — Common throughout southern Brazil.

65) "*Carrapicho*" (*Aeschynomene falcata* var. *pleurijuga*): — in almost the whole of South America, in Brazil, etc.

66) "*Lentilha do campo*" (*A. brasiliiana*): — Pará.

67) "*Sensitiva mansa*" (*A. sensitiva*); nutritive ratio 1:2.8. *A. americana* Liv. (Glazion), *A. tyacursis* n. sp. Tomb. (Glazion), *A. marginata* and *A. hystrix* are also good forage plants.

68) *Cassia rotundifolia*. — Throughout Brazil, Central America, the Lesser Antilles.

69) "*Feijãozinho*" (*Rhynchosia minima*). — In the States of the North and in the districts of the South with a temperate climate. Must not be confounded with "*olho de pomba*" (*R. phaseoloides*), the leaves of which are supposed to contain a poison, whereas the former is quite harmless.

70) *Vigna vexillata*: — Australia, India, Tropical Africa, Central America and part of Brazil. Good forage plant.

(1) See R. 1920, No. 1097. (Ed.)

71) "Feijão de praia" or "batata sana" (*Vigna luteola*): — Pará, Amazonia, São Paulo. Very much liked by horses.

72) "Wassourinha" (*Stylosanthes viscosa*). — Associates with grasses. Requires cool soils. Cattle are very fond of it. There are 10 species of this genus in Brazil.

73) *Clitoria cajanifolia* Benth. = *Lotus fluminensis* Well. — Common throughout Brazil and in Central America. Bears the name "espe-lina falsa". The same common name is also given to *C. guyanensis*, a good forage plant of the interior of Brazil. There are 15 species of this genus in Brazil.

74) "Oro" (*Phaseolus panduratus*). — Excellent forage plant of the Northern States; the hay contains 18.8 % of digestible protein.

This genus contains 28 species in Brazil, all of them excellent forage plants; the principal of them and their habitats are: — *Ph. Martii*, Ceará — *Pl. longipedunculatus*, Ceará, Pará, Piauí, etc. — *Ph. prostratus*, Rio de Janeiro, São Paulo, Rio Grande do Sul, Minas — *Ph. longifolius*, Rio de Janeiro — *Ph. bruxilensis*, idem — *Ph. lasiocarpus* ("panapanátania" in Pará), Amazonia, Rio Grande do Sul, etc.

75) "Postomeira" or "trifolho hirsuto" (*Eriosema crinitum*): Pará, Minas, Goyaz, São Paulo — *E. longifolium*, *E. stipulare*, *E. strictum*: Goyaz — *E. violaceum*: Rio de Janeiro — have not yet been studied.

76) "Trevo" (*Trifolium polymorphum*) and "trevo branco" (*T. repens*) native in pastures of Rio Grande do Sul.

77) "Manduvira grande" (*Crotalaria paulina*) and "Manduvira pequena" (*C. vitellina*) common throughout Brazil, excellent forage plants.

78) "Feijão de boi" (*C. incana*), much esteemed in Ceará; its dry matter contains 19.5 % of nitrogenous matter. *C. stipularia* and *C. vespertillo*, very nourishing forage plants, grow in Minas and Rio de Janeiro.

79) *Cassia calycioides*. — Common in Goyaz, Piauí, Ric, Pará. The plant, which is not tall is liked by cattle.

80) *Certosema virginianum*. — Throughout Brazil. Other Brazilian species: — *C. pasenorum* — *C. brasilianum* — *C. rotundifolium* — *C. arenarium* — *C. grandiflorum*. — *C. rubescens* — *C. hastatum*.

FORAGE PLANTS BELONGING TO OTHER FAMILIES. — Compositae. — "Cravórana" or "cravoda roça" (*Ambrosia polystachya*); nutritive ratio 1:3.4.

Gentianaceae. — "Asperana" (*Menyanthes brasílica*): — Pará, Rio, Goyaz.

Marantaceae. — "Arumarana" (*Thalia geniculata*; *T. pubescens*): — throughout Brazil.

Amarantaceae. — "Ervanço" or "perpetua" (*Telanthera polygonoides*, *T. ramosissima*, *T. brasíliana*): — Ceará, Rio, etc. Nutritive ratio 1:4.

Euphorbiaceae. — "Velame do Campo" (*Croton campestris*) and many species of "mandioca campestre".

Solanaceae. — "Couvetinga" or "Capeira branca" (*Solanum auriculatum*), of great nutritive value; it is used in Minas.

Ulmaceae. — "Crindiuva" (*Sponia micrantha*):— throughout Brazil. Good forage plant for dairy cattle.

POISONOUS OR SUSPECTED LEGUMINOUS PLANTS. — *Ph. semierectus* ("fãijão de rola," feijão de pombinha"), common throughout Brazil and suspected to contain in its leaves a cyanogenetic glucoside; the same is the case with *Teramnus volubilis*, *T. uncinatus*, *Dioclaea latifolia* ("feijão bravo"), etc. On the other hand the following species have harmless leaves and consequently make good forage, but their seeds are known to contain a cyanogenetic glucoside or are suspected of doing so:— *Ph. lunatus* ("fava Belém") — *Ph. amazonicus* — *Ph. caracalla* — *Ph. appendiculatus* — *Ph. obliquifolius* — *Pachyrhizus bulbosus* ("jacatupéô" — *Canavalia gladiata* ("fava de quebranto" or "feijão mandatô") — *C. versicolor* var. *obtusifolia* ("feijão fava brava") — *Dioclaea violacea* ("coróonha"), etc.

POISONOUS PLANTS BELONGING TO OTHER FAMILIES (1). — Known under the general name of "ervas" they are numerous. The writer notes:—

Compositae — "Mio-mio" (*Baccharis coridifolia*) (2), more common in Southern Brazil. — "Carrasco do campo" (*B. tarchonanthisoides*) — *Homatozona artemisiaefolia*.

Apocynaceae — "Rosa dos campos" (*Dipladenia illustris* var. *tomentosa*; *D. i.* var. *spigelaellora*; *D. i.* var. *velutina*; *D. gentianoides* var. *longiloba*):— Minas, São Paulo, Goyaz, etc.

Acanthaceae. — "Herva do gado" (*Chactothylax lythroides* Lindan = *Heinzelia lythroides* Nees) — a few species of *Ruellia*.

Dioscoreaceae. — Different species of *Dioscorea*.

Passifloreaceae. — "Maracujá de raposa" or "maracujá de rato" (*Passiflora toxicaria*), fruit poisonous, and several other species.

Rubiaceae. — "Herva de rato" or "tangeraca" (*Psychotria Marcgravii*) — "douradinha" (*P. xanthophylla*) and a number of others. The genus *Psychotria* alone includes 12 species, almost all poisonous. They are shrubs which grow on the edges of woods in the middle of forage species; sometimes cattle eat them and are poisoned.

Loganiaceae. — "Arapabaea" (*Spigelia anthelmia*); several other species.

Thymelaceae. — "Embira branca" (*Daphnopsis brasiliensis* and *Funijera utilis*).

Umbelliferae. — "Herva capitão" or "acariçoba" (*Hydrocotyle quinqueloba* var. *angulata* and other varieties of the same species — "Cicuta" (*H. leucocephala*).

(1) See R. 1917, No. 1034: *Rhynchosia phaseoloides* and *R. minima* considered as poisonous for cattle in the State of Rio de Janeiro. (Ed.)

(2) See R. 1910, No. 477. (Ed.)

1053 - Composition of the Forage Plants "Guinea grass" (*Panicum maximum* and *P. jumentorum*) and "malojillo" (*P. barbinode*) grown at Porto-Rico. — DOMÍNGUEZ, P. A. L., in *Gobierno de Puerto Rico, Departamento de Agricultura y Trabajo, Estación Experimental Insular, Rio Pedras, Circular No. 61*, pp. 35, bibliography of 10 publications. San Juan, 1922.

The "hierba del Pará" or "hierba del Paral" or "malojillo" or "malojilla" (*Panicum barbinode* = *P. muticum*) (1) and the "hierba de Guinea" or Guinea grass (*Panicum maximum* and *P. jumentorum*) are acclimatised and widely distributed in Porto-Rico, where they have found very favourable conditions, the former especially on the north coast, where the rainfall is abundant; the latter, more resistant to drought, on the south coast. They are much relished by cattle.

The annexed Table gives the averages of analyses made at the Rio Piedras Agricultural Experimental Station. The writer also gives the analysis of the hays: in the general average there was 8.13 % of moisture in the hay of *Panicum barbinode*, and 7.05 % in the hay of *P. maximum*.

The writer compares these data with those obtained for the same forage plants, when cultivated in other countries; he refers to several experiments made by other writers to determine their nutritive value and gives formulæ of rations with supplements of concentrates.

*Percentage composition and nutritive coefficients  
of Panicum barbinode and P. maximum, grown in Porto-Rico.*

	Moisture	Protein	Fats	Crude cellulose	Carbo- hydrates	Ash	Nutri- tive co- efficient
<i>Panicum barbinode:</i>							
Average of all samples (9) . . .	75.97	2.15	0.63	6.47	9.97	2.10	5.3
Samples grown on clay soils. . .	75.23	2.03	0.58	6.12	8.13	2.49	4.9

F. D.

(1) Some writers give this plant the name of *Panicum molle*, but it belongs to another species. (Author's Note)

1054 - Para Grass (*Panicum barbinode*) and Paspalum (*Paspalum dilatatum*) in the Island of Guam. — BRIGGS, C., in *Guam Agricultural Experiment Station, Bulletin* No. 1, pp. 1-44, tables 15, pl. 6. Washington, Dec. 2, 1921.

Most native forage gramineae in Guam have a low feeding value.

For the last 10 years, the Guam agricultural Experiment Station has made a series of trials with native grasses in the feeding of livestock work, and have proved the necessity of replacing these grasses by imported gramineae of superior quality, such as Para grass (*Panicum barbinode*), and Paspalum (*Paspalum dilatatum*). Both these grasses are adapted to Guam conditions, being very vigorous growers during the wet season, and on the other hand, possessing special drought-resistant qualities (particularly the paspalum) which render them valuable during periods of exceptionally dry weather.

*Panicum barbinode* was introduced into Guam by the Agricultural Experiment Station in May 1910 from the Hawaii Agricultural Experiment Station, where it had been introduced from the Fiji Island in 1902.

It is a coarse grass with prostrate runners; the stems grow upright when the ground is fairly covered with grass, and the plant reaches a height of 2 to 15 feet. It forms a good pasture grass if carefully laid down. It is readily propagated by seeds, roots, cuttings and by whole stalks. High yields are obtained on lowlands, and these may be increased by the application of farmyard manure or fertilisers. Livestock eat the grass readily.

Both *Panicum barbinode* and *Paspalum dilatatum* should be well established before they are used as pasture. Para grass will support one animal per acre of grass the whole year round and Paspalum can support much heavier grazing.

*Paspalum dilatatum* was first introduced into Guam in 1909 by the Experiment Station. Seed was obtained from the United States Department of Agriculture. Paspalum is a perennial having a deep fibrous root system, and is a bushy grass when not sown too thickly. It is propagated by seeds or cuttings, but preferably by root cuttings planted 1 foot apart. It is especially suited for pasture and gives a good yield for at least 9 months of the year.

It is adapted to a wide range of soils but grows best on rich and moist lowlands; it will however thrive on comparatively poor and rocky soils. It is estimated to pasture at least 1 to 3 animals per acre all the year round when grown on fairly good soil.

Each of these grasses has an excellent feeding value and a high protein content, 16.30 % average for *Panicum barbinode* and 14.9 % for *Paspalum dilatatum* (air dried).

1055 - Forage Sorghums. — VINALL, H. N. and GATTY, R. E. (Office of Forage Crop Investigations, Bureau of Plant Industry), in *United States Department of Agriculture, Bulletin* No. 981, pp. 1-68, figs. 25, bibliography of 20 works. Washington, December 21, 1921.

Sudan grass was introduced into the United States from Africa in 1909, and from the one bag or eight ounces of seed has come practically all the Sudan grass now being grown in the country. The crops sown

increase every year; the value of the 1918 crop was estimated at over 10 million dollars. Sudan grass is to-day grown successfully in Australia, South America, the Philippines, Hawaii, Porto Rico and Cuba.

The plant is now technically known as *Andropogon sorghum sudanensis*, although it was originally introduced from Africa under the name of *Andropogon halepensis*, which belongs to a nearly related species, Johnson Grass (Aleppo sorghum), which differs from it in the possession of rhizomes. The latter form is confined to the Mediterranean basin, while Sudan grass is peculiar to Central and South Africa (see appended map, p. 1236).

*A. halepensis* is much grown in the Southeastern States of the Union, but it lacks the forage qualities possessed by *A. Sorghum sudanensis*.

The latter is known under several other names, of which one is *Holcus Sorghum sudanensis* (Piper) Hitchc. The author gives a botanical description of the plant and establishes its relationship with closely allied forms, nearly all of which are of African origin. Among them may be mentioned: Tunis Grass (*Andropogon sorghum virgatus* Hack [Piper] — Kamerun Grass (*A. S. effusus* Hackel) — Tabucki Grass (*A. S. verticilliflorus* Stendel) — Chicken Corn (*A. S. Drummondii* [Nees] Hackel, or *Holcus Sorghum Drummondii* [Nees] Hitchc) — a wild sorghum (*A. S. Hewisoni* Piper). The author also mentions the hybrids, especially Austin's "Johnsorgo", obtained from the cross Honey sorgho × Johnson grass (1).

Sudan Grass does not thrive in a cold climate and cannot be grown to advantage at high latitudes, nor within 200 miles of the Northern boundary of the United States. Excessive heat and moisture such as are found on the S. Atlantic coast and the Gulf of Mexico are, however, also not suitable for this plant as it is subject to the attacks of plant and animal parasites. Under other conditions it produces a more or less good crop, because although it has a high water requirement, it is able to withstand protracted periods of drought and recovers quickly when rain comes. Sudan grass is of most value in an emergency for making hay; it forms good summer pasture and is useful as a soiling crop but is not so suitable for silage as maize or ordinary sorghum. Care must be observed when using it as pasture for cattle on account of the prussic acid it contains.

The author gives information regarding the sowing and harvesting of Sudan Grass, its cultivation as a catch-crop, and when mixed with legumes. He also mentions its diseases and enemies together with the best means for their control.

Sudan Grass seed should be planted about  $\frac{1}{2}$  inch to  $1\frac{1}{2}$  inches deep on moist or heavy soils, and from 1 to 3 inches deep on dry or lighter land. For hay production it is best to drill or broadcast 20 to 25 pounds of seed per acre in the humid regions, and 10 to 15 pounds per acre in the drier portion of the United States.

(1) See R. May-June 1922, No. 534. (Ed.)

For seed production, 3 to 4 pounds of seed per acre are sufficient, drilled in rows 36 to 42 inches apart; the rows should not be too far distant from each other or the roots will develop to an extent that renders subsequent operations difficult. Except in irrigated districts, seed production is now-a-days unprofitable, for the yields are low and the prices uncertain, further there is a great danger of the admixture of Johnson grass seed, and it is practically impossible to separate the seeds of the two grasses by any mechanical means. The author gives the microscopic characters of both kinds of seed. Sudan Grass can easily be crossed with other sorghums. In order to prevent natural crossing, Sudan grass intended for seed production should never be sown on a field which has been under sorghum the previous year, or within 80 rods of other varieties of sorghum. It should not be cut for hay until it has headed, otherwise the yield is much reduced. Sudan Grass dries slowly and must be given plenty of time to cure. Mixed plantings of *A. Sorghum sudanensis* and legumes such as soy beans are profitable only in the more humid regions. The same diseases and insects that attack other sorghums also injure Sudan Grass. *Sphacelothecum sorghi* Link and *Colletotrichum cereale* Manns can be controlled by treating the seed with formaldehyde. Rotation of crops is also very effective. L. V.

1056 - **Experimental Growth of "Ghessab" (*Pennisetum spicatum*) in Sicily** (1). — SCAVONE, G., in *Giornale degli Allevatori*, Year XVIII, No. 2, pp 12-13. Catania, 1922.

After noticing the surprising rapidity of growth of "ghessab" in the crops which he had grown at Bengasi, the writer wished to try it near Syracuse, with sowings on irrigation land. It was sown on the 20th May and mown on the 1st July, leaving along the irrigation furrows the finest plants for seed production; a second cutting was made at the end of July. During the previous autumn the land had been deeply ploughed and manured, and during the winter it was put under beans. The good results obtained are shewn in the following account made out for a hectare:

#### EXPENDITURE.

70 kg. of seed at 2 lire . . . . .	140 lire
6 days ploughing at 40 lire to break up, flatten and furrow the ground for irrigation . . . . .	240 "
22 days manual labour at 10 lire preparing the ground for irrigation, loosening the soil, sowing, making 6 or 7 waterings, 2 being for the second crop . . . . .	220 "
4 daily labourers (at 10 lire) and 6 women (at 5 lire) for mowing, harvesting the part left for seed, and collecting the seed . . . . .	70 "
Rent of irrigable land for 4 months . . . . .	400 "
Cost of after manuring and sundries . . . . .	230 "
<b>Total expenditure . . . . .</b>	<b>1300 lire</b>

(1) See R. July-Aug. 1920, No. 747. (Ed.)

## RECEIPTS.

First crop:—350 qx. of grass at <i>lire</i> 7.50 . . . . .	2625 <i>lire</i>
Second crop:—150 qx. of grass at <i>lire</i> 7.50 . . . . .	1125 "
4 qx. of seed at 180 <i>lire</i> . . . . .	720 "
Pasturage on the 2nd crop and a hundred bundles of grass stalks . . . . .	130 "
	<hr/>
Total receipts . . . . .	4600 <i>lire</i>
Deduct total expenditure . . . . .	1300 "
	<hr/>
Net profit per hectare . . . . .	3300 <i>lire</i>
	<hr/>

The grass stalks are useful for field coverings and specially for nurseries and hot-beds.

By sowing the seed obtained, in the following year, uniform germination was secured but the growth was less luxuriant. However the half field intended for forage gave two abundant crops; on the other hand the half left for seed flowered well but gave a very small amount of seeds, which could not be collected, as when barely in the milky stage they were attacked by swarms of wasps (*Vespa germanica* and *V. vulgaris*) which ate up the whole of the inside. Birds were also very destructive.

The unsatisfactory results of this second experiment are attributed by the writer to several causes:— not sufficiently careful ploughing — lack of manure — cold and wet season — degeneration of the seed; that used in the first experiment had been brought from Bengasi. F. D.

1057 — **Mangolds in Combination with Maize.** — Succi, A., in *L'Italia agricola*, Year 50, No. 8, pp. 265-268, Piacenza, Aug. 1922.

The writer calls attention to the economic advantage of growing mangolds mixed with maize, a combination which he has tried with success for about twenty years. The mangolds are sown between the lines of maize and at the same time or a little earlier. The two plants spring up and grow together; the maize then develops rapidly and the growth of the mangolds gradually slows down until it stops completely; by degrees as the maize begins to ripen the pressure is eased and the mangolds again begin to grow and after the maize is harvested, develop quite normally.

At this time, the beginning of autumn, the soil is the seat of a powerful chemico-biological activity by which the mangolds are able to profit; they leave therefore to the next crop, which is generally wheat, smaller quantities of fertilising principles and especially of nitrogen; it is therefore necessary to make up the deficiency by abundant manuring of the maize when combined with mangolds or by applying a quick acting fertiliser to the wheat.

That there is no danger of the mangolds dying during the suspension of growth has been ascertained by the writer even in the case of its combination with Caragua giant maize, as well as in southern districts with dry summers and in light mellow volcanic soils.

The combination allows for compensation for the damage which in some years drought causes to the maize, for the reduced growth of the maize allows the mangolds to grow larger.

Lastly, the writer gives the appropriate cultural rules:— The soil to be sown should be crumbled; the space between the lines of maize should not exceed or but slightly that of maize grown by itself, e. g. for early Reggio dwarf maize, it should measure 40-50 cm.; no special attention is necessary for the associated crops; weeding and earthing up are done at the same time; the uprooting and transplanting of the mangolds causes no injury to the maize.

Sugar beet is much less suitable for growing with maize; whatever variety is grown the roots can only be used for feeding cattle; it is therefore better to grow mangolds in combination with maize as they give a more abundant crop.

D. F.

1058 - **Olive-Growing in the South-West of the United States.** — KINMAN, C. F. (Pomologist, Horticultural and Pomological Investigations), in *Farmers' Bulletin* 1249, *United States Department of Agriculture*, figs 28, pp. 43, maps 2. Washington, February, 1922.

OIL  
PRODUCING  
PLANTS

Olive-growing in the United States is confined to California and Arizona. It was introduced by the Franciscan Missions about a century and a half ago, and has increased yearly, so that in 1919 the area under olive-trees in California was 15 160 hectares, and in 1917 there were 246 hectares of oliveyards in Arizona.

The United States imported 149 350 hectolitres of olives and 313 740 hectolitres of olive-oil in 1919. Until 1900 California and Arizona both produced olive-oil, but since that date the whole crop of olives has been preserved in the green state, or when ripe. As there are large tracts in the country suitable for olive-growing, the United States would find it profitable to encourage the development of the industry.

The chief centres of olive cultivation are: the Sacramento Valley, the San Joaquin Valley, the coast of Central California, South California and Arizona.

The author describes the climatic and soil conditions etc. necessary for olive-growing.

The varieties grown are not very numerous. The oldest is the Mission variety, but during the last 30 years of the nineteenth century, more than 80 varieties were introduced from Spain, Italy and France. Since no more oil has been manufactured, these foreign varieties have been superseded by others which bear larger fruits.

After the "Mission" variety, the most important varieties are: "Manzanillo", imported from Spain; this tree produces larger and earlier ripening fruit than the "Mission" and is suitable for regions with early frosts; the tree is vigorous and has a spreading habit of growth — "Ascolano" a native of Italy, bearing some of the largest fruits of oval shape produced by the trees in America — "Sevillana" (Spanish) very widely cultivated, with long oval fruits of excellent quality — "Redding" im-

ported from France, much cultivated, being regarded as the true Picholine, with small fruits yielding much oil — "Nevadillo" a somewhat smaller variety than the Mission; the fruits are regular in shape, but not large enough for preserving.

The author describes the various methods of propagating the olive-tree: from seed, slips and grafts — the distances at which it should be planted — the methods of cultivation — pruning — and irrigation.

The date of gathering the crop varies greatly according to the situation of the olive-yard. In the hot districts of California olives can be picked as early as October, whereas in some parts of the coast, they are not harvested before February.

Olives to preserve well must be sufficiently but not over ripe. Although the colour should be a good guide, it cannot be trusted.

Olives are ready for gathering when their pulp contains 17 % of oil, e. g. for the Mission variety. This percentage is reduced to 15 % in the case of "Manzanillo". Other varieties are picked when relatively green.

In order to prevent injury, the fruit is always hand-picked.

As soon as the olives are collected, they are graded by a sorting machine, the fruit of the different varieties being treated separately.

After sorting the fruits are placed in tanks to undergo the treatment necessary for their preservation.

The bitterness of the olives is removed by a bath of potash solution; afterwards they are carefully aerated to give them a dark colour, washed in cold water and left for some days to soak in salt water, after which they are removed from the tanks, placed in bottles of salt water and put in a water-bath or autoclave.

The author describes the diseases and parasites which attack the olive-tree in the United States.

Among the insects is *Saissetia oleae* Bern (black scale), while of the bacteria, *B. savastanoi* (knot), is the most important. Die-back or exanthema, and Dry-rot are two of the most serious diseases encountered in the olive-yards.

P. C.

#### SUGAR CROPS

1059 — **Comparative values of Various Nitrogenous Manures for Sugar Cane Growing, in Java.** — KUYPER, J, in *Archief voor de Suikerindustrie in Nederlandsch Indië*, 1922, *Mededeelingen*, No. 3, pp. 145-154 + 6 diagr. Soerabaja, 1922.

For several years field experiments have been made, under the direction of the Pasoeroean experimental Station for sugar cane cultivation, for the values of several nitrogenous manures. Sulphate of ammonia, the manure in general use, the average dose being 425 kg. per hectare, serves as a basis of comparison.

During the last 10 years 162 comparative tests have been made between sulphate of ammonia and nitrate of soda and it has been possible to shew that for sugar cane these two manures have the same value; sulphate of ammonia however is to be preferred as not being hygroscopic.

Cyanamide of calcium is not equal to sulphate of ammonia; in about

a hundred tests with cyanamide, the sulphate gave an equal result 24 times and 53 times a better result.

A mixture of nitrate and sulphate of ammonia supplied by the "Badische Anilin und Soda Fabriken" proved too hygroscopic, owing to the conditions of the tropical rainy season. Urea, supplied also by the above mentioned firm, gave the same results as sulphate of ammonia with which it was compared in 12 field experiments; it is therefore considered that urea will form a good substitute for sulphate of ammonia. A more detailed examination was made with ground nut cake. This manure showed itself inferior to sulphate of ammonia but it did better in light soils. It is more efficient when combined with sulphate of ammonia. In all the experiments the amount of nitrogen furnished by the different manures was equivalent.

J. K.

1060 — **Use of the Refractometer in the individual Examination of Sugar Beets.** — MUNERATI, O and MEZZADROLI, G., in *Le Stazioni Sperimentali Agrarie Italiane*, Vol. I, V, No. 4-6, pp 163-173 Modena, 1922.

Since 1913, the writer have used at the "Stazione Sperimentale di Bieticoltura" at Rovigo the sugar refractometer to supplement the examination with the polarimeter for the testing of beets for selection. Their long experience thus acquired enables them to report as follows:— the refractometer (sugar type) is very useful for the individual analysis of beets, but it cannot take the place of the polarimeter, except in the case where an approximate idea of the percentage of sugar in the beet is sufficient; the data which the polarimeter and the refractometer give supplement and control one another. The method of examination with the refractometer can replace by reason of its greater accuracy and easier use the method of immersion in a solution of salt or sugar of known density, for classification according to the specific gravity of the roots. The second polarimetrical examination (system of double analysis), which is ordinarily made in selection laboratories to control a preliminary analysis of individuals which have shown a high sugar content, may be replaced by an examination with the refractometer. This method is equally accurate and avoids the risks of spoiling caused by double immersion.

The extra staff and cost entailed by reading the refractometer does not exceed 15-20 % of that which is required for ordinary polarimetrical analyses. The use of the refractometer may be of great value in cases in which it is only necessary to ascertain the density (dry matter) of the juice, or to fix approximately the value of a beet, without making an examination with the polarimeter.

1061 — **Chests of Red Cedar (*Juniperus virginiana*) for Protecting Clothing against Damage by Moths (*Tineola biselli* Humme).** — BACK, R. A. (Entomologist in Charge of Stored Product Insect Investigations, Bureau of Entomology) and RABAK, FR. (Chemical Biologist, Drug, Poisonous and Oil Plant Investigations Bureau of Plant Industry), in *U. S. Department of Agriculture, Bulletin* No. 1051, pp. 1-14, bibliography of 18 works. Washington, April 13, 1922.

AROMATIC  
PLANTS ETC.

Red cedar (*Juniperus virginiana*) commonly known as Tennessee or Virginia red cedar, is one of the most widely distributed trees in the

United States ; it is found as far west as the Rocky Mountains, and in Tennessee, Virginia and North Carolina it occurs in large areas of nearly pure forest. It sometimes reaches a height of 90 ft., but usually averages 40 to 50 ft. or less. In general, the red cedar is a straight tree pyramidal in shape. The wood is light, close-grained, compact and durable. The heartwood is red and strongly aromatic (1) while the sapwood is white and odourless.

For centuries chests made of red cedar have enjoyed the reputation of protecting clothing stored in them from the ravages of clothes moths. The authors undertook a comprehensive study of the effect of such chests upon the adults, eggs and larvae of the southern or webbing clothes moth, *Tineola bisellielli* Hummel to see how far these chests were really an adequate protection.

The experiments had a positive result. Chests made of heartwood of red cedar are effective in protecting fabrics from the ravages of the clothes moth if they are beaten, brushed and exposed to the sun before being put away. The authors experimented with 9 chests from the time of manufacture until the chests were 9 years old and are of opinion that they will retain their protective powers indefinitely, if well-cared for. Special precautions must be taken to prevent the chests losing their characteristic odour which is the active factor ; they shut tightly and must be left open as little as possible.

Adult moths can live from a fortnight to a month in the chest and lay their eggs, but as they do not eat and the young larvae promptly succumb, no harm is caused by their presence. On the other hand, larvae 3 to 4 months old continue their development. These larger larvae are capable of doing a good deal of damage, although their powers appear to be somewhat diminished by the effect of the chests. The larger the larvae when they enter the chest, the more resistant are they to the aromatic odour, until they reach an age or size, not easily defined, when they acquire the faculty of feeding and developing normally within the chests.

Larvae hatching from eggs within the chests die in most instances within 2 or 3 days, and practically all succumb within a fortnight. If hatched outside and introduced into the chests in clothing, they soon show a tendency to cease feeding and rarely live over the first or second week. It is important that all goods intended for storage in cedar chests should be cleaned, beaten, brushed and sunned in order to remove or kill as many of the moths' eggs and larvae as possible. Special attention must be given to all seams, creases and pockets. Such clothing, if stored at once in good cedar chests, should be sufficiently well protected.

E. K.

(1) The heartwood contains from 2 to 4 per cent of a pale yellowish-brown volatile oil of which the principal constituents are alcohol cedrol, the sesquiterpene alcohol cedrenol and the sesquiterpene cedrene ; the characteristic odour is probably due to the two former compounds. (Ed.)

1062 - **Belladonna and Foxglove cultivated in the Province of Florence, Italy.** — ALESSANDRI, I. (Laboratorio di Chimica Farmaceutica del R. Istituto di Studi Superiori di Firenze), in *Archivio di Farmacologia sperimentale e scienze affini*, Vol. XXXI, No. 9, pp. 143-144 and No. 10, pp. 145-153. Rome, May 1 and May 15, 1921.

The writer has examined a specimen of *Atropa Belladonna* taken from wild plants at Vallombrosa (950-1050 m.) collected in the months of August and September, which had almost completely fructified, and a specimen taken from 2 year old plants cultivated in experimental plots of the "R. Istituto Forestale alle Cascine" (40 m.), collected in the months of June and July, and obtained by sowing seeds of Vallombrosa wild plants. The quantitative analysis of the alkaloid was made according to the method suggested by CAESAR and LORENTZ. The average of three determinations gave 0.297 % of alkaloid for the first specimen, and 0.192 % for the second; the quantity of moisture was approximately equal for both, viz., 4.66 and 3.95 % respectively. The German pharmacopoea requires a minimum of 0.30 % of alkaloid and consequently cultivation in the plains has provided a drug with insufficient atropine, while the wild plants of the mountain zone could be used for extraction of the alkaloid.

The writer has also examined three specimens of *Digitalis purpurea*. One of them was taken from plants grown at Vallombrosa from imported seed: the other two came from plants cultivated at the "Cascine" after sowing Vallombrosa seed; in one case they were transplanted, in the other not.

A physiological test was made on frogs, applying FOCKE's method, but using a 5 % infusion instead of 1 %. The effect passing from the second specimen to the first and third was in decreasing order, though between the last two there were only slight differences. The coefficients calculated according to FOCKE's formula were, as average of two determinations: — 0.231 — 0.122 — 0.1255 %. The ultimate chemical test made according to the Italian Military Pharmacopoea which fixes a minimum of 0.14, gave respectively the following percentages of digitalin: — 0.322 — 0.150 — 0.181; the three specimens contained approximately the same quantity of moisture (4.0 — 5.87 — 4.54 %). On the whole, the two series of data agree. They indicate that the cultivation of the foxglove is to be recommended and also that wild plants may be suitable. It is however desirable that further researches should be made and supplemented by quantitative tests, to establish these conclusions. L. V.

1063 - **Wormseed (*Chenopodium ambrosioides*).** — BRU, P., in *Revue vétérinaire*, Vol. LXXIV, No. 4, pp. 217-225. Toulouse, April 1922.

Wormseed is a plant with the properties of a vermifuge and specially effective against round worms (ascarids, trichocephali, ankylostomes, strongyli, etc.), and as such, largely used in America. In Maryland (United States) *Chenopodium ambrosioides* var. *anthelminthicum*, which is richer in active principles, is specially cultivated. Plants of this variety are 1 m. high, with stiff stalks, branches covered with hairs, narrow leaves, 5 to 7 times as long as they are broad, pointed marginal denticulation; near the end of the stalk, the leaves are shorter and are finally scarcely visible.

The floral glomerules are collected in closely packed whorls without bracts and form as a whole, a compact terminal cluster. A strong, penetrating aromatic odour is set free from all parts of the plant, due to an essential oil secreted in the hairs and parenchymatous glands. The American variety is replaced in France by *Chenopodium ambrosioides* var. *subfruticosum* very common in the west and south and known locally under the names of Mexican tea, Mexican ambrosia and goose-foot vermifuge. It grows on rubbish heaps and sub-spontaneously with alternate lanceolate leaves, with undulating rather than dentate edges, and wider than those of the American variety; the flowers are greenish and arranged all along the stalk in axillary glomerules. In tropical regions, in Brazil, in the Antilles and in Dahomey a third variety is found — var. *Sancta Maria* which from a pharmacological standpoint, differs from the preceding varieties as these differ between themselves, only in the content of the active principle.

Plants of *Chenopodium* contain a volatile essential oil (essence of *Chenopodium*) composed of ascaridol  $C_{10}H_{16}O_2$  (65 % on the average), cymol (22 %) and dioxyterpen. The active principle is ascaridol. The essence is obtained by distillation of the seeds or the tops of the plant when they have almost reached maturity. The writer describes its therapeutic and other properties.

#### HORTICULTURE

1064 - Vegetable Growing in Island of Guam. — BRIGGS, G., in *Guam Agricultural Experiment Station, Bulletin No. 2*, pp. 1-66 Washington, June 1922

Before the occupation of Guam by the United States, only a very few vegetables were grown by the natives. Since then distinct progress has been made throughout the island. Nearly all the common vegetables can be grown. However, methods adopted for the various crops in the temperate zone generally require some modification in the Tropics; seeds often fail to germinate or the plants do not yield any fruit.

Owing to the lack of definite information concerning tropical horticulture, the Guam Agricultural Experiment Station has undertaken the development of this work since its establishment in 1909. The methods to be adopted are based on the results obtained and are given in detail in the bulletin under consideration.

Amongst other points discussed are included: suitable soils; seed; manures and fertilisers; preparation of seed-bed; planting; cultivation; fences and windbreaks; diseases and pests; detailed cultural directions for the various crops: viz. acelga (*Beta cycla* and *B. vulgaris cycla*); amargoso (*Momordica charantia*); arrow-root (*Maranta arundinacea*); Asparagus (*Asparagus* sp.); banana (*Musa sapientum*); lima beans (*Phaseolus lunatus*) and variety "chochomeco" etc.; cowpea (*Vigna sinensis*) and variety "fijole"; cerebilla (*Doichos lablab*); seguidilla (*Psophocarpus tetragonoloba*); mungo (*Phaseolus aureus*); maize cabbage; calabaza (*Lagenaria vulgaris*); carrot (*Daucus carota*); cassava (*Manihot manihot* (= *M. utilisissima*); chayote (*Sechium edule*); collards (*Brassica* sp.); condor (*Benincasa cerifera*); cucumber (*Cucumis sativus*); egg-plant (*Solanum melongena*); horse-radish (*Cochlearia armoracia*); lettuce; mint; musk-

melon (*Cucumis melo*); mustard (*Brassica juncea*); okra (*Hibiscus esculentus*); onion; papaya (*Carica Papaya*); parsley; patola (*Luffa aegyptiaca*); peas; pechay (*Brassica chinensis*); peppers; pigeon pea (*Cajanus indicus*); plantain (*Musa paradisiaca*); potatoes; *Cucurbita* spp.; radish (*Raphanus sativus*); roselle (*Hibiscus sabdariffa*); spinach (*Spinacia oleracea*); sweet potato (*Ipomoea Batatas*); taro (*Colocasia esculenta*); tomato; turnip; water melon (*Citrullus vulgaris*); yam (*Dioscorea* spp.); yam bean (*Pachyrhizus tuberosus*).

1065 — **Cultivation of Citrus Fruits in Rhodesia.** — TURNER, A. G., in *Department of Agriculture, Salisbury, Rhodesia, Bulletin No. 124*, 23 pp. Salisbury, June 1922.

ARBORICULTURE

During the last 5 or 6 years, great progress in citrus fruit cultivation has been made in several parts of Rhodesia. The great problem to be solved is that of transport; in 1921, only part of the consignments received at the various ports could be shipped. The author advised co-operation amongst the growers as being the best means of overcoming the difficulty, and in the first half of 1922, a co-operative Society was founded known as the "Fruit Growers' Exchange of South Africa, Ltd." In spite of the lack of tonnage in 1921, about  $\frac{1}{3}$  of all the citrus fruit exported that year by the whole Union of South Africa (240 000 cases), came from Rhodesia and the exports this year are expected to be twice as large.

The average prices fetched by Rhodesian oranges in 1921 were as follows: — wholesale price in England 23 shillings per case; in Rhodesia, the price was 16/6 net (i. e. after deduction of the costs of railway carriage and freightage, lading and unloading charges, commission etc.); in the orange gardens, the fruit was sold for 10 shillings per case. These oranges find a ready sale in Europe, for they come on the market at a time when other oranges are not available.

One case of first-class fruit can be obtained from an orange tree 5 years of age, while the crop of a tree in full bearing, viz, when 10 years old, will fill three or four cases.

The author studies the following questions: choice of locality — selection of varieties, the following being recommended as being most in demand by the export trade: Washington Navel — Valencia Lale — Jaffa — Joppa — Mediterranean Sweet — Paper Rind St. Michael; the two first being special favourites — planting an orange garden — irrigation — cultivation — manuring — pruning — spraying and fumigation.

1066 — **Vine-Growing in Alsace.** — BURGER, G., in *Progrès agricole et viticole*, Year 39, No. 23, pp. 544-548 Montpellier, June 3, 1922.

VINE GROWING

The area cultivated under vines in Alsace is 20 000 ha. The production is somewhat variable, being 725 000 hl. in 1920 and 368 850 hl. in 1921, and white wines are estimated to make up 90 % of the total production.

Alsatian table wines are distinguished according to the vines. Ordinary wines are produced by: — Bourgeois, Chasselas, Kniperlé, Silvaner. They resemble German Moselle wines. Fine wines come from the vines:

— Gentil, Riesling, white Pinot, Traminer, and resemble the German Rhine wines. The most famous districts are:— Ribeauvillé, Riquewihr, Ammerschwiler, Mittelwihr, Hunawihr, Beblenheim, Turkheim, Eguisheim, Rouffach, Guebwiller in the Upper Rhine; Barr, Kinzheim, Dambach, Molsheim, Obernai in the Lower Rhine.

The wines of Alsace are characterised by fine bouquet combined with a pleasant acidity and are of a mellow type. These good quality wines represent a new class for France, the Alsatian wines bring of a different character from the French.

Their cost is generally high, owing to the amount of manual labour required for production. Alsatian wines must therefore try to take the place of the old German wines in the market, mainly in the markets of Paris, Belgium and England.

#### FORESTRY

1067 - **Mangrove Swamps in the Dutch Indies.** — BECKING, J. H., DEN BERGER, L. G. and MEINDERSMA, H. W., in *Tectona*, Vol. XV, No. 7, pp. 561-611, 2 figs., bibliography of 22 publications. Buitenzorg, July 1922.

In the Dutch Indies, mangrove swamps are found on the coasts which are less exposed to the open sea such as those of the bay, delta and internal seas and especially on more or less muddy lands subject periodically to sea water flooding. It is not known exactly whether the mangroves improve the fertility of the soil, and they are probably only a secondary factor. Various morphological and physiological characters result from these conditions. SCHIMPER called the mangrove xerophytic because of the high saline concentration which the plants must endure and of their low moisture evaporation. However HOLTERMANN and Von FABER proved that transpiration could be considerable so that SCHIMPER's theory is not entirely accurate.

The swamps in which the mangroves grow and their periodic submersions render special organs of transpiration necessary and these are generally represented by the roots. The pneumatophores are roots or portions of roots which are transformed and provided with organs of transpiration or lenticels.

Many species are viviparous. The seeds germinate on the tree and take root when they fall into the mud. They can float for a long time without sinking in the water like the fruits of non-viviparous plants. The number of species is limited. In the Malay archipelago there are reckoned to be 28 and conspicuous among them are *Rhizophora*, which grows on the sea coast, *Bruguiera* and others which grow in the interior and on less marshy land.

The writer also gives indications for identifying the species of mangroves. He describes the various genera, indicating their chief properties and describing the wood as it appears under an ordinary pocket lens.

The descriptions are summed up diagrammatically in 10 tabular statements containing respectively:— 1) the diameters of trees of normal growth — 2) a list of the values of the various timbers according to the scheme of classification of the Buitenzorg experimental forestry station —

3) the method for determining the wood with the use of a pocket lens — 4) a list of the values of the various woods as fuel — 5) a classification of fuels — 6) a tabular statement for determining the wood — 7) a tabular statement for determining the fuel — 8) the working of the fuel in the Dutch Indies — 9) a tabular statement of the tanning qualities of mangroves — 10) a tabular statement for valuing tanning barks.

By means of a few examples, the writer shows the importance of the exploitation of tanning barks in the Malay archipelago and furnishes information regarding the manufacture of cutch. The commerce in mangroves is done on a large scale but with systems which are not yet economical.

1068 — **Wooden Chests made of *Juniperus virginiana* for the Protection of Insect Attack on Clothes.** — See No. 1061 of this Review.

## LIVE STOCK AND BREEDING

1069 — **The Screw-Worm Fly (*Cryomyia macellaria* Fabricius) and other Diptera parasitic on Stock in the United States.** — BISHOPP, F. C., MITCHELL, G. D. and PARMAN, D. C., in *United States Department of Agriculture, Farmers' Bulletin* 857, pp. 3-19, figs. 7. Washington, January 1922.

HYGIENE  
OF CATTLE

The screw-worm fly occurs from the extreme southern part of South America northward into Canada, but it seldom becomes abundant in the Northern States being chiefly found in the warmer parts of the Union (Texas, Oklahoma, New Mexico, Arizona and Southern California) where it causes enormous losses to the stock raisers. The various stages of the insect are so well known that it is unnecessary to describe them.

The fly appears (according to the latitude and the season) from the first of April to the middle of June.

The insect decreases in numbers in July and August unless the weather is cloudy and rainy, but again becomes abundant in the early autumn, its activities only ceasing with the heavy frosts. A warm humid atmosphere is best suited to its development.

*Chrysomya macellaria* breeds in decaying matter, especially the carcasses of large animals, and if these could be disposed of properly, no cases of infestation of living animals would occur. Practically however all animals are more or less subject to attack and it infests in decreasing order of frequency cattle, hogs, horses, mules, sheep, goats and dogs. Numerous cases of the infestation of human beings have been recorded.

The eggs are deposited in the wounds of living animals and the young larvae, as soon as they hatch out, burrow into the flesh of their host excreting an irritating substance that breaks down the tissues and may result in the general poisoning of the system. Sometimes calves are attacked at the time of birth when the worms penetrate the navel. At a later stage, infestation takes place by way of the mouth occasionally resulting in loss of teeth or in death. Generally the flies are attracted by coagulated blood, and infestations occur after surgical operations

(castration etc.) or after serious attacks of other parasites (ticks, horse-flies etc.). In severe cases, where there are an enormous number of larvae, the host loses appetite, becomes emaciated and hides in the undergrowth. While fatal cases are not infrequent, most of the loss is due to the reduction of flesh, the expense entailed in treating the animals and the money spent on screw-worm medicines.

**CONTROL MEASURES.** — The best method of control is the burning of any dead animals; this not only stops the breeding of all blow-flies, but prevents the dissemination of dangerous diseases e. g. anthrax, black-leg and hog cholera. The method of burning the carcasses depends to some extent upon the locality. It is desirable that the carcasses should be burnt on the spot, and in cases of anthrax this is essential. If burning is impracticable, the carcasses may be buried beneath at least 2 ft. of closely packed soil. Should it be absolutely impossible to burn or properly bury a carcass, many of the maggots may be destroyed by exposure to the sun.

**PREVENTIVE MEASURES.** — Even in the most heavily infested districts, losses from screw-worm at calving time can be largely avoided by arranging for the cows to calve between December 1 and the middle of April. In the northern regions, this time may be extended from about November 1 to June 1 (1). Branding and castration should be carried out between December 1 and May 1; greater care should be taken in handling the cattle, and the de-horning period ought to be shortened. As supplementary measures, the following may be advised *a*) the destruction of ticks; *b*) the clearing of the brush and undergrowth; *c*) the use of poisoned bait and traps for the destruction of the adult insects.

**TREATMENT OF INFECTED ANIMALS.** — It is important that herds should be watched carefully during the screw-worm season. Those familiar with the injury caused by the parasite can easily tell if a wound is infested, for there is usually a free discharge of watery blood and the wound appears as if recently caused. For destroying the larvae in a wound there is nothing better than chloroform; a deep lesion should afterwards be cleaned out with water containing 5 % carbolic acid; tannic acid followed by pine-tar or some of the creosol dips being afterwards applied as a repellent for flies.

Although only the larvae of *Chrysomya macellaria* penetrate the sound tissues of living animals, the maggots of the black blowfly (*Phormia regina* Meig.) and of the green-bottle fly (*Lucilia sericata* Meig.) infest the wool of sheep while those of the flesh-fly (*Sarcophaga* spp.) attack suppurating wounds.

The above three species are carrion breeders and only when very numerous do they infest wounds on living animals; the best means therefore of controlling them are those already recommended in the case of *Chrysomya macellaria*.

E. F.

(1) This would of course mean a change in the present practice of leaving the bulls with the herd continuously. (Authors' Note)

1070 - **Splenic Inflammation of Pigs in Prussia and the Causes of its increased Frequency.** — WIEMANN (Reg. und Veterinärarzt, Berlin), in *Berliner tierärztliche Wochenschrift*, Year XXXVIII, No. 15, pp. 169-171. Berlin, April 13, 1922.

In 1912, ELSÄSSER and SIEBEL (1) called the attention of breeders to the rapid and extraordinary increase in cases of splenic inflammation of pigs in Prussia; the same year the Prussian Ministry of Agriculture and the Imperial Bureau of health caused researches to be made regarding the causes of the increased frequency of this disease; they made a careful microbiological examination of anatomical material taken from 238 cases. These are classed by the writer in 4 groups (according to the gravity of their anatomopathological injuries and the diffusion of the germs) and tabulated according to their origin.

Regarding the origin of the disease, it was evident that it should be looked for in the foods given to the animals and especially in those coming from foreign countries. The latter in fact formed a very considerable portion of the food of the pigs, especially in Hanover and Schleswig-Holstein, because in these countries the fattening of pigs had increased to such an extent that the local production of barley was insufficient for the feeding requirements and it was in those districts that cases of the disease were most frequent.

Subsequent researches indicated fish meal ("Fischmehl") as the probable vehicle of the pathogenic germs, a food consumed in large quantities, because it was cheap and at the same time considered to be very nourishing; however under normal conditions, it proved to be free from bacteria. It was then thought that the fish meal might be adulterated by the addition of substances containing the germs of splenic inflammation, and sufficient evidence was soon collected to detect bone meal of Indian origin ("indisches Knochenmehl"). The Prussian Government ordered extensive investigations to be made to ascertain definitely: — (a) whether the fish meal was manufactured in infected localities, and how it was made — (b) whether other matter was mixed with the fish meal either at the place of production or in trading, and if so, the nature of that matter — (c) whether foreign or only local fishmeal was ordinarily found on the market and whether the foreign meal was sold to the public after undergoing special manipulation or mixture with other products. These enquiries led to a definite result: among the numerous samples sent in for examination at the Institute of Hygiene at the Veterinary College at Berlin, a large percentage of samples of fish meal contained bone meal, which in almost all cases contained germs of the disease.

It was then ascertained, both in Prussia and in other States of the Empire, that certain large manufacturing firms constantly adulterated the fish meal with considerable quantities of Indian bone meal and it was understood that the danger of this product was already known by the Governments

(1) ELSÄSSER and SIEBEL, Ueber die gesundheitpolizeiliche Beurteilung des Fleisches bei lokalem Milzbrand bei Schweinen, in *Zeitschrift für Fleisch u. Milchhygiene*, 1912, No. 8-9. (Author's note)

of the United States and of New Zealand, who had prohibited its importation. Another proof of the fact that the increased frequency of splenic inflammation in pigs was due to the adulteration of the food with bone meal was afforded during the war, which prevented the importation of this product:— the number of cases of the disease which was, for the whole of Germany, 2706 in 1914, fell to 112 in 1915, to 133 in 1916, to 34 in 1917 and to 30 in 1918. # ANATOMY AND PHYSIOLOGY

1071 — **Experimental Contribution to the Knowledge of the "Working Conditions" of Draught Animals under different Dietary Conditions.** — ALBERTONI, L. in *Le Stazioni sperimentali agrarie italiane*, Vol. LV, No. 4-5-6, pp. 173-262, bibliography of 46 publications. Modena, 1922.

Work done at the Royal College of Veterinary Medicine at Bologna.

After a wide review of present knowledge on the subject of the influence of different rations on the "working conditions" of draught animals, the writer describes his experiments on this question.

The following points are considered:—

I. — VARIATIONS OF THE PERCENTAGES OF GLYCOGEN AND OF GLUCOSE IN THE MUSCLES OF THE FRAME AND OF GLYCOGEN IN THE LIVER, UNDER THE INFLUENCE OF DIFFERENT DIETS. — 1) *Importance of glucose and glycogen for muscular contraction.* — 2) *Quantities of glucose and glycogen which may be found in the animal organism.* — 3) *Quantities of glucose and glycogen which may come from the ration* : how much of them the ration should contain in order to supply them again to the muscles. — 4) *Origin of the glucose of non-nitrogenous extracts and of crude cellulose* — 5) *Origin of the glucose of proteins and of fats.* — 6) *Summary on the capacity of the ration of herbivorous animals to supply glucose to the muscles* : "The rations of our herbivorous animals in which for hygienic and economic reasons, carbohydrates always predominate, should be such that they are able to maintain in the muscles the maximum quantity of glycogen which they can contain if, apart from the chemical relationship of simple foods to glucose, other causes which may influence that formation do not intervene." — 7) *CHAVEAU'S theory on the production of work.* — 8) *State of nutrition of animals and their provision of glycogen.* — 9) *Method of research followed in these experiments.* According to CHAVEAU'S theory on the production of work:— 1) Glucose is the immediate food of the intramuscular combustion of work — 2) Glucose can be derived from carbohydrates, albumens, and fats — 3) The food materials replace one another by isodynamic weights.

CHAVEAU considered glucose as being derived from fats by incomplete oxidation and from albumens by hydrolysis with the formation of decomposition products unutilisable as plastic material. In each case there would be a loss of energy, but the numerous and conclusive experiments of ZUNTZ, of his collaborators ATWATER and BENEDICT and other scientists lead to the conclusion "that, in the development of force nutritive substances replace each other in proportion to their provision of utilisable energy."

The experiments of the writer do not relate to this question "except

from the practical stand point, at least, it may be considered as solved, " but to the choice of foods for the production of work.

He proposed to determine " which are the foods that enable an animal to return the total output of work that may be expected from their composition; which are, in short, the foods which will best maintain an animal in a condition for work and by what means they may be able to influence it. " In these experiments the animals had been kept resting and well fed, sometimes even *ad libitum*.

II. — PROBABLE CAUSES OF VARIATION OF THE PERCENTAGE OF GLYCOGEN IN THE MUSCLES.

III. — 1) *Choice description and analysis of foods.* The writer used :— pasture, grass hay (almost exclusively of *Dactylis glomerata*), lucerne, oat grain, beans, maize, rice, barley; as protein food, Emmental cheese; as fatty food, lard) — 2) *Composition of forages, such as is determined by analyses and its importance in regard to these researches.* — 3) *Choice of animals, their preparation for feeding experiments, distribution of rations, observations regarding the behaviour of the animals.* — 4) *Methods employed for the quantitative analysis of glycogen in the muscles and in the liver, and for the quantitative analysis of glucose in the muscles.* For glucose :— extraction of the muscle by repeated boiling, filtration of the broth, defecation with excess of nitrate of mercury, filtration, precipitation of the reagent excess by a current of sulphuretted hydrogen, filtration, neutralisation and concentration of the liquid, quantitative analysis of glucose according to ALLIHN'S method; for the determination of glycogen PFLÜGER'S method was used.

IV. — DESCRIPTION OF THE EXPERIMENTS : — 1) on horses — 2) on rabbits — 3) on guinea pigs — 4) on white rats.

The results of experiments made on the horse and the mule are summed up as follows : — 1) The ration of pasture grass and oats produced a greater quantity of muscular glycogen than the ration of pasture or of oats alone. — 2) the diet composed only of grass hay and straw given in sufficient quantity for the nourishment of resting animals, produced very much less glycogen in the muscles than the maximum which could be found in them. — 3) The addition of oats and rice to the maintenance ration, composed of grass hay and straw, considerably increased the amount of muscular glycogen — 4) Oats and rice, each given in proportion to the nutritive units which they contain, produced in the horse and the mule different quantities of glycogen. — 5) The semi-tendinous muscle of the horse and the sterno-humeral examined on the same animal and at the same time showed a remarkable difference in the percentage of glycogen : 23.5 % more in the former than in the latter. — 6) The mule did not reach the percentage of muscular glycogen of the horse fed on the same ration; the latter exceeded the mule by about 68 %. — 7) A horse kept on pasture only at first, and oats only afterwards, showed a negligible difference in the quantities of glucose contained in the semi-tendinous muscle (3.88 and 3.66 per 1000 respectively).

V. — 1) *Influence of the percentage of protein in the ration on the pro-*

*duction of muscular glycogen*: from most of the experiments made up to the present, it results that the protein ration, especially if it is not deprived of carbo-hydrates, is favourable to the production of glycogen — 2) *Nitrogenous foods in the practical feeding of working animals.* — 3) *Conclusions regarding the influence of the quantities of proteins in the ration on the sources of muscular energy.* — 4) *Foods rich in carbo-hydrates.*

Casein renders the muscles of rats rich in glycogen: the fat in which it was administered and the excellent state of nutrition of the animals, did not prevent the deposit of a considerable amount of glycogen in the muscles. Using other protein foods ROSEMBERG and MERING got the same results, while SEITZ, with ducks overfed with albumen, found the glycogen reduced to traces and replaced by fat: apparently, it may therefore be concluded that proteins do not all behave in the same manner for the production of the two principal substances of muscular reserve. "It remains to be ascertained experimentally whether it is necessary to make a distinction between the proteins which produce glycogen in the muscles and those which produce fat, or whether the formation of fat in the liver and the corresponding disappearance of glycogen are produced when proteins alone are fed continuously in large quantities, so that an alteration of the chemistry of the hay may result.

Decrease in the quantity of carbohydrates to the advantage of proteins in the ration of herbivorous animals in no way hinders the production of glycogen (which is largely assured by the rest of the ration); it is even favourable to it in an indirect manner, for a large quantity of protein in the ration insures to the protoplasm of the muscular fibres the maximum power of accumulating reserve substances. Abundant feeding does not always cause, by the fattening it entails, a decrease of glycogen in the muscles. The diet of rice produces, both in the muscles and in the liver, a large quantity of glycogen, so long as the percentage of protein in the ration does not decrease below what is sufficient to balance the nitrogen requirements of the animal, or so long as it is maintained above that limit. It may even happen that foods with a carbohydrate basis, well known to be producers of glycogen (those for example, which are composed essentially of barley, maize, sugar, and probably also those with potatoes, chestnuts, carobs, foods with wide nutritive ration) do not produce glycogen in the muscles because they are insufficient to maintain, in the muscular fibres and in the circulation of the muscle, the reserve which maintains the turgescence of the cells, and which is very probably the necessary condition to enable the muscular protoplasm to preserve, to a high degree, the fundamental metabolism, the power of elaboration and the faculty of accumulating non-nitrogenous energetic substances. It is thus explained how rations in which carbohydrates predominate may be less suitable than protein rations for the production of sources of muscular energy and consequently of work, in cases of serious impoverishment in nitrogen of the whole organism, *e. g.* race horse in the period of training, acclimatisation crisis, breeding season, etc. In all these cases, eggs, meat, dried blood may prove the best restorers of strength and may be preferred.

VI. — (1) *Probable causes determining the difference of production of muscular glycogen between diets composed of carbo-hydrates, and applications to the technology of work, resulting from that difference of behaviour.*

The experiments of the writer lead to the conclusion that common foods have different physiological values. Using the results obtained with rats and making the productivity of muscular glycogen from rice equal to 100: barley was 100 — cheese 72.4 — maize 69.00 — oats 57 — lard 44 — beans 32.75. The quantity of muscular glycogen which is found in animals subjected to various diets compared with an equal quantity of glycogen of the liver is distinctly different: high in a rice diet (10.2 — 13.54 %) and still higher in a cheese diet (14.8 — 41.30 %) and a diet of bacon (26 %), it falls to 9.2 — 6.17 % in a diet of oats, and to 8.2 — 6.4 in that of beans. If the physiological values of several foods are considered we reach "the surprising fact that the rations universally preferred for working animals are the least suitable for producing glycogen in the muscles": thus oats and beans produce less glycogen than rice and barley. "We are therefore led to admit that an animal may be in full possession of its strength while having but little glycogen; and it may be in an excellent state of nutrition without having its maximum reserve of glycogen. The writer considers that diets rich in carbo-hydrates such as were largely given in his experiments, were sufficient to maintain the animals in an excellent condition of nutrition, although they were poor producers of glycogen, and gave muscles rich in fat; those, on the other hand, which have favoured the production of glycogen, gave muscles less rich in fat.

2) *Working condition of draught animals fed with rations producing different quantities of glycogen.* — "Generally it may be said that glycogen favours the functional efficiency of muscular tissue and that, by assuring the greatest rapidity of chemical, functional and restorative reactions, it favours in that way the rapidity of contraction".

3) *Importance of the quantity of reserve substances in the muscle for the working condition of animals.*

4) *Frequency of contractions and provision of oxygen in the muscles.*

5) *Of different working conditions in which the muscle may find itself under the influence of diet which is to be preferred?*

Should the formation of glycogen or of fat be preferred in the muscle? In other words should we prefer respectively feeding with a basis of barley, rice, sugar, carobs, or with a basis of seeds of leguminous plants, or again a diet of oats, the action of which is intermediate between those of the other two diets?

The muscle which consumes fat, for an equal quantity of energy used, gives the same out put as the muscle which consumes glycogen; and besides, fat accumulates in the muscles in greater quantity because it is deposited as such; glycogen combines with 2 or 3 times its weight of water; fat has, further, a calorific power equal to 2.4 times that of glycogen.

If therefore we consider the problem of the sources of muscular energy from the sole standpoint of the amount of energy, the feeding of the animals should have as basis the use of substances forming muscular fat.

But glycogen has a very peculiar signification for the optimum output of the muscles and for sudden muscular contraction; it may apparently, be said that, when sufficient glycogen can be accumulated in the muscle for accomplishing a required work (the work not being very prolonged or else the animal having the power to store glycogen in large quantity), it is rational to procure its formation. When the work is intense and difficult for the means at the disposal of the animal a diet permitting the formation of a sufficient quantity of glycogen should also be chosen. Lastly, the choice of a food producing a large amount of glycogen might also be rendered necessary by hygienic reasons, for example to maintain a higher percentage of moisture in the tissues. Consequently the choice of the food will depend: — 1) on the intensity, the duration and the nature of the work — 2) on the aptitude of the animal to store up one or the other reserve substance; that faculty depends on the species, race (among horses the Eastern races and their derivatives tend to store up glycogen more especially whereas draught breeds store up fat), climate, sex, etc. — 3) on other factors which determine the working conditions, such as temperament and the quantity of haemoglobin.

6) Some of the specific effects on the working condition of animals, attributed to foods, find their explanation in the results of these researches

#### FEEDS AND FEEDING

1072 — **Rules for Feeding Cattle.** — SCARAMUZZI, D. in *Le Stazioni sperimentali a riarie italiane*, Vol. LV, Nos. 4-5-6, pp. 109-124. Modena, 1922.

In order to give rules to the farmer who neither wishes to waste forage nor to make unintelligent economies, the writer, using mean analytical data contained in the treatise by Professors MENOZZI and NICCOLI, *L'alimentazione del bestiame*, has calculated the percentage proportions of different foods to be used, so as to obtain a ration the nutritive ratio of which decreases successively from 1 : 4 to 1 : 2.

As foods, he has taken into consideration those which have the greatest importance for southern Italy, that is to say all the mixtures which it is possible to form by combining two of the following feeds: — clover hay — vetch hay — straw of cereals — bran — oats — carobs — beans — refuse of olives — husks of grapes — linseed cake.  
F. D.

1073 — **Use, as Cattle Food, of certain Waste Products from Chick-peas, Peas and Beans.** — LAY, C. (R. Stazione chimico-agraria di Torino), in *Le Stazioni sperimentali a riarie italiane*, Vol. LV, No. 4-5, pp. 125-128. Modena, 1922.

CHICK-PEAS. — Of the numerous varieties of chick-peas grown in Italy, some have seeds with hard teguments, so that they must be decorticated for use as human food. Such are the chick-peas with black or red tegument, grown especially in the Province of Bari (annual Italian production 7000-8000 q.) and prepared for use in Piedmont with modern machinery. From these peas are obtained about 75 % of endosperm ("cicerata") and 25 % of waste material from decortication, composed about half of tegument and the rest of endosperm. The waste material is used as cattle food either as it is or mixed with bran or with milling refuse.

For sheep, these waste materials are generally first moistened ; to horses they are fed dry ; for young pigs, they should be ground very fine. Price : — wholesale 79 *lire* the quintal ; retail 90-95 *lire* the quintal.

From the analysis of two samples of decortication waste, one of black chick-peas and the other of red chick-peas, the writer obtained respectively the following percentages :— Hygroscopic moisture by drying at 100°, 11.90 — 10.76 ; Proteins ( $N \times 6.25$ ), 5.25 — 6.20 ; Ash, 5.24 — 5.28 ; Crude fats, 0.42 — 0.95. Cellulose, 27.86 — 25.10 ; Nitrogen-free-extracts, 49.33 — 51.71 ; Pentosans, 15.81 — 14.90.

The ash contained :— Calcium oxide 46.29 — 45.30 ; Potassium oxide 26.52 — 25.38 ; Magnesium oxide 16.08 — 16.98 ; Phosphoric acid 2.66 — 3.02 %.

BEANS. — On decortication in the machine, the beans yield 68-74 % of endosperm and 26-32 % of tegument with a loss of about 2 %, whereas by hand about 85 % of endosperm and 15 % of tegument are obtained. The decortication waste of beans with the machine contains therefore about one half endosperm waste ; the price is the same as for the chick-pea waste. Percentage composition of the endosperm and of the teguments respectively :— Moisture 11.81 — 12.43 ; Proteins ( $N \times 6.25$ ) 27.81 — 9.25 ; Fats 1.53 — 0.21 ; Cellulose 3.02 — 30.15 ; Ash 3.53 — 2.85 ; Nitrogenous-free-extracts 52.30 — 45.11 ; Pentosans, 4.50 — 4.28.

PEAS. — Decortication in the machine gives 55-60 % of cleaned seed (endosperm) and 40 — 45 % of tegument, against 80 % of endosperm and 20 % of tegument by hand decortication. The price of the decortication waste is the same as in the case of chick-peas. Percentage composition of the endosperm and tegument respectively :— Moisture 11.05 — 11.15 ; Proteins ( $N \times 6.25$ ) 23.62 — 7.18 ; Fats 1.24 — 0.75 ; Cellulose 1.35 — 29.73 ; Ash 2.76 — 3.00 ; Nitrogenous-free-extracts 58.98 — 48.19 ; Pentosans, 4.96 — 19.58.

CONCLUSION. — The waste products of decortication by machine of chick-peas, beans, peas constitute excellent cattle foods, as they consist, to the extent of about one half of fragments and flour of the internal part of the seed (endosperm). F. D.

1074 - **Improvement of Stock Breeding in Morocco.** — VELU, H., in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VIII, No. 26, pp. 736-740. Paris, 19 July 1922

The improvement of stock breeding methods in Morocco depend mainly :— (a) on the possibility of increasing the herds — (b) on a definite aim in breeding, in order to specialise in the production of cattle, pigs and sheep — (c) on the choice of methods to be adopted to obtain the necessary improvements in quality.

The great factors which are outside human control and which must be taken into account at the outset and in the course of the work, are essentially the climate and the parasitic organisms or carriers of disease. As in all hot countries, environment is of the greatest importance. Diseases,

**STOCK  
BREEDING**

even the gravest and the most common, are largely dangerous because they attack animals which the climate has reduced to a state of bad health and vital exhaustion. In Morocco animals die mainly of hunger in summer, of hunger and cold in winter (1).

The organisation for the control of numerous internal and external parasites is also a factor of essential importance. Preventive measures against external parasites are almost exclusively based on arsenical dips: the writer therefore advises that the sale and use of soluble crude arsenical products should be allowed in Morocco. The control of internal parasites, which is more difficult, requires the adoption of enclosed areas and the removal of stock from pastures in order to interrupt the cycles of development of parasites which have no intermediate hosts and to destroy these hosts when they exist.

In conclusion, breeding in Morocco, depends on the organisation of preventive measures against disease and modification of the environments which favour the development of parasites. The improvement of environment is an economic problem, for it is a case of ascertaining whether extensive breeding is possible in Morocco or whether it must be replaced by semi-stall rearing. The control of parasites is further a problem of colonial policy, for, to put it into practice, the hostility of the natives must be overcome.

E. F.

#### CATTLE

1075 - **The Work of the Central Syndicate for the Exportation of Charolais Cattle.** -

HITIER, H., in *Bulletin de la Société d'encouragement pour l'industrie nationale*, Vol 134, No 7, pp. 617-621 Paris, July 1922.

The Charolais breed of cattle which is particularly common in the Departments of the Allier, the Cher, the Indre, the Loire, the Nièvre and Saône-et-Loire, is considered to be one of the best breeds. Shortly after the end of the European war, the local breeders, with the object of making their produce known abroad and to induce cattle-breeding countries to use them to improve their herds, constituted a federation of the various agricultural societies and syndicates of the above-mentioned Departments. This federation adopted the name of "race charolaise" as official title, and grouped in a single "Herd-book of the Charolais breed for the Nièvre, Saône et Loire and adjacent Departments" the local genealogical books which had been founded since 1887. They formed subsequently the "Syndicat d'exportation de la race charolaise" as an agency to study the means of establishing relations with foreign markets and to undertake the sale of breeding animals.

The publication reviewed is a report on the work of this Syndicate, which first printed and distributed a propaganda pamphlet, accompanied

(1) Drought, the high cost of forage, the brackish water given for drinking, cause collectively chronic and often fatal digestive troubles. The syndrome which results forms the subject, from a strictly veterinary standpoint of another publication by the writer. (Summer-autumn mortality and its relationship with the influence of environment in Morocco, in *Revue de Zootechnie*, No. 9, pp. 897-900. Paris, June 1922, which reproduces, in part, the considerations which have just been related above). (Ed.)

by photographs and translated into several languages, and it next took into consideration the necessity of sending to the countries of export a number of breeding animals selected with a view to attract the attention of breeders. Owing to the assistance of several private breeders, the Syndicate was able to overcome initial financial difficulties and it at present, is dealing with the inoculation of some breeding animals destined for Brazil and other South American States, where *tristeza* (piroplasmosis) is raging.

1076 - **The Identification of Cattle by Means of Nose-Prints.** — PETERSEN, W. E., in *Journal of Dairy Science*, Vol. 5, No. 3, pp. 249-258, figs. 6, Baltimore, May 1922.

The various breeding associations have always been confronted with a serious problem in the proper identification of animals for registration and of animals on official test. All other means having proved unsatisfactory, O. H. BAKER, of the American Jersey Cattle Club, suggested using nose-prints for the purpose. The author describes the method of taking the prints and the best way of identifying the prints so obtained. The most satisfactory results were given by mimeograph news-print paper and black stamping-pad ink. From different tests made with some 350 cattle the author drew the following conclusions: 1) no two animals have identical pattern nose-prints, therefore these prints will enable positive identification; 2) the taking of nose-prints is simple enough to be practical; 3) it is possible to identify prints as being of the same animal, even if they are not perfect; 4) the pattern remains the same through life; 5) this test is practical for the identification of cows on official test and may prove valuable in connection with the registration of all solid colour cattle; 6) the method affords a positive means of identification when claim for loss is made under livestock insurance policies. 1077 - **Studies on Reproduction of Cattle.** — I. GRAU, A., L'âge de la reproduction chez l'espèce bovine, in *Revue de Zootechnie*, No. 9, pp. 869-880. Paris, June 15, 1922. — II. MAC CANDLISH, A. C., Studies in the Growth and Nutrition of Dairy Calves, in *Journal of Dairy Science*, Vol. V, No. 3, pp. 301-321. Baltimore, May 1922.

I. — **THE REPRODUCTION AGE IN CATTLE.** — While it is indispensable, in a well managed breeding establishment, to breed from the best animals, it is also necessary to consider at what age breeding should take place.

**Bulls.** — From what age in the life of the animal and up to what age should a bull serve? About the age of 2 years service may take place almost daily without harm, but the number of cows which one bull can serve would be fifty or sixty at most. It is only very vigorous bulls reaching their third year who can annually serve as many as 80 or 100 cows. Also if service takes place during part of the year only it will be necessary to reduce the number of cows which the bull can cover. This is why in the case of an important herd the proportion of one bull for every 50 cows is desirable.

It may be profitable to replace a full grown bull by a younger bull, a year old, which will grow and which will pay for its keep by its increased value while growing. The advantage of retaining the full grown bull is

that its capacity is known whereas that of the young bull is not, however good may be its appearance.

It would be a serious economic error to apply strictly to the male breeding animal the famous doctrine of making use of cattle during the period of growth. That idea may be extended to oxen kept almost up to 4 years old for beef or else for working up to 4 or 5 years and then to be fattened.

The bull however is the founder of the herd and should be kept as long as possible from the time that it becomes a source of improvement. It is possible to maintain a bull in good breeding condition if it is allowed to run in the fields at times, instead of being kept always in a stall. Should this not be possible, the bull when full grown ought not to be over-fed or it will become too fat.

Hay would form a suitable basis for a ration with a few oats as an addition, but no cake should be given. If it is desired to obtain strong, healthy animals in the herd, it is absolutely necessary to pay close attention to the food of the selected bull, increasing it when young so that the bull may grow up quickly but restricting it from the age of about two years and a half so that the animal may not become too fat.

*Cows.*— For cows the breeding age is, so to say, the inverse of that for the males. Would it be profitable to make cows calve as early as possible in their second year or would it be better to await the third year? The writer quotes good reasons urged by partisans of both methods. In his opinion the best rule for breeding is that under which the animals are free in their movements and have plenty of fresh air.

Moreover grass is often considered the ideal food and with it the essential function of the organism will be best accomplished, the blood will be richer and development will be better assured. The young cows should be suitably fed and should go out to pasture to the greatest extent; there would certainly not be any harm in arranging that they should have their first calf between the ages of 28 and 30 months. In the case of dairy cows, not only would one calf and one period of lactation be gained, but their subsequent yield would be increased.

Cows belonging to a dual-purpose breed should not have their first calf until about 3 years old. In the special case of a select herd, there may also be occasion not to send to the bull before 18 months but to wait for 6 or 12 months according to whether it is a question of a dairy breed or not. Certainly better animals would be obtained and better qualities might be developed.

The writer advises that good bulls and cows should be kept as long as possible, and that the inferior animals should not be retained for breeding.

II. — STUDIES IN THE GROWTH OF DAIRY CALVES. — 1) *Duration of gestation.* — The variations of the period of gestation have hitherto been little studied. The writer quotes researches made on this subject by SPENCER, WING and FLEMING and the conclusions drawn from their observations. He himself made experiments in order to ascertain: — the influence which the age of the cow at the time of bulling and the season during which bulling took place might have on the duration of gesta-

tion: the relationship which exists between the sex of the calf and the duration of gestation, and the influence which the age of the cow may have on the latter. These observations, made on 369 gestations, led the writer to conclude:— 1) that the average period of gestation in dairy cows is 280 days — 2) that this duration is not variable according to breed; 3) that the sex of the calf does not appear to have any influence on the duration of gestation — 4) that the proportion of male and female calves was about equal — 5) that on the average 82.6 % of the calves remain from 271 to 290 days in the uterus — 6) that the age of the cows at the time of bulling was without influence on the duration of gestation — 7) that gestation was not influenced by the season in which bulling took place.

2) *Weight of calves at birth.* — The writer relates the work done on this subject by HEVARY & MORRISON and ECKLES. According to the researches which he made personally on the subject: — 1) of the influence which the age of the cow at the time of bulling might have on the weight of the calf at birth — 2) of the relation between the weight of the cow at the time of bulling and that of the calf at birth — 3) of the influence of the season during which bulling took place on the weight of the newly born calf — 4) of the influence of the duration of gestation on the weight of the calf — the writer concluded: — 1) that the average weight of calves at birth was 32.65 kg for males, 29.47 kg for females and 31.29 kg for all the calves — 2) that among pedigree calves, the heaviest were Holsteins, next Ayrshires, Guernseys and Jerseys — 3) that on the average, at birth the weight of calves of no special breed is the lowest, that of pure bred calves is the highest and that of half-bred calves very nearly the same as that of pure-bred calves — 4) that the average weight of newly born calves increases with the age of the cows, until the cows reach the age of 5 years, after which the weight of the calves decreases in an irregular manner — 5) that increase in the weight of the cows denotes an increased weight of the calves; this increase however is not directly proportional to that of the cow — 6) that possibly calves born between the months of April and October may be lighter than those born during the rest of the year; there are however considerable variations in the weights of calves born in the two periods — 7) that the duration of gestation has little influence on the weight of the calf; on the other hand, the nearer the duration of gestation is to the normal, the nearer the weight of the calf is to the normal weight, while their weight at birth increases when the duration of gestation deviates from the normal.

(3) *Rate of growth of dairy heifers.* — After referring to the researches of ECKLES, WATERS, MAC CANDLISH and ROBERTSON, the writer describes the method which he adopted in his researches on this subject. From his experiments he draws the following conclusions:— 1) Apparently there are few cases of loss of weight after calving — 2) The live weight of the animals increases most rapidly — 3) According to body measurements, it appears that the dimensions of breadth, depth, and height follow one another in the order of the rate at which they increase — 4) There seems to

be little difference between calves born in winter (that is to say between the 1st October and the 31st March) and those born in summer (from the 1st April to the 30th September), except that the heifers born in winter attain, at the time when bulling commences, higher weights and bodily proportions than those born in summer — (5) There seems to be a sufficiently distinct relation between the live weight (expressed in kg) of the animals and the product of their heights, depths and breadths (expressed in cm.).

D. S.

1078 — **Some Results of Reeding Milch Cows at Experiment Stations in the United States.** — WINTHERS, S. R., in *Heard's Dairyman*, Vol. LXIII, No. 12, p. 419, figs. 4. Fort Atkinson, Wis., April 7, 1922

Dairy cattle feeding experiments are being conducted at the 5 Stations of the Dairy Division, United States Department of Agriculture with the threefold object 1) to ascertain the productive capacity of cows and their ability to maintain weight when their ration is deprived of grain; 2) to ascertain the profitableness of feeding grain to milch cows; 3) to study the production of milk, butter, etc.

The author mentions results already obtained on these points: A Holstein (Helen Nilkje Calamity) made a creditable record, although from the age of about 8 years she was given no grain, her ration consisting of roughage alone. On lucerne hay, maize silage and pasture grass this animal yielded 470 pounds of butterfat in one year. The following twelve months, the same ration supplemented with a liberal ration of grain was fed to the cow with the result that the milk and fat production were respectively 25 499 and 823 pounds.

As regards the economical results of feeding roughage exclusively, varying conditions have to be taken into account. In dairy districts where the product is sold on a butterfat basis, the increased production due to the addition of grain to the ration might not yield much return; on the other hand, where the produce is marketed in the form of milk, the investment in grain might be very profitable. The author gives other instances of good records of Government cows kept at the above-mentioned Stations of the Dairy Division.

E. F.

1079 — **Comparison of early, medium and late maturing Varieties of Silage Maize for Milk Production.** — WHITE, G. C., CHAPMAN, L. M., SLATE, W. L., and BROWN, B. A., in *Journal of Dairy Science*, Vol. IV, No. 4, pp. 333-347, fig. 1. Baltimore, July 1922.

The experiment made by the authors is an attempt to determine the relative economy of milk production by growing early, medium or late varieties of maize for silage.

The varieties used to represent the 3 types were early, Pride of the North, Medium, Leaming; late, Eureka. The researches were carried out at the Storrs Agricultural Experiment Station (Connecticut, United States) upon Holstein, Jersey and Guernsey cows of ages varying from 2 ½ years to 10 years and 10 months.

It was found that late-maturing varieties, under favourable conditions,

are decidedly superior in yield to the early varieties, both as regards total tonnage and dry matter. The following five years averages were obtained for green maize: early group, cut at hard dough stage, 24 774 lb. per acre, water content 73.80 % — medium group, soft dough stage, 32 947 lb. per acre, water 78.09 % — late group, kernels just forming, 40 648 lb., water 80.16 %.

Pride of the North contained 25.74 % dry matter in silage; Leaming 25.17 % and Eureka 19.43 %. It must however be remembered that the season allowed Leaming to mature more than usual, so that the crop used in the feeding tests had practically the same percentage of dry matter as Pride of the North and gave very similar results.

The cows were fed silage as well as hay and a grain ration, the latter consisting of maize + wheat bran and cotton seed meal (3 : 3 : 2) having a nutritive ratio of 1 to 3.8 and carrying 14.8 % digestible protein and 71.71 % digestible nutrients. The hay consumed was 4 lb. per head and per day.

The feeding trial proper lasted 100 days, after a preliminary feeding first upon regular herd silage, and later on the experimental silage.

The amount of silage consumed per day by each group was as follows 1st group (early maize) 44.977 lb — 2nd group (medium) 45.739 lb. — 3rd group (late) 45.537 lb. The amount of dry matter furnished by the silage per day to each group was respectively 11.232 lb. — 11.519 lb. — 9.081 lb.

The grain was fed in proportion to the weight of the animals, the object being to keep them at a uniform weight. By this plan, most of the food was used for maintenance and production, a very small amount contributing to the development of the foetus in early gestation. The average daily consumption of grain was 9.972 lb. by the early group — 8.314 lb. by the medium and 11.604 lb. by the late.

The following Table gives a summary of some of the most important data.

	1st group	2nd group	3rd group
Average daily milk yield. . . . .	lb. 28.286	22.938	29.206
" " fat " . . . . .	lb. 1.0878	1.0455	1.0788
Total daily solid yield . . . . .	lb. 3.5769	3.1578	3.5990
Average initial weight . . . . .	lb. 1054.4	963.3	1046.8
Average increase (+) or loss (—) in live weight in 100 days . . . . .	lb. + 17.64	+ 22.33	— 14
Grain consumption per 100 lb. milk (1) . . . . .	lb. 35.405	35.816	39.780
Grain consumption per 1 lb. solids in milk. . . . .	lb. 2.752(2)	2.593	3.249

(1) The relatively high grain requirement per unit of production for all the groups is due to the small hay allowance.

(2) The better record made by group 2 in solids production is due to its lesser maintenance requirements.

The results thus show a saving for 100 pounds of milk of 4.37 pounds of grain for the group fed early maize as compared with the group given late maize. Ton for ton these data seem to indicate the greater economy of the early silage. This is further emphasised by the fact that the group given early maize gained a little in weight, whereas the group fed late maize lost slightly in weight.

1080 - **Quantity of Feed consumed by a Heifer from time of Birth to Lactation Period.** — See No. 1095 of this *Review*.

#### GOATS

1081 - **The Goat as an Economic Factor.** — CRÉPIN, J., in *Le Lait*, Year II, No. 5, pp. 313-320. Lyons, May 1922 (1)

Goats are divided into three main fundamental racial branches. The most important has its original home on the great central plateau of Asia ; next comes the group of African races which has its habitat in the Abyssinian Mountains ; lastly the European branch has its origin in the great block of the Alps. Long hair and a light iris are characteristic of Asiatic origin ; very short, silky and glossy hair on a coat of bright, vivid colour, and dark flashing eyes, indicate African origin. The goat in Europe has undergone such deep racial changes that its ethnic characteristic is no longer of serious interest for most breeders. However, in the massif of the Saint Gothard, a goat has been discovered which may be regarded as exemplifying the morphological unit of its species in the required degree. It appears in many varieties of coat, but has in all cases precisely the same economic value. It bears the stamp of a group of races which is necessarily that of the European goat, and of the typical European race. This breed is the largest and the coat is short haired and habitually of many colours, white being only found in cases of albinism. The coats of the Alpine goat are characterised by dull tints, generally shading off from black to tawny and from tawny to light through all shades of grey. The spots are marked in streaks on a ground which, at the extremities of the body, on the belly and the limbs is lighter in colour or is accentuated by a darker shade. A dark stripe often covers the whole length of the spine. The forehead of the Alpine goat has, in profile, a frontal boss. There is, also, near the muzzle, a small swelling indicating a good feeder. According to the writer, it is a mistake to think that there is one goat of the plains and another of the mountains. However, as regards pasture, it does well only in high regions. The most surprising fact in the biology of the goat is that this animal, which seems naturally intended to live in a wild and primitive state of life is admirably adapted to a diet absolutely different from that what appears to be its natural diet. Thus when abundantly fed it gives double the amount of milk which it would give normally.

Under the influence of good training, the lactation of the alpine goat can be prolonged over two years without interruption. The fact is all the more remarkable that an animal capable of supplying 6-7 and even 8 litres of milk per day at the height of its lactation draws this consider-

(1) See : R. 1913, No. 1062 ; 1916, No. 205 ; 1918, No. 794 ; 1921, No. 83. (Ed.)

able mass of milk from a reserve of live substance the weight of which barely exceeds 60 kg. with 6 to 7 kg. of blood. The writer adds that this animal, which reaches maturity only at 4 to 5 years of age, is able to produce young from the age of one year and remains fertile till over the age of 20 years. It is even economically advantageous to profit by its precocity, for if made to produce when very young, its milking power increases and its appetite increases to enable it to meet the double physical expenditure, viz., that required for production and that for growth. The writer does not attach any value or economic importance to the horns, or to the colour of the coat for which the Swiss pseudo-races are recommended. He also notes that it is now possible, by simple measures of cleanliness etc. completely to conceal the peculiar flavour of goat's milk. If therefore goat's milk is no longer distinguishable in taste from best cow's milk and if also malodorous he-goats need no longer be kept in the herds, the writer no longer sees that there can be any reason to object to the use of dairy goats in the food services. In this connection the diffusion of an improved race of goats may be a matter of high importance. Its use on a large scale would greatly improve the diet of children and invalids and would provide a powerful element of control of tuberculous infection. Without claiming that the goat has in itself a concrete principle which immunises it against the microbe, it is possible to assert that the goat never contracts tuberculosis spontaneously. There is a pseudo-tuberculosis which attacks goats exposed to damp cold, but the milk cannot exercise its physiological properties in the organism of the newly born or invalids unless it is administered raw and in its integral form and properties.

The goat is the only animal which can supply children and sick persons with milk in this ideal form. The writer recommends the diffusion of the only European goat, which appears to be not only the authentic thoroughbred of the European race, but also the heaviest milker of the species. It is this race which should be improved by selection and have its excellent qualities established.

1082 — **The Pasturing of Pigs.** — DIFFLOTH, P., in *La vie agricole et rurale*, 11th year, Vol. XXI, No. 29, pp. 57-61. Paris, July 22, 1922 (1)

PIGS

The pasturing of pigs is a practical and advantageous method, which in certain countries, gives extremely valuable results. Pigs however owing to the nature of their digestive organs make a poor use of cellulose but economic considerations permit a reconciliation between theory and practice. With a system of pasture for well kept pigs, and a judicious use of supplementary green crops there is very little need of dry foods, for months at a time and the result is a valuable economy. In spring and at the beginning of summer pigs get a supplement of dry foods. In autumn also, when the sows litter and until the young pigs are weaned,

(1) See: R. 1912, No. 374 — R. 1914, No. 1153 — R. 1915, No. 942 — R. 1916, Nos. 889, 1104 — R. 1917, No. 836 — R. 1921, Nos. 1033, 1260 — R. 1922, Nos. 193, 296, 460, 617. (Ed.)

a little grain is indispensable for the ration. The Americans adopt as a practical rule the giving about  $1\frac{3}{4}$  litres of grain per sow each day as a supplement. At every other period, the pastures suffice and assure the best profit. Grain, if obtained economically, will always be valuable, as also cotton and ground nut cakes.

The pasturing of pigs is specially indicated in regions which contain large areas of clearings and of unenclosed woods. In America wooded lands are beginning to be used largely for maintaining pigs in spring and at the beginning of summer, when pasture crops are scarce. The ground-nut then supplies the change required for completing the fattening of the animals. This method costs little for the production of a pound of meat, but with the rapid increase in the production of pigs, breeders have had to examine more closely the phases of this method of rearing and to make various pastures utilisable in all months of the year. The result has been the establishment of several systems of crop rotation. The principal profitable forage crops grazed by pigs are:—

1) *Oats and rye*. — Both are much appreciated as green forage in every farm rearing pigs. Some breeders sow a large stretch of oats, letting the whole be grazed up to the 1st March, then one part is enclosed to be grazed up to June while the remainder is left to ripen. This plan is to be recommended, as it assures pasture at a season when economical food is scarce. Moreover it allows the regulation of the portion reserved for grain according to the actual resources of the farm. Needless to say, the plot which is intended to furnish grain should not be "too closely" grazed if it is desired to avoid a serious falling off in the grain crop. Certain winter oats grow again vigorously after having been grazed and stand pasture well.

2) *Turnips*. — It is especially from January to May that turnips are a valuable resource; earlier or later, other food resources in full yield become available. Two judicious sowings of turnips will cover the difficult period.

3) *Millet*. — Its qualities are much appreciated, and it has the great advantage of providing food at the beginning of spring, at a time when cheap feeding is difficult to find. Sown early, in March, it may be grazed towards the middle of April. It is well to graze the plant early to make it tiller. Millet is a quick growing plant, capable of feeding many pigs for each unit of area. When young this forage is liked by the pigs; but it should not be allowed to become woody. If grazed up to the last, millet will be available up to the middle of July. With three sowings arranged in series in March, April and May, the period of grazing can easily last up to September.

4) *Sorghum*. — Is often sown in alternate rows, sometimes with millet. Sorghum stands grazing worse than millet and if browsed down to the ground, it suffers much. Even thus the young millet as being more tender is preferred and sought out by the animals, which gives the sorghum time to grow and reach a height at which its consumption is profitable and its resistance more assured. These two plants therefore sup-

plement each other and give variety to the feeding. Sorghum can also be used as a green food.

5) *Early Maize*. — Planted in spring it may be grazed or cut about the middle of July. Some breeders grow it alone, others in alternate rows with ground nuts. When the maize is cut green the pigs on pasture will eat the ground nut on the spot and this method gives an earlier fattening food. If it is desired to have at disposal a useful food as early as possible, early varieties of maize are sown, with early horse beans broadcasted between the rows of maize. On heavy soils the horsebean may be replaced by the dwarf kidney bean.

6) *Ground nut*. — Ground nuts fatten pigs at very small cost. Two varieties are grown for pigs:— the North Carolina, or African ground nut, sometimes called the Georgia groundnut, and the Spanish groundnut. The former is a large cropping variety, Planted early in spring, it begins to produce in the middle of September and gives an abundance of good food up to January and even March. It will fatten, without supplement, 7 to 10 pigs per ha. Planted early, the Spanish groundnut. is ready for pasture in August, 6 weeks earlier than the Carolina variety, at a time when "finishing" food is scarce. Its yield is much less, according to certain growers. Although groundnuts supply a rapid fattening and pigs make remarkable increases in weight, they should not be fed exclusively with them for a period of more than 60 to 90 days; otherwise digestive disturbance would be caused. Sows with young should only be allowed to feed among the groundnuts with caution.

1083 — **Distribution of Enzymes in the Alimentary Canal of the Chicken.** — PLIMMER, R. H. A. and ROSEDALE, J. L. (Biochemical Department, Rowett Research Institute for Animal Nutrition, University of Aberdeen and North of Scotland College of Agriculture), in *The Biochemical Journal*, Vol. XVI, No. 1, pp. 23-26 London, 1922.

POULTRY  
BEARING

Lactase has so far never been found in the intestine of chickens. The authors fed chickens from hatching for a period of over three months with a ration containing lactose and noted its assimilation. Assimilation of disaccharides is usually preceded by hydrolysis to monosaccharides, and as this would imply the presence of lactase, the authors made an examination of the different parts of the digestive system to discover where the lactase was to be found. Their experiments confirmed the fact that it is absent from the intestine but a small amount was detected in the pancreas, the crop and the gizzard. They then extended their investigations to 8 other enzymes specifically concerned in the digestion of the common foodstuffs and obtained the following results:

The distribution of the sucroclastic enzymes corresponds for the most part with that in the animal, diastase and lipase are generally present in the pancreas of animals; on the other hand there are differences in the distribution of the proteoclastic enzymes; the animal has trypsin acting in alkaline media, the chicken in both alkaline and acid media. The enzyme of the proventriculus, which in the chicken corresponds with the stomach of an animal acts only in acid medium.

	Crop	Proventriculus	Pancreas	Intestine whole	Duodenum	Illum	Caecum
Invertase . . . . .	o	o	.....	+	.....	.....	o
Diastase . . . . .	+	o	+	+	.....	.....	+

## BEE-KEEPING

1084 - Insulating Capacity of Double-Walled Bee-Hives. — PHILLIPS, E. F., in *United States Department of Agriculture, Department Circular* 222, 10 pp Washington, May 1922.

The great number of double-walled bee-hives on the market, where they find ready purchasers among bee-keepers by whom they are largely used, has given rise to considerable discussion as to their comparative merits. In order to decide the question, the author carried out a series of experiments and obtained the following information:

The shape of the hive has a considerable influence upon its insulating power, and therefore upon its capacity for preventing loss of heat and protecting the bees from winter cold. The heat escapes most readily from the bottom and the insulation of the walls and top is never so complete as to prevent a large amount of heat from being dissipated.

Bee-keepers however never trouble about the insulation of the bottom of the hive, as they are under the impression that the heat escapes through the top. It is a mistake to uncover the front of the hive, even if it faces south, for if any part of the hive is left with only a single wall, or without some other means of protection, all the efforts made to keep the rest of the hive warm are to a great extent nullified.

In the double-walled hives on the market the heat escapes so readily from the bottom, that little is lost through the roof and still less through the walls.

An air-space left between the two walls does not retain the heat as well as a layer of some material that is a bad conductor, especially if the interstices are very small. Convection currents which dissipate the heat are doubtless always present in the dead angles of the cavity of the hive. The board forming the ceiling should extend as far as the external wall upon which the roof rests. It is more effective to close the double wall only, than merely to shut the opening of the hive.

A thicker layer of insulating material should be used than is generally the case. If sawdust is used, the layer ought to be 10 to 15 cm. thick.

1085 - "La Loque" (*Bacillus alvei*) a Bee Disease. — CHEVILLOTTE-MEVEL, O., in *L'Apiculteur*, Year LXXI, No. 8, pp. 270-272. Paris, Aug. 1922.

This disease is caused by a special bacillus (*Bacillus alvei*), a distinct species, according to the writer, but capable of assuming different forms dependent upon its degree of virulence and the nature of environment in which it develops. The therapeutic treatment may also be preventive, and consists in the use of antiseptics (salicylic acid, mixture of carbolic acid and tar, formaldehyde, naphthol  $\beta$ , etc.). The writer was only able to get incomplete results by using antiseptic syrups, which have no effect on larvae already infected.

The best and most scientific prophylactic method is permanently to disinfect the hive with formic acid or 10 % solution of formol; to do this, paraffin wax should be smeared on the insides of several tin boxes (the lids of blacking boxes may be used) to a depth of 1 to 1.5 cm. and they should be filled with the following mixture:— Formic acid or commercial formaldehyde, 2 parts — Alcohol, 1 part — Water, 6 parts. These tins are placed in the hive and the mixture is renewed every week. Generally 3 or 4 doses are enough; sometimes, however, it is necessary to prolong the treatment. E. F.

1086 - Sericulture in Libya. — FORLANI, K., in *Bollettino della R. Stazione Sperimentale di Gelscoltura e Bachicoltura di Ascoli Piceno*, Year 1, No 1, pp. 23-30. Ascoli Piceno 1922.

SILKWORM  
REARING

Breeding of the domestic silk worm was started at Bengasi in 1915 and gave fairly good results. On the initiative of Prof. DE CILLIS (Director of the Agricultural Bureau of the Government of Tripolitania) the breeding of other silk producing insects (which might find in Libya the conditions of environment necessary to their existence) was tried successively, these being:— *Philosomia arrindica* (which lives on the castor oil plant), *Attacus bombinia* of the Sudan (which can live on *Ziziphus*), *Attacus cynthia* (which lives on the *Ailanthus*) and *Attacus cecropia*; but the results were negative.

Breeding of domestic silkworms continues to increase as shown by the following Table:—

Years	Kg. of fresh cocoons	Kg. of dry cocoons	Unit of price	Gross yield
1916	400	135	18	2 430
1917	1 200	400	30	12 000

The propagation of the mulberry tree is under Government control: 2671 plants were distributed in 1916 and 9743 in 1917. In spite of various ailments, which sometimes rage in the broods, it is not uncommon to find in properly built premises productions of 75 kg. of fresh cocoons per ounce of eggs.

According to DE CILLIS (1), MAZZOCCHI-ALEMANNI and LEONE,

(1) DE CILLIS, E., Cinque anni di sperimentazioni agrarie in Tripolitania, *Agricolt. Colon.*, XV, No. 6. (Author's note)

the second fortnight in March is in Libya normally the most suitable time to start breeding, and the premises which are most suitable for native breeding seem to be silkworm nursery huts, partly underground, with walls above ground. For the methods of breeding, suspended sieves, made of local material such as reed grass, palm leaves etc. have proved suitable; for wood, the wild flora are very suitable:— *Brassica Tourneforti* (in arabic "hassluss"), *Pituranthus tortuosus* ("gazzali"), *Raetama raetam* ("rtam"), *Euphorbia guyoniana* ("lebbin"), mid-ribs of the leaves of the date palm, etc. Pure breeds have shown themselves the more likely to give a high quality yield, but are much less resistant to surrounding adverse circumstances, it is thought therefore that the Chinese bi-yellow and multi-yellow crosses are the most suitable breeds.

The silk market of Tripoli at any rate up to a few years ago was almost exclusively supplied with Chinese silk, because owing to the primitive systems of spinning in use the thread of the local cocoons was much weaker than the thread of the Chinese cocoons. The Italian standard most commonly used is 8/100.

Chinese silk coming from Shanghai is classed as follows in the Tripoli market.—

White Steins, blue Phoenix extra.  
Yellow ST, n° 1 yellow Mayung.  
Yellow ST, n° 2       "       "

The silk most in request for making burnous is the yellow silk ST No. 1

The silk-producing industry is domestic and it is ordinarily carried on by the Jewish population (1). E. F.

1087 - Value of Maintaining an even Temperature during the Incubation of Silkworms' Eggs. — ACQUA, C., in *Bollettino della R. Stazione sperimentale di Gelicoltura e Bachicoltura di Ascoli Piceno*, Year 1, No. 1, pp. 13-23. Ascoli Piceno, March 1, 1922

A constant temperature or a slight and gradual rise is recommended for the incubation of silk worms' eggs, and accidental sudden thermometrical changes are considered as very injurious to breeding results: GRANDORI (2) also considers a constant temperature essential, especially during early stages of fertile development. On the other hand, VERNON reports that eggs electrified as soon as they are laid (to cause out of season hatching) may be subjected without injury to temperatures little above 0° and may remain at that temperature for several weeks, and MARTINI has obtained the normal development of eggs treated with hyd-

(1) Information regarding the treatments to which silk thread is subjected in Libya before being distributed to the trade, is contained in an Article entitled "Il Commercio e la lavorazione della seta", published by the *Bollettino d'Informazioni del Ministero delle Colonie* (1921). (Author's notes.)

(2) GRANDORI, M., I problemi vitali della bachicoltura nel momento attuale. Trent. 1921. (Author's note)

rochloric acid and then kept during the summer for several weeks in a refrigerator. The matter is therefore up to the present, a subject of controversy which the writer has tried to settle by proposing to answer the two following questions:— 1) Does a sudden chill during incubation necessarily cause a state of deterioration which may be seen in a higher percentage of unhatched eggs and by irregular progress in breeding? (2) Does this sudden chill produce different results according as it affects different periods of incubation.

Experiments have been made on the following breeds:— indigenous yellow, gold Chinese, white Chinese, Chinese cross ♀ white × ♂ yellow), Chinese cross (♀ yellow × ♂ white), double-strain yellow cross (♀ yellow × ♀ gold), double strain yellow cross (♀ gold × ♂ yellow). In all the cases severe chilling, even when prolonged for several hours (12-24), during incubation, did not produce the disastrous effects which would generally have been expected: there was only a slight increase in the percentage of unhatched eggs and a prolongation of the hatching period, but no injury was caused to the breeding and no decrease of yield as was proved by the average weight of the cocoons of the different lots which were used in the experiments. In reality, there was no contrast, as was only to be expected, between the behaviour of the egg treated for out of season hatching (which is not affected by retardation through chilling) and the behaviour of the egg normally hatched in spring.

It also happens that incubations of indigenous yellow eggs, treated with hydrochloric acid and intended for summer breeding, made at a constant temperature, showed no difference from those exposed to varieties of temperature by day and night, either in the progress of breeding or in the percentage of mortality. During incubation, there was no critical period at which particularly harmful consequences might be caused by a sudden chill; in the different lots of the experiment, the change in temperature was made at very various times and it had, *for all equally*, the same small differences relatively to the control lots. If there had been a critical period, it must have clearly shown its effect by a high percentage of eggs unhatched in the lots which underwent a change on a particular day.

It is easy to see the practical lesson to be derived from these experiments: if an accidental temporary fall in temperature takes place during incubation, the heat in the incubation rooms should not be increased suddenly but gradually.

E. F.

1988 - **Forced Hatching of Silkworms' Eggs with shortened Hibernation.** — I. ACQUA, C., in *Bollettino della R. Stazione Sperimentale di Gelisicoltura e Bachioltura d Ascoli Piceno*, Year 1, No. 1, pp. 3-9 Ascoli Piceno, March 1, 1922. — II. IDEM, *Schiusura estemporanea del seme bachi a ibernazione abbreviata ed esame della pebrina*, *Ibidem*, Year 1, No. 2, pp. 45-48. Ascoli Piceno, June 1, 1922.

The writer has made the two following series of experiments:—

1) On November 21, 1921, he treated with strong hydrochloric acid, for 20 minutes, two lots of silkworm eggs one of the native yellow race the other of double-strain yellow (♂ yellow × ♀ gold) which had up to that

time never been subjected to temperatures below  $15^{\circ}$ . After thorough washing, the lots treated were placed in a refrigerator at  $4^{\circ}$ - $5^{\circ}$  in which they remained for 45 days; they were taken out on January 5, 1922 and subjected to a forced incubation up to  $26^{\circ}$ . On January 17, the first hatchings began; they lasted 6 days and gave the following results for 300 eggs taken at random from the whole of the treated lot and of the control lot:—

	Native yellow	bi-yellow
Treated eggs. . . . .	Hatchings 287	Hatchings 257
Untreated eggs . . . . .	" 7	" 82

These results shew that *the treatment with hydrochloric acid does not cause hatching of old eggs, but predisposes them sufficiently to secure hatching by the help of the subsequent action of cold limited to half the normal time.*

(2) In the second series of experiments, the writer reversed the two stages of the process: a total of 20 samples of native yellow eggs was placed in the refrigerator for 33 days (from November 15 to January 17), then the treatment with hydrochloric acid described above was given and the incubation started. Hatchings took place at the end of January; they were complete and very numerous in the treated lots but very few in the controls. Therefore, *the treatment with hydrochloric acid is as effective before as after hibernation.*

The results indicated by the sentences in italics have great practical importance: it is known in fact that at present, owing to the application of the law regarding the control of silk-worm eggs, they must be subjected to microscopic examination, to insure their being free from pebrine. Technical necessities require that this examination should be made just before hatching; it follows that adding to the period preceding the normal hibernation, the period necessary for examination and for a second contingent examination, a very advanced stage is reached. The material impossibility of carrying out the examination in good time is eliminated by the method adopted by the writer, which reduces to less than half the period of hibernation required and, consequently, gives a practical solution of the problem.

It might be thought that this method hinders the development of the pebrine germs which may be contained in the eggs treated, but this risk is excluded by the researches of the writer, of which he gives an account in the second of the Articles reviewed. In the moths belonging to two sets in series 1) a slight infection of pebrine showed itself; it was thought therefore that the eggs also were partly infected; in fact the examination of the young caterpillars hatched under special treatment contained a slight percentage of infected individuals.

A second and more rigorous test was undertaken by means of two

other series of experiments made one at the beginning and the other at the end of March 1922. The lots in the first series were treated with hydrochloric acid for 15 or 20 minutes, then with electricity for 5 minutes: it was ascertained on the whole that the percentage of cases of infection with pebrine was slightly decreased by the action of the acid. On the other hand the electric treatment caused no differences in the control lots. The lots of the second series, treated with hydrochloric acid only, differed in no way from the control lots; the writer therefore thinks that the difference in the first case was fortuitous and that it is permissible to conclude that the treatment with acid does not check the development of pebrine in infected eggs. E. F.

1089 - **On the Relation of Pebrine Infections in Bombyx Moths and in the Eggs at rest and just before Germination (Expediency and Desirability of Testing a modified Method of preparing Silkworm-Eggs).** — LOMBARDI, L., in *Bollettino della R. Stazione Sperimentale di Gelicoltura e Bachicoltura di Ascoli Piceno*, Year 1, No 2, pp. 48-57 Ascoli Piceno, July 1, 1922.

Ordinarily eggs of the silkworm at rest do not show clearly the pebrine corpuscles but in the case of intense infection some corpusculary eggs are sometimes found even in the state of rest. The writer has examined with the greatest care numerous sets of eggs coming from infected moths and has attempted to establish a certain relation between the degree of infection at the state of rest and that ascertained just before hatching. The work was supplemented by the examination of the moths, which was done in the following manner:— 500 cells, 56 of which contained infected moths, were taken out of a group of yellows which had a considerable percentage of infection (10 %). The test was made by crushing in a mortar one wing with 3 drops of water; a drop of this mixture taken up on a rod was placed between two sheets of glass; the corpuscles found in each space were then counted and the examination of a certain number of spaces gave the average; in the case of certain individuals the corpuscles were too numerous to count and others (where counting was possible) formed a series from 260 to 0.5.

After the examination of the moths, the writer examined the eggs at rest, by crushing for the purpose each egg in a drop of water. After complete hibernation these sets of eggs, were separated and placed to incubate and later just before germination each egg was again examined. The writer examined 100 eggs at rest and 150-200 just before hatching.

A lot of Chinese gold eggs in which infection was less intense were examined: out of 500 sets of eggs, only 39 were infected and there were, as a maximum, 19 corpuscles per space.

The writer gives, in tabular form, the results of these examinations, and draws from them the interesting conclusion that not only the slightly infected moths but also those heavily infected, can furnish sound eggs. In microscopic selection, such as is made by breeders, a certain quantity of sound eggs are therefore rejected, but this must be considered for the present as a necessity of the general method of examination, which it is impossible to change.

The comparisons made between the degree of infection of the eggs at rest and that of the eggs when about to hatch have given results which do not enable any relation to be established between what the microscope reveals in the examination of eggs at rest and in that made at the moment when the eggs are about to hatch. It is not therefore possible to calculate the approximate percentage of actual infection by means of the number of infected eggs found in the former case.

Lastly the writer suggests that in the preparation of the summer eggs and in cases where it is desired to delay hatching by placing the cells in a refrigerator, only cut wings should be included; this method does not in any way prevent the examination for pebrine, since when infection is found in the body of the moth it is always present in the wings; moreover it offers very marked practical advantages, such as the elimination of the putrefiable bodies of the moths and protection against *Dermestes* which often devour both moths and eggs.

E. F.

1090 - **Duration of Virulence of the pathogenic Agent of Jaundice in the Silkworm.** -

ACQUA, C. in *Bollettino della R. Stazione Sperimentale di Gelsicoltura e Bachicoltura di Ascoli Piceno*, Year 1, No. 1, pp. 10-12. Ascoli Piceno, March 1, 1922.

It is known that the hemolymph of the silk-worm attacked by jaundice shows very numerous polyhedric granules (probably degenerative products), which are very effective in the propagation of the disease on account of their intimate connection with the pathogenic virus. Now as the diseased silkworms when the skin is broken give out blood which is very rich in granules and may contaminate the sieves on which breeding takes place, it is expedient to find out whether the disease can be thus transmitted from one year to another, if there has been no systematic disinfection. The writer has therefore undertaken experiments to determine how long the polyhedric granules can preserve their virulence: in 1920, he obtained an experimental development of jaundice by means of granules collected in the spring of the previous year and preserved without any special precautions: in 1921, the results were positive for other granules collected in 1920 and negative for those of 1919. It is therefore clear that infection is easily transmissible from year to year, by means of sieves or other contaminated material, while in the second year virulence appears to be extinct. In any case, rigorous disinfection is absolutely necessary in the districts where jaundice is particularly virulent as for example Campania.

E. F.

**FISH  
BREEDING**

1091 - **Pisciculture in Switzerland in 1921** (1). - *Rapport du Département fédéral de l'Intérieur, in Bulletin suisse de Pêche et de Pisciculture*, year 23, No. 7, pp. 103-107. Neuchâtel, July 1922.

CONFERENCES. - For the first time since 1914, a meeting of the Commissioners of fisheries in Lake Constance, nominated by the adjacent States, took place on September 23 1921 at Friedrichshafen. Among the subjects discussed may be mentioned: - the application of the regulation defining a certain width for the mesh of the bag of the drag net -

(1) See R. Nov. 1921, No. 1152. (Ed.)

the adoption of uniform conditions for the duty on fishing permits for the upper lake — the supervision of fishing in the upper lake — the tax on motor boats — regulations relating to the collection of the fry of the feras, (*Coregonus fera*), etc.

Various questions relating to fishing in Lake Constance, the Lower lake and the Rhine were dealt with by correspondence between the representatives of the interested Governments.

The negotiations with France for the establishment of an agreement regarding fishing on Lake Lemman led to international conferences in the course of which a draft convention was completed. Others were initiated for an understanding regarding fishing in the Doubs.

Progress was also made with preliminary work on the revision of the Italian-Swiss Convention regarding fishing and regulations for its practical working during the year.

FISHING IN LAKE CONSTANCK. — According to the statistics of fishing in Lake Constance (including the Lower lake), Swiss professional fishermen took, in 1921, 175 244 kg. of fish, to a value of 351 439 fr.

SUPERVISION OF FISHING. — For payments to the staff engaged in supervision, the Cantons spent 210 402 fr.; 50 % of which was re-imbursed by the Confederation. For the destruction of animals injurious to fishing the Cantons spent 1251 fr.

A course for fishery guardians took place at Lucerne from the 25th February to the 3rd March.

CONTAMINATED WATER, FISH LADDERS AND SANCTUARIES. — In a certain number of cases the "Département Fédéral de l'Intérieur" intervened with the competent Cantonal authorities to prevent or rectify the pollution of water by factory refuse. The measures to be taken for the protection of fish at the time of construction of factories using water power or other hydraulic works have received special attention. Numerous schemes for the correction of river banks have been prepared. A Bado-Swiss international Commission, was charged with the drafting of rules to be followed in future to improve and utilize the waters of the Rhine between Bâle and Lake Constance.

PISCICULTURE. — During the hatching season of 1920-1921, 218 fish-breeding establishments have been at work. The 176 036 000 eggs hatched produced 136 461 000 young fry including 314 058 summer fry and yearling fish turned out into public waters under official control. The young fry belonged to the following species (in thousands): — salmon (*Trutta salar*) 953 — hybrid salmon-trout 150 — lake trout (*Trutta lacustris*) 2916 — brown trout (*Trutta fario*) 9985 — rainbow trout (*Salmo irideus*) 818 — American grayling (*Salmo fontinalis*) 14 — char (*S. salvelinus*) 3323 — grayling (*Thymallus vulgaris*) 3360 — coregons 100 155 — pike (*Esox lucius*) 14 787.

The Confederation paid over to the Cantons, for division among the fish breeding establishments the sum of 49 060 fr. by way of contributions for rearing and turning out the fry.

Through its Fisheries Department the Government of the United States

made a gift of 50 000 fertilized eggs of the rainbow trout (*Salmo irideus* and of the salmon of the great lakes of North America (*Christivomer namaycush*) to the "Département suisse de l'Intérieur". These will be dealt with in the various fish breeding establishments and used for stocking certain rivers and lakes.

#### VARIOUS ANIMALS

1092 - American Moles as Agricultural Pests and Fur Producers. — SCHEFFER, T. H. (Assistant Biologist, Bureau of Biological Survey), in *United States Department of Agriculture, Farmers' Bulletin* 1247, pp. 3-23, figs. 16. Washington, March 1922.

There are in the United States 5 species of true moles: the common mole, *Scalopus aquaticus* found in the plains of the Eastern State — the star-nosed mole (*Condylura cristata*) and the Brewer mole (*Parascalops breweri*) common in the greater part of Pennsylvania, New York and New England, Michigan, Minnesota and to the north of these states — the Townsend mole (*Scapanus townsendii*) of the Pacific Coast States which is the largest of its kind and more abundant locally than any other species and the Gibbs mole (*Neurotrichus gibbsii*), another West coast form, but so rare as ordinarily to escape notice.

The author describes the external characters, specific and differential, of these species, their habits, development, food, natural enemies the damage they cause, means of control, the preparation and utilisation of mole skins. The bulletin is too long to allow more than a brief summary; the following are some of the most interesting and least known facts mentioned.

Contrary to the generally received opinion, the mole does not confine itself to regular periods of work each day (morning, noon and evening), but is equally active at any hour, especially at seasons when there is no great variation in temperature during the 24 hours. Moles are probably never dormant and do not hibernate; they however extend their surface runways at times when soil conditions are favourable, e.g., after rains in summer or during periods of thaw in winter.

Moles grow and develop with extraordinary rapidity.

They are however slow breeders, the number in a litter is commonly 3 in the case of the Townsend mole and 4 with the common eastern mole. The Townsend mole forages in gardens more than the ordinary species.

As regards the supposed natural enemies of the mole, hawks and owls take only a small toll. Poisoned mixtures are of little use, and traps are much more effective. Of these there are many simple types on the market. The trap should be set in runs made in moist rich soil, but no part should project into the cavity, or the moles will burrow beneath it.

Moles may be trapped successfully in the Pacific coast country at any season of the year, and elsewhere when the weather permits. If the trapping is for the purpose of obtaining fur, winter and midsummer are the most favourable seasons, as the pelts are then in the best condition. Care must be taken to use traps that do not tear or damage the skins.

The pelts are classified according to the appearance of the leather

side ; good class skins are of a clear tan colour, while inferior skins are spotted or blotched with bluish-black. Although mole-skins have long been articles of considerable commercial importance, all the pelts used by furriers in America up to about 1917 were obtained through importation from London, the prices paid annually being between 2 and 3 million dollars.

The Bureau of Biological Survey has recently stated that the skins of the common American mole (*Scalopus aquaticus*) are quite as good as the imported skins of *Talpa europaea* while those of the common large mole of Washington and Oregon are of superior quality. Since these facts have been recognised, a local trade in moleskins has arisen and about 50 000 dollars' worth of American pelts were marketed in 1918, and in 1919 the business increased by nearly 25 %. E. F.

### FARM ENGINEERING.

1093 - **Power Farming in Egypt.** — CASORIA, M., in *L'Egypte contemporaine*, Year XIII, No. 62, pp. 80-82. Cairo 1922

AGRICULTURAL  
MACHINERY

In agricultural practice in Egypt, power farming, although its great advantages are recognised, has not spread in proportion to the great extent of land which might be so cultivated ; the reasons are as follows :—

- 1) The net cost is still too high.
- 2) The fact that machines are wanted only for certain work and the delay caused by repairs, owing to the lack of workshops in the districts.
- 3) The difficulty, in certain parts of Lower Egypt, of carrying out power farming owing to the close network of irrigation canals.
- 4) The lack of positive data regarding the net cost, deduced from a test of at least three months uninterrupted work.

The writer concludes that if the manufacturing firms agreed to carry out a definite test, with the approval and assistance of the Ministry of Agriculture, which would make clear the economic and industrial advantages of this mechanical system of cultivation with types of small, medium and large tractors, the result would be convincing, and Egyptian farmers, seeing these advantages, would replace the old methods of agriculture by the mechanical system. G. D.

### RURAL ECONOMY

1094 - **Receipts and Payments in the Cultivation of Ghessab in Sicily.** — See No. 1056 of this Review.

1095 - **The Feed Cost of a Heifer from Birth until the Beginning of the first Lactation Period.** — MC CANDLISH, A. C. (Iowa State College of Agriculture and Mechanical Arts, Ames), in *Journal of Dairy Science*, Vol. V, No. 4, pp. 348-361. Baltimore, July 1922.

Table I gives a summary of the author's previous work in determining the feeds required by dairy heifers grown to the producing age.

TABLE I.

	Authority		
	BENNETT and COOPER	HAYDEN	TEDEMAN
Months fed . . . . .	24	26 1/2	24
Feeds :			
Whole milk, pounds . . . . .	342	459	445
Skim milk, pounds . . . . .	3165	3330	2953
Grain . . . . .	547	1710	737
Dry roughage . . . . .	2649	2634	3145
Silage and soiling . . . . .	3603	4042	2938
Pasture, days . . . . .	294	322	300

The animals used for these experiments which lasted for 5 years, were 40 in number and consisted of pure-bred and grade Holstein, Guernsey and Jersey heifers and pure-bred Ayrshires. Twenty-four of the heifers calved between October 1 and March 31 and were classed as winter heifers; the other 16 which calved between April 1 and September 30, came under the head of summer heifers. In each of these groups, the heifers calved at the average age of 29 "months", the month not being a calendar month, but a period of 30 days.

The average birth weights were 68 lb. for the winter heifers, 64 for

TABLE II. — *Feeds consumed in 29 months (from birth).*

		Cows calved in winter	Cows calved in summer	All the cows
Milk . . . . .	days	3 5	3.5	3.5
Pure milk . . . . .	kg.	690	590	652
Skim milk . . . . .	"	956	991	969
Crushed Maize . . . . .	"	724	673	704
Maize gluten feed . . . . .	"	31	55	40
Crushed oats . . . . .	"	140	118	129
Wheat bran . . . . .	"	229	206	220
Linseed cake . . . . .	"	140	118	129
Linseed cake (crushed) . . . . .	"	15.4	16 3	15.9
Total of concentrated feeds . . . . .	"	1382	1299	1348
Total of ensilaged forage . . . . .	"	1855	2028	1924
Total of hay . . . . .	"	129	158	141
Pasture . . . . .	days	323	368	341
Lucerne hay . . . . .	kg.	1623	1127	1425
Sugar cane forage . . . . .	"	98	99	98.5
Maize forage . . . . .	"	474	493	445

the summer heifers and 67 lb. for all the animals. The average weights at the beginning of the lactation period were 1010 lb., 941 lb., and 982 lb. for the winter, summer and both groups respectively. The average live-

weight gains from birth to the beginning of lactation were 942 lb., 877 lb and 915 lb.

The average daily live-weight gains throughout the trial were respectively 1.09 lb., 1.01 lb., and 1.05 lb.,

The author reckons the feed prices per ton as follows: Crushed maize 10 dollars — hominy feed 20 dollars — Ground oats 15 dollars — wheat bran 20 dollars — linseed oil meal 32 dollars — cottonseed meal 32 dollars — lucerne hay 12 dollars — sugar-cane forage 8 dollars — maize forage 10 dollars — maize silage 4.50 dollars — soiling 4 dollars — whole milk per 100 lb. 2 dollars — skim milk per 100 lb. 0.25 dollars — sucking, per day 0.06 lb. — pasture per day 0.05.

In total feed cost of production, the ranking was: winter heifers, 109.89 dollars; summer heifers, 102.43 dollars, and all heifers, 106.81 dollars each.

The average feed cost per lb. of increase in live weight was 117 cents. in all groups. F. D.

1096 - **Variations in the Cost and Sale Prices of Butter before the War, and from 1913 to 1921, in the United States.** — Ross, H. A. (Illinois College of Agriculture), in *Hoard's Dairyman*, Vol. LXIII, No. 6, pp. 192-193, Fort Atkinson, Wis., February 24, 1922.

The author has plotted curves for the cost price of the fat content of butter with the object of comparing the economic position of butter-producers between 1918 and 1921 with their condition before the War. For this purpose the average amounts of feeds required for the production of one pound of butter were multiplied by the price of these feeds for every month from September 1918 to October 1921. The cost price each month was compared with the price, for the corresponding month for the period 1909-1913. The results obtained were expressed in terms of the 1909-1913 average made up to 100; thus, if for instance the cost price was 200 for any given month, it is double what it was before the War.

If the chart giving these results is examined, it will be seen that from September 1918 to June 1920, the cost price continually increased, reaching during the greater part of this period, a figure double the pre-War average; from June 1920 however there was a rapid fall, which during the last months, brought the prices slightly below those obtaining before the War. This means that the same quantity of the same feeds has a lower value now than just before the War broke out.

The author made a similar chart of the sale prices of butter, comparing the average monthly price on the Chicago market with the quinquennial average of the corresponding months during the 1909-1913 period. This curve (from September 1918 to December 1920) tends to assume the same form as the preceding curve with slight variations in either direction. This result does not indicate that the cost price of the fat was nearly equal to that of the butter, but that the ratio of the cost and sale price was the same as before the War. Thus, if the cost price of the fat was 200, the price of butter was about double what it had been in pre-War days.

As stated above, there was a considerable fall in the cost price of fat between January 1921 and January 1922, whereas no proportional drop took place in the prices of butter. It is however true that the price of butter cannot be regarded as corresponding exactly to the price paid to the producer for the fat; the expenses of handling the butter account for some of the difference between the present and pre-War cost of butter.

Although the cost price varies in each case, the graphic index shows the relative position of each producer and proves that the dairyman who made a profit before the War now makes a higher profit, while any loss, where it occurs, is less, which signifies that the present economic position of the butter producer is better than it was during the 1909-1913 period.

In short, given the present cost of fats and feeds, it is advisable for the dairy farmer to increase the cereal ration of his cows up to the point of obtaining a corresponding rise in the milk yield. E. F.

### AGRICULTURAL INDUSTRIES

#### INDUSTRIES DE PENDING ON PLANT PRODUCTS

1097 - **Composition of Wines of Lees and Lees of Wine.** — SEMICHON, L., in *Comptes rendus de l'Académie des Sciences*, Vol 171, No 18, pp 1179-1182 Paris, May 1, 1922

The comparison between the wine first drawn off (choice wine), the wine taken off the lees by decantation and the wine taken from the lees by pressing in bags has given respectively in analyses made by the writer: Alcohol % in volume:— 10.55 — 8.50 — 8.95; Total acidity as sulphuric acid 5.50 — 5.40 — 5.45 — Fixed acidity as sulphuric acid 5.10 — 5.0 — 4.90; Volatile acidity as sulphuric acid 0.40 — 0.40 — 0.55 %; Dry extract at 100°: 21.27 — 32.75 — 32.82; Total ash: 2.45 — 2.65 — 2.70; Soluble ash: 2.25 — 1.90 — 1.85; Alkalinity of the ash in bitartrate of potash, per litre: 5.07 — 1.62 — 1.67; Bitartrate of potash: 4.13 — 1.83 — 2.08; Total tartaric acid in bitartrate of potash, per litre: 5.05 — 2.39 — 2.45; Total potash in bitartrate of potash, per litre: 4.59 — 4.14 — 4.17; Sulphate of potassium: 0.31 — 0.34 — 0.35; Phosphoric acid: 0.175 — 0.471 — 0.455; Polarimetric deviation: 0 — 0 — 0; Total alcohol + acid: 16.08 — 13.90 — 14.40; Alcohol Ratio: extract 4.3 — 2.1 — 2.3. These analyses show that there are in the wines of lees compared with the wine drawn off:— 1) a decrease of about 2° in the alcoholic strength — 2) constancy in total acidities, fixed and volatile — 3) increase of dry extract of at least 50 % — 4) slight increase of ash, with decrease of soluble ash and increase of insoluble ash — 5) considerable decrease of alkalinity in the ash, reaching  $\frac{2}{3}$  of the original amount — 6) decrease of 50 % and more of bitartrate of potash and total tartaric acid, while the total potash scarcely decreases by 10% — 7) increase of phosphoric acid, the quantity of which is more than double — 8) very sensible decrease of the total alcohol + acid; increase of the acid ratio: alcohol; decrease of 50 % in the alcohol; extract.

*The bitartrate of potash lost was replaced by biphosphate of potash in pro-*

*portions corresponding to their molecular weights.* — These characters, which are peculiar to wines of lees arise from the digestion process which takes several weeks and are due to old yeasts undergoing decomposition and which have been carried away in quantities with the wine at the time of racking and which are afterwards deposited and constitute the greater part of the lees. The fact that these yeasts are rich in phosphates, lime and magnesia, explains both the peculiar characters of the composition of wines of lees, and the origin of the tartrate of lime in the lees. During the period of rest in small receptacles and before decantation, the proportion of yeasts in process of decomposition is very great with regard to the volume of wine; a molecular exchange is made between alkaline-earth biphosphates which the yeasts diffuse in the wine and the bitartrate of potash which the latter contains. The bitartrate of lime which is formed is deposited and passes entirely into the lees, thus reducing the cream of tartar in the wine; the biphosphate of lime in the lees on the other hand is transformed into very soluble biphosphate of potash which is found again in the wine of lees after decantation or filtration.

The decrease of alcohol is due either to evaporation or to flowers of wine (*Mycoïderma vini*). The increase of dry extract is due to the passing into the wine of nitrogenous substances which the dead cells have diffused in the wine.

**PRACTICAL CONCLUSION.** — It is preferable to pass the muddy lees, left after the first drawing off, immediately through a filter press rather than to leave them for a long time to digest. Wine so extracted by the filter press would have an approximately similar composition to that of normal wine.

F. D.

1098 — **Should Apples for Cider Making be washed?** — GIRARD-VATON, D., in *L'Alimentation moderne et les industries annexes*, new series, Year 19, No. 20, pp. 87-88 PARIS, July 1922.

In Germany, Switzerland and in other countries, it is considered necessary to wash the apples before making cider. In France on the other hand that practice has partisans and opponents. The first remark that generally the apples are covered with dust, mud, dejecta of insects, micro-organisms and refuse of all kinds as well as with a kind of perspiration which they undergo after the fruit is gathered. Even if they look clean, this syrupy perspiration forms a very good stratum for the development of numerous germs. The above-mentioned impurities are mixed with the pulp during crushing; they pass into the must and give the cider a disagreeable taste and smell. On the other hand, the view is held that washing removes the ferments which help fermentation, that it dilutes the must by the water which is added, and lastly that it takes away from the cider, part of the perfume coming from external matter.

The writer has made some researches with the object of determining the quantity and the nature of substances removed by washing. He has subjected several varieties of cider apples to washing, using 20 kg. of each variety. The matter removed by washing varied between 2.05 gm. and

26.85 gm., or the equivalent of 102.5 — 1342 gm per ton, that is to say entirely negligible quantities. The impurities removed formed an unpleasant mud which became even worse after calcination.

Analyses have given on the average the following results:—

Dry extract with "bain-marie" . . . . .	7.258 g
Total sugar . . . . .	4.630 "
Tannin . . . . .	0.023 "
Pectic matter and albuminoid- . . . . .	1.412 "
Ash . . . . .	0.704 "
Total acidity as malic acid . . . . .	0.191 "

For a ton of apples, the loss of sugar which is the most important, would be scarcely 281.5 gm. If washing is prolonged the quantity of matter removed increases; hence, the apples should not remain long in the water and excessive movement should be avoided. After washing it is recommended to dry the fruit. This may be done by means of machinery which should be found in all good cider factories

L. V.

1099 - **The Olive Oil Industry in Greece.** — BOGRIS, D (Inspector of Industry at the Ministry of National Economy), in *L'Economiste d'Athènes*, Year 2, No 27, pp 417-422 Athens, 1922

The annual production of olive oil in Greece amounts on the average to about 73 million *okas* (1 *oka* = 1250 kg), not including that of Macedonia. As the home consumption is from 35 to 40 million *okas* and as New Greece has enough for its requirements and can export olive oil, there remains for export at least 22 million *okas*.

The Greek olive oils are often too acid and sometimes have a disagreeable taste. While in no European State is it permissible to sell as food oil of acidity above 5 degrees (total acidity as oleic acid), the oils retailed in Greece commonly have an acidity of from 15 to 20 degrees, sometimes as much as 30 degrees, in the latter case they are injurious to health.

These drawbacks are due:— 1) to the deterioration of the olives owing to their late collection and bad storing; 2) to the imperfect mechanical plant of the oil factories, 3) to the want of cleanliness in the oil factories.

The writer suggests the adoption of legislative measures to enforce the adoption of scientific methods in the manufacture of the oil as is done in France, and formulates a series of proposals concerning:— bases of valuation of the oils — measures in favour of the consumers — measures against uncleanness in the oil factories — measures for the finest olive oils.

F. D.

1100 - **Manufacture of Tapioca Starch at Porto Rico.** — GORBEA, PLA (Jefe, División de Química), in *Revista de Agricultura de Puerto Rico*, Vol. VIII, No. IV, pp. 39-41. San Juan, June 1922.

The writer suggests that this plant, which is cultivated in all tropical and sub-tropical countries, is capable of great development in the island, especially for the manufacture of its starch which is very much in request for size. A short estimate is given of the cost of a small factory for an output of 120 qx. of starch from 600 qx. of manioc every 24 hours.  
P. C.

1101 - **The Value of Ohio Wheats for Bread-Making.** — CORBOULD, M. K., in *Bulletin of the Ohio Experiment Station*, No. 350, pp. 187-219, with several figs. Worster, Ohio, June 1921.

The spring wheats grown in Ohio belong to the hard variety and are suited to the climate of the Northern part of the State. The winter wheat is subdivided into hard, semi-hard and soft types. The hard winter wheat flour has a high gluten content and is suitable for bread-making, the semi-hard flour is also recommended for the same purpose and cake and pastry-making. The soft winter flours must be blended with a stronger kind, if used for bread-baking, but are very suitable for all other baking-purposes.

The author gives the names of the soft and semi-hard Ohio varieties of wheat which yield the smallest percentage of bran. Soft wheats usually produce a great deal of bran.

A comparison between the wheats grown by the Department of Agronomy at the Ohio Experiment Station has proved that the semi-hard wheats which produce good yields per acre and give general purpose flour are best for Ohio growers.

Musty flour, if free from odour, may be used for bread-making. The flour of sprouted wheat has an improved bread-making quality, if the plumule has not grown longer than the kernel.  
L. V.

1102 - **Manioc Bread.** — GUABRADO, G. A. (Laboratorio de Investigaciones, Sanidad, Habana), in *Sanidad y Beneficiencia* Vol. 27, No. 3-4, pp. 145-146. Havana, March-Apr. 1922

Manioc ("yuca") grows wild in Cuba, where it resists the most severe drought. It supplies the aborigines with bread, and for a quarter of a century has formed the chief food of the rural population of the island.

The starch content could be increased by scientific cultivation. The manioc is not well managed at present; for instance, the extraction of the starch is carried out in a primitive manner and a large amount remains in the pulp, also 450 000 kg. of starch and 225 000 kg. of glucose have to be imported annually into Cuba, whereas it should be possible to export these products on a large scale.

Dr. CALVINO, Director of the "Estación Agronómica Nacional" of Cuba has prepared bread and flat cakes of manioc containing 10%

of wheat flour and has submitted them for examination to the Scientific Laboratory of Sanidad.

Manioc bread, externally, looks very much like that made from wheat, but, on account of lack of gluten, it is not so soft. It is slightly bitter but the taste is pleasant. It crumbles and moistens well during mastication. Like wheaten bread, manioc bread soon becomes stale, but its freshness may be restored by moistening and holding over a fire. The flat cakes are better than those made from wheat.

Regarding its nutritive value, the following Table gives the results of analyses; it should be stated that for the wheaten bread the figures given represent the average of 5 years analyses.

*Analyses of manioc bread and wheaten bread.*

	Manioc bread	Wheaten bread
Moisture . . . . .	26.00 %	29.31 %
Protein (N $\times$ 6.25) . . . . .	11.25	13.45
Starch and reducing sugars . . . . .	49.11	54.42
Fats . . . . .	8.60	1.18
Cellulose . . . . .	4.00	0.63
Ash . . . . .	1.04	1.00
Phosphoric acid in the ash . . . . .	(0.074)	
Acidity calculated as acetic acid. . . . .	0.40	1.40
Calories per Kg. of dry matter calculated according to the metabolic formula . . . . .	4606	4081

If the use of manioc for making bread was extended, better utilisation of the plant would result.

L. V.

1103 — **The Clarification of unfermented Fruit Juices.** — CALDWELL, J. S. (Plant Physiologist Office of Horticultural and Pomological Investigation), in *United States Department of Agriculture, Bulletin No. 1025*, pp 1-30, bibliography of 35 works. Washington, January 23, 1922.

When unfermented fruit juice, such as that of apples or grapes, is prepared by the methods ordinarily employed, a more or less copious precipitate is formed after pasteurisation consisting of cellular debris and substances coagulated by heat. For this reason, a second pasteurisation is effected after an interval, and the formation of a coagulum in the final container is prevented, but the liquid remains permanently turbid and opaque from the presence of considerable quantities of suspended colloidal materials.

In the case of a few heavily pigmented varieties of grapes, the deep colour of the juices masks their turbidity and renders them attractive to the eye. The juices of most white grapes are too opaque to have an inviting appearance, and although their bouquet and flavour are often superior to the pigmented juices, their turbidity counts so heavily against them that no systematic attempts have been made to put them on the market, and they are little used even where pale-coloured grapes abound.

Unfermented apple juice, or "sweet cider", is to a large extent a seasonal product and consumed in considerable quantities in the autumn. Pasteurised unfermented cider has not gained greatly in popularity, the preference being given to synthetic drinks, pasteurised ciders being pronounced "muddy" and unattractive.

In view of the reception given to the clear attractive juices prepared by zealously guarded special methods, it is probable that the consumption of unfermented juices would be largely increased if simple and efficient methods of making brilliant transparent juices of unaltered beverage quality, were generally available.

To discover some such method was the object of the author's researches on apple and grape juice.

It was found that the ordinary filtration does not give satisfactory results when applied to apple, grape and grape-fruit juices, as they are difficult to filter and contain considerable quantities of colloidal material which passes through ordinary filters. Clarification by means of proteolytic enzymes is possible, but requires too much technical skill and supervision.

The addition of tannin and gelatine, casein, fish glue, egg-albumen and blood is unsatisfactory, for precipitation is slow and incomplete, the chemical composition of the juices is altered, and their palatability and flavour are affected. The preparation of a suitable silicic-acid gel is tedious and difficult and the precipitation obtained by its use is imperfect and slow owing to the clogging of the filters. Of the inert adsorbing agents, carbon is not suited for apple and grape juices as it removes flavouring substances, is a decolourising agent, and does not entirely remove pectins and gums, also, fine particles of carbon which pass through the ordinary filters remain in suspension and are finally deposited on the sides of the container. Diatomaceous earth is by far the most satisfactory aid to the filtration of fruit juices yet employed, for it removes the colloidal materials and leaves intact the colouring and flavouring substances. As obtained in the markets, diatomaceous earth contains varying amounts of wax derivatives which impart perceptible foreign flavours to most juices, but these objectionable materials are readily removed by heating the earth to redness for a short time. Earth that has been used may be "revivified" for future use by similar treatment.

The juice to be clarified should be allowed to stand undisturbed for 12 to 18 hours in order to permit the cellular debris to settle, and should then be siphoned, or decanted, from the sediment. The best results are obtained when the juice is thoroughly mixed with the diatomaceous earth at the rate of 6 to 8 pounds per 100 gallons and immediately filtered. During filtration, the juice on the filter must be well agitated at intervals to keep the earth in suspension and prevent obstruction of the filter.

The author describes the construction and operation of some simple but effective filters. For semicommercial operations he advocates a filter composed of a thick paste of diatomaceous earth supported by a nickel wire screen and a cloth; filtration is assisted by a suction pump. For household use, satisfactory results are obtained by gravity filtration

through a disk of earth somewhat thicker than the one described above. The vessel used should be at least 60 m. high and must be kept almost constantly full. Heating the juice before filtration has many advantages. If the heating is effected in open vessels or tanks, the temperature of the juice should not be allowed to exceed 130° or 140° F (44.5 — 60° C) nor should it remain long at this temperature in the case of apple juice or delicate grape juices as deterioration in flavour is easily produced. A few varieties of grape yield juices may be heated to 170° F (71° C) without injury.

By means of the above described process, preliminary pasteurisation and storage are eliminated; this shortens the process of preparation, decreases the losses, and improves the appearance of the product. Juices thus treated remain perfectly clear and transparent when bottled and pasteurised, and retain the characteristic flavour and quality of fresh juices.

L. V.

1104 — **Analyses of Italian preserved Fruits.** — ZAY, C (R. Stazione chimico agraria di Torino), in *La Stazione sperimentale agraria italiana*, Vol. LV, No. 16, pp. 129-135. Modena, 1922.

The writer, being unable to find any analyses of Italian fruit preserve in the literature of agricultural chemistry, has analysed a series of preserves, jams and jellies of various fruits prepared by several Piedmont Firms.

The results (detailed in a tabular statement) show that the products of Italian industry do not differ essentially from those prepared in foreign countries, to which also they are in no way inferior.

PRODUCTS**

1105 — **Studies on the Biology of Lactic Acid Bacteria.** — GORINI, C (Laboratorio Bacteriologico della R. Scuola Superiore di Agricoltura, Milano), in *Journal of Bacteriology*, Vol. VII, No. 2, pp. 271-276. Baltimore, March 1922.

The author gives a short account of the studies he has made of recent years on the bacteria producing lactic acid, these micro-organisms include the lactococci and the lactobacilli.

**LACTO-PROTEOLYTIC PROPERTY** — Many of these bacteria first coagulate and afterwards dissolve casein. Their action is checked by the addition of calcium or other substances, and depends upon certain factors of which one of the most important is *temperature*. As early as 1897, the author noticed that high temperatures promote the fermentation of lactose, whereas low temperatures are favourable to the proteolysis of casein.

He subsequently studied these processes more in detail. It appears that many bacteria when cultivated at 25°-35° C, show no lactic-proteolytic property, though this appears at 15°-20° C, i.e., the temperature maintained during the ripening of cheese. The composition of the medium is a matter of great importance. Thus even in 1902 the author observed that some bacteria dissolve casein but not gelatine, while others break up gelatine and leave casein intact, and certain species have a proteolytic action on both. The author also emphasises the injurious effect exerted upon proteolysis by the products of the process itself; these

are found in ordinary milk as a result of the great increase in the microorganisms before sterilisation. The *sterilisation method* is another important factor. If milk is sterilised at a high temperature, till it becomes brownish in colour, it can no longer be used for the demonstration of proteolytic properties; this explains the negative or almost negative results obtained by certain investigators.

**BACTERIAL FLORA OF THE MILK DUCTS.** — It has been shown that microorganisms are found on the udder, in spite of external cleanliness and healthy condition of the cow. This bacterial flora may be either useful or injurious both from the hygienic and dairy-industry standpoints. For this reason, the author made a selection of milch cows by the composition of their mammary flora and judged the quality of the milk yield according to the results of the fermentation tests.

**HEAT RESISTANCE.** — The author has proved that the non-sporiferous lactic acid bacteria resist temperatures of over 100° C owing to the formation of a protective layer of casein.

**SPORE-FORMING BACTERIA.** — The author isolated a *Bacillus acidificans-presamigenes-casei* present in cheese and also found a similar form in silage; and considers that spore-forming lactic-acid producing and lacto-proteolytic bacteria are very wide-spread.

**VISCOSITY.** — The power of lactic acid bacteria to render milk viscous before making it acid has been observed by several investigators. The author recognises that this is a constant property of many bacteria which has passed unnoticed because it is transitory during the fermentation process.

**APPLICATION TO THE CHEESE-MAKING INDUSTRY AND TO ENSILAGE.** — Selected lactic acid bacteria assist the ripening of cheese by 1) eliminating the putrefaction and gas-forming bacteria; 2) accelerating the maturation process. The same may be said as regards their effect upon ensilage. Lactic acid bacteria give very good results, especially if an impermeable bed is used, when the forage is half-dry, provided the air is excluded by so heaping up the silage, that the internal temperature rises to 35°-40° C. Inoculation gives excellent results particularly when the silage is not of a kind to set up spontaneous lactic acid fermentation.

Many of the author's results have recently been confirmed by other workers including BARTHEL, BOCKHOUT, DE VRIES, BURRI, ESTEN, EVANS, HARDINGS, HARRISON, HOFFMANN, LÖHNIS, ORLA JENSEN etc.

## DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

**GENERAL** 1107 - Correlation between the Aluminium Content of Sugar Beet and Bacterial Infection. — See No 1031 of this Review

**RESISTANT CROPS** 1108 - Various Plants introduced into the United States resistant to certain Diseases and Pests. — See No 1031 of this Review

**PARASITIC DISEASES OF VARIOUS CROPS** 1109 - The Ascomycete *Ophiobolus cariceti*, as the Cause of Take-all of Cereals and Grasses. — 111/PATRICK H M THOMAS H I and KIRBY R S in *Mycologia*, Vol XIV, No 1, pp 303 figs 1 pl 1 Lancaster, Pa 1922

In July 1920, penithecias of a species of *Ophiobolus* were observed at East Rochester (New York) on wheat plants showing characteristic symptoms of the take all disease, subsequently reported in various localities in the State and also elsewhere (1)

The fungus has been obtained in pure culture and repeated inoculations have shown it to be a specific agent of this disease

This fungus, after comparative experiments made with material from America, England, Italy, France, Japan and Australia, has been classified as *O. cariceti* (Berk and Br) Sacc

A complete diagnosis of the parasite is given G T

1110 - Observations made in New York State on the Take-all Disease of Cereals and Grasses (*Ophiobolus cariceti*) (L). — KIRBY R S in *Phytopathology*, Vol XII, No 2 pp 66-68 figs 3 pl 3 bibliography of 31 works Lancaster, Pa 1922

A survey made in 1921 in New York State demonstrated that the 'take all' disease caused by *Ophiobolus cariceti* (Berk and Br) Sacc was present in nearly one half of the winter wheat fields of 16 countries in the west of the State. The disease was as severe as that described in Australia and Europe. The average damage in the 78 fields found infected in 1921 was about 2%, and the maximum damage in any one field was about 20%.

The most typical symptom of the disease is a dwarfing of the host plant, which includes a reduction in height, in the number of tillers, in the number of heads, and in the size and amount of grain produced. The yield of an infected plant was on an average about 1% that of a healthy plant

(1) See *R Jm* 1921, No 104 (Fd)

(2) See No 1109 of this Review (Ld)

The fungus is confined to the roots and lower internodes of the host, where a pronounced discolouration occurs. A typical plate of mycelium is found between the leaf sheath and the culm, and perithecia are produced in abundance, more than 100 having been found on single culms of wheat and *Agropyron repens*. As a result of inoculations under glass, typical perithecia were produced on wheat, barley, rye and one or more species of the following wild Gramineae:— *Agropyron*, *Bromus*, *Ulymus*, *Festuca*, *Hordcum*, *Hystrix*, *Lolium* and *Phalaris*.

None of the 54 varieties of wheat tested in the greenhouse, showed any marked degree of resistance to take-all. These varieties included specimens of the following species: *Triticum sativum*, *T. compactum*, *T. turgidum*, *T. durum*, *T. dicoccum*, *T. Spelta*, *T. polonicum* and *T. monococcum*.

The causal organism was isolated and grown in pure culture on numerous media. Typical perithecia have been produced in pure cultures. In the present investigation seeds from infested plants did not act as carriers of disease. Soil from infected spots in the fields acted as a distributing agent for several months, but at the end of 8 months, soil which had been kept in the laboratory did not act as a carrier. Pieces of infected straw containing perithecia were very effective carrying agents; the virulence of the organism had not decreased at the end of 8 months.

*G. cariceti* requires a condition of alkalinity for optimum growth. This explains why the addition of alkaline substances to the soil has been observed to favour the spread of disease whilst the addition of acid-forming substances has the contrary effect.

The most promising methods of control seem to be: the practice of four to five year rotations; the eradication of wild gramineae and cross-fertilised cereals, which may act as hosts; discontinuation of the practice of digging in wheat stubble for 3 years preceding the sowing of wheat; cleaning the wheat seed thoroughly to remove all bits of straw which might carry perithecia; the discontinuance of the practice of liming the soil before sowing. Other suggested methods of control are late sowing and the use of resistant varieties, although definite results have not been obtained in either case.

1114 - Leaf-Spot Disease of Tobacco caused by *Phyllosticta Nicotiana* in North Carolina. — WOLF, F. A., in *Phytopathology*, Vol. XII, No. 2, pp. 99-101. Lancaster, Pa., 1922.

For several years in succession, a leaf spot disease of tobacco has been noted in North Carolina, both upon seedlings in the nursery, and upon more mature plants in the field. Brownish spots are formed irregular

in outline, varying in size from 1 to 10 mm., lightest in colour near the centre, and bordered with pale or yellowish-green. Pycnidia of a *Phyllosticta* (identified provisionally by the author as *Phyll. Nicotiana* E. and E.) are seen in the dead tissue.

The fungus has been isolated and grown in pure cultures and successful inoculations of seedling tobacco plants under glass have been made.  
G. T.

1115 - *Soja max*, *Dahlia rosea* and *Cosmos bipinnatus*, new Hosts of *Bacterium Solanacearum*, in North Carolina. — WOLF, F. A., in *Phytopathology*, Vol XII, No 2, pp 98-99. Lancaster, Pa, 1922

In August 1921, specimens of *Soja max* sent from Columbus (N. Carolina), of *Dahlia rosea*, and of *Cosmos bipinnatus*, collected in Raleigh, were attacked by wilting, less marked in the case of the soybean, probably owing to the woody nature of the stems and petioles.

Upon microscopic examination of the xylem tissues, bacteria were observed; these were isolated from each host, and eventually identified as *Bacterium Solanacearum*, and according to the author the diseased condition of the three plants may be attributed to this bacterium

G. T.

1116 - *Bacterium Solanacearum* injurious to various cultivated Plants in the Philippines (1). — WELLES, C. G., and ROLDAN, E. F., in *The Philippine Agriculturist* Vol X, No 8, pp 393-398 3 pl Los Baños, Laguna, 1922

The disease produced by *Bacterium Solanacearum* E. F. S. is one of the most serious of the maladies which attack the tobacco plant in the Philippines. It is common in all the tobacco-producing regions, and causes an annual loss of between 5 and 15 % of the crop; on seriously affected soil, 50 % of the crop may be destroyed. Although seedlings in the nursery are attacked as well as adult specimens, the plants that have been lately set out suffer most

The disease also attacks the tomato and egg-plant on a large scale according to observations made near Manila and in the Province of Laguna. In the fields of the Los Baños College of Agriculture, 70 to 100 % of the tomatoes, egg-plants and tango plants (*Chrysanthemum coronarium*) were found to be suffering from the malady. Nearly all the tomato plants were killed while still young, the egg-plants arrived at the fructification stage, but none of the fruits ripened. *Chrvs. coronarium*, like *Ricinus communis*, was attacked at all stages of development.

The disease is characterised by the more or less rapid and complete withering of the organs of the plant which unless it has reached an advanced stage, usually succumbs. Old plants although they wilt and wither manage to survive.

Numerous unsuccessful attempts to control this disease have been made at Los Baños. GARNER, WOLFF and MOSS state that the only

(1) See also R Aug. 1922, No 875. (Ed)

remedy is a five-year rotation during which all the host plants of *Bact. Solanacearum* are rigidly excluded from the infected soil.

It has been found that the egg-plant suffers little from the disease if sown in the rainy season so as to ripen in December. G. T

1117 - *Fusarium* sp., a Deuteromycete injurious to the Tomato Plant in North Queensland. — POLLOCK, N A R, in *The Queensland Agricultural Journal*, Vol XVIII, Part. 1, pp 10-12 Brisbane, July 1922.

Some five or six years ago, a disease due to a species of *Fusarium* was noticed for the first time in the Bowen district where the tomato is cropped annually over considerable areas. In this district, the disease is of general occurrence and few areas even on virgin soil are free from the infection.

The disease has also been observed at Townsville and Cooktown, but it does not seem to exist in other areas where tomatoes are grown for market such as Guthalungra, Gumlu, Cloncurry, Charterstown, Cape-River etc.

The fungus attacks the roots and spreads through the fibro-vascular tissue which when cut in sections is seen to be brownish. The first indication of attack is usually the yellowing of one or more of the bottom leaves followed by the wilting of one or several branches. Where the plant has no tap-root, one branch is usually first affected followed later by others, until ultimately the whole plant dies. The period from the first sign of attack to the death of the host, varies according to its power of resistance and the severity of the infection, so that the plant may die at once or linger on for several weeks.

It is possible that the disease may extend to the fruit, but no external or internal signs of its presence have hitherto been detected.

The disease sometimes shows itself a few weeks after the plants have been set out, it is usually not found in those left in the seed-bed even if they have been neglected.

Self-sown plants appearing in fields where tomatoes were grown the previous season frequently show no signs of infection. One case of the serious infection of self-sown plants has been observed, but the land was sown with another crop, and probably some damage was done to the tomato-roots during cultivation.

While so far no variety of tomato has proved immune, some varieties are more resistant than others. Early maturing varieties such as 'Chalk's Early Jewel' appear more subject to the disease than the main crop varieties.

No data are available as to the length of time the fungus may retain its vitality in the soil in the absence of any plant host, but there is abundant evidence that the infection increases when tomatoes are grown in succession upon the same ground.

It has been noted that the fungus spores were probably carried by the seed in the first instance, but when diseased and healthy plants are set out together, the disease can be contracted through the soil.

It is clear that the fields on which diseased plants have grown can carry infection, and that it may be transmitted to other fields by implements or other mechanical means.

The disease may also make its appearance on the roots, but the author is of opinion that the fungus generally enters by means of lesions due to want of care in lifting young plants in the nursery, or inflicted by different tools etc.

An experiment was carried out in this connection; when setting out the plants their roots and stems, as far as the bottom leaves, were dipped in a solution of 1 part copper sulphate to 500 parts by weight of water with a view to sterilising the broken rootlets, at the same time they were watered with a similar or weaker solution. Although complete immunity was not gained, the treated plants were longer in developing the disease than the untreated.

The author believes that crop rotation is the chief factor in the control of this disease. Sweetening of the soil by liming, and increasing the amount of plant food by the application of fertilisers to insure vigorous growth are necessary processes. In addition to the foregoing and equally important are the raising of disease-resistant strains and careful attention to seed selection

G. T

1118 - *Cercospora Melongena*, n. sp. of Hyphomycete injurious to Egg Plant in the Philippines. - WELLES, C. G., in *Phytopathology*, Vol. XII, No 2, pp 61-65 figs 2 Lancaster, Pa., Feb 1922

A spotting of the leaves of the egg plant has been observed recently in Los Baños, Laguna Province (Philippine Islands), especially on the lowest and oldest leaves. Chlorotic irregular shaped spots, frequently fusing, appear first on the upper surface of the leaf, later reaching the under surface. With age, the central portions of the lesions, which may cover an area of 6 to 8 mm. dry up and turn greyish-brown and show concentric rings. In advanced stages of spotting, the dead tissues fall out leaving a shot-hole effect.

According to the author the agent responsible for this disease is a new species of *Cercospora* which he describes and names *C. Melongenae*.

The native variety of egg plant has a long black fruit, turning yellow when ripe, and this has been seriously damaged by this disease, while the Siamese variety, small round and yellow fruit, is but slightly affected. All the plants in the district where the disease was first notified were infected, with from 50 to 100 % of the leaves attacked.

Several experiments have shown that spraying with Bordeaux mixture every two weeks is sufficient to hold the disease in check. However, comparison between sprayed and unsprayed plants has shown no important difference as regards setting or development of fruits. On the other hand, spraying tends to increase longevity of leaves and the general vitality of the plants. From these results it seems that spraying is not justified from the commercial standpoint for mature plants, unless the disease threatens to be unusually severe resulting in serious defoliation. Should

this occur, especially with young leaves or seedlings, spraying may be relied upon as a control measure. G. T.

1119 - **Banana Freckle (*Phoma Musae*) in the Philippines.** — LEE, H. A., in *Phytopathology*, Vol. XII, No. 2, pp. 101-102, figs 1 Lancaster, Pa., 1922

On both green and ripe bananas in the public markets in the Philippines, sometimes dark reddish-brown and sometimes black, minute distinct and hard spots were noticed. Usually they occur in large numbers and in some cases in masses on the fruits. Similar spots are seen on the leaves, but rather more streaked.

The varieties known locally as Latundan, Borongan, Lacatan and Saban of *Musa Sabientum* are affected.

Examination of the spots shows the presence of pycnidia and spores which resemble very closely those of *Phoma Musae* Carpenter, previously reported in the Hawaiian Islands as the cause of the "banana freckle"

The disease is much more abundant at the close of the wet season than during the dry season. As bananas in the Philippines are grown entirely for local consumption, the disease here does not cause the loss which occurs in the banana industry in Hawaii

It has recently been reported that this disease is widespread in the Sulu Archipelago, and in the Island of Mindanao in the Philippines. These islands are sparsely populated, and no bananas have been imported from the western hemisphere which indicates that the banana freckle is indigenous or at least has existed a long time here.

There is a continual migration of labour from the Philippines to the sugar plantations of Hawaii, and it may be supposed that a few infected fruits have been introduced in this way into the banana plantations of Kalili Valley, adjoining Honolulu, where the disease was first reported for Hawaii. G. T.

1120 - ***Penicillium expansum*, Stem End Rot of Apples, in California.**

BARNUM, C. C. in *Science*, new series, Vol. LV, No. 1435, pp. 707-708 Utica, N. Y., June 30, 1922.

During the late spring of 1921 a large number of apples which came from a lot removed from a cold storage temperature of 32° F and kept for a few days at 45° F, started to decay at and around the base of the stems. When placed in a moist chamber, these apples very soon decayed without wrinkling, becoming soft and watery. Decay was of a sharply defined nature and the affected parts could be easily removed. Normally these decayed apples were soon covered with green mould. On examination of the stems of apples in storage it was found that many were green as the result of fungus conidia, which after cultivation were identified as *Penicillium expansum* Lk.

No mention is made in the literature of the subject as to the entrance of a decay-producing organism through the stem. The decay of apples, which is ordinarily caused by *P. expansum*, is invariably mentioned in connection with abrasions of the skin, such as insect punctures and wounds or injuries of a mechanical nature. Some authors refer to infection as

entering through the calyx, but no-one has ever notified stem end infection.

During the autumn of 1921, large mature Yellow Bellefleur apples were collected from trees in a Berkeley garden. These were picked with the fruit spurs attached, carefully washed in alcohol, mercuric chloride solution 1-1000 and distilled water, consecutively. The leaves were clipped from the spurs to facilitate the process, but the spurs were not removed. Moist chambers were sterilised and prepared, the spurs were then removed from each apple and conidia of *P. expansum* were applied to the freshly exposed surface at the ends of the fruit stems, and the apples were then placed in the moist chambers. Control fruits similarly treated, but not inoculated, were kept under the same conditions in the laboratory. Of the six apples thus treated four developed the characteristic stem rot and were soon completely decayed. The control apples remained in good condition for 3 months.

Yellow Newtown apples were picked in the same manner at Watsonville (California), and brought to Berkeley. On October 17, 1921, three of the ripest of these apples were treated and inoculated in the same way as the Yellow Bellefleur specimens. On November 18, the form of decay of all three apples was identical with that observed on fruits naturally infected. Six Yellow Newtown apples were treated in the same manner and inoculated with the same organism several days later than the previous group, and they all showed signs of the typical decay. In every case the controls remained in good condition. After six weeks all the apples inoculated were entirely decayed and covered with green conidia. Cultures of these Conidia appeared identical in every way with the original culture. Further inoculations were made with re-isolated cultures on carefully sterilised apples. At the same time other apples were inoculated with the original culture. Results were identical, the typical *Penicillium* decay showing itself at every puncture. A *Penicillium* isolated during the autumn of 1921 from decaying plums was found to give rise to typical decay in apples after inoculation. This plum *Penicillium*, inoculated into the stems of three Yellow Newtown apples caused typical stem end decay after three weeks. The same *Penicillium* was found later to be identical with the original *Penicillium* isolated from apples.

Preparations were made from the infected leaves on some of the apples used in the experiments and typical colonies of *P. expansum* were developed. About 15 % of the colonies were identified as belonging to the *Penicillium* species; a considerable number were responsible for typical *P. expansum* decay when inoculated into ripe apples. This fact would seem to indicate the abundance of the fungi in the trees at harvest time.

These results prove that stem end infection of apples is possible. Observations made by the author indicate that this mode of infection is quite common among apples in California, especially on Yellow Newtowns. Although checked by cold storage, the rot makes some progress at a temperature of 45° F and at room temperature decay is rapid.

G. T.

1121 - Observations on the Erysipheae *Microsphaera quercina*, *Sphaerotheca mors-uvae* and *Oidium farinosum*, in Italy. — TROTTER, A., in *Annali della R. Scuola superiore d'Agricoltura in Portici*, Vol. XVII, pp. 3-11 (extract). Portici, 1922.

*Microsphaera quercina* (Schw.) Burr. — On the upper surface of oak leaves collected between the 20th and 30th of November 1920 at Zaffaria Province of Messina (Sicily), which were covered with the characteristic "oidium", the writer noticed some perithecia of *Micr. quercina*, previously found in Italy, in the Province of Bologna (1) and at Rome (2).

*Sphaerotheca mors-uvae* (Schw.) Berk. and Curt. — This Erysipheae reported as found for the first time in Italy in 1914 (3), had, however, been previously observed in August 1904, at Tornetti di Viù, in the Province of Turin. From 1912, the writer had found it in the Province of Avellino (Celsi, Forino and Avellino), where it may have been introduced by means of infected plants of *Kibes* coming from Northern Italy. At the present time the presence of the fungus is certain in Piedmont (Province of Alessandria (4), Novara (4) and Turin), in Lombardy (Milan and Pavia) (5), in Venetia and in Campania (Prov. of Avellino).

*Oidium farinosum* Cooke. — On apple trees grown in the nurseries of the Royal School of Oenology and Viticulture at Avellino, an extensive attack of *Oidium farinosum* has been observed for several years, taking place in spring. The fungus had been only recently reported in Italy, and especially in Northern Italy, whence it may have reached Avellino on young wild apple plants. This conidial form — which, according to the writer, should be attributed, in the present case, to *Podosphaera leucotricha* (Ell. and Ev.) Salm — shows a great tendency to propagate itself, especially on young nursery plants, the buds of which are attacked to such a degree that they die and dry up in a very short time. According to the writer, wild plants, obtained from seed and not yet grafted, were all more or less badly attacked, while the grafted plants had vigorous grafts, with buds almost entirely unharmed. G. T.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS

1122 - Observations on the Coccidae of Egypt. — HALL W. J., in *Ministry of Agriculture, Egypt, Technical and Scientific Series, Bulletin No. 22*, pp. 1-51, pl. 3. Cairo, 1922.

GENERAL

A record of the fifty-six species of Coccidae of Egypt to be found in the collections of the Ministry of Agriculture. It is probable that over a hundred identified species exist in the country, and doubtless some new to science will be collected, when it is found possible to make a detailed examination of the desert flora as a whole.

A brief description is given of the external characters of the species

(1) See R. Feb. 1920, No. 264 (Ed.)

(2) See R. May 1921, No. 508 (Ed.)

(3) See R. Dec. 1914, No. 1188. (Ed.)

(4) See R. July 1922, No. 785. (Ed.)

(5) See R. Dec. 1914, No. 1188 (Ed.)

enumerated with references to any peculiarities. The microscopic characters are only mentioned when the preparations made by the author show any distinct divergence from type. Information is added as to bibliographical sources in which will be found descriptions and illustrations of the various species. A complete list of the host plants is also given, and in the case of species which have proved recognised pests, certain observations are made as regards the outbreak and the control measures adopted, including the legislative orders.

In the appendix, a short list of the Coccidae collected in Palestine at the end of 1921, is given

G. T.

INSECTS, ETC  
INJURIOUS  
TO  
VARIOUS  
-----

1123 - *Vespa germanica* and *V. vulgaris*, Hymenoptera injurious to the Ghesab (*Pennisetum spicatum*) in Sicily. - See No. 1036 of this *Review*

1124 - *Calligrapha exclamatoris* and *Mordellistina pustulata*, Beetles, Injurious to *Helianthus* spp. in Manitoba, Canada. - CRIDDLE, N., in *The Canadian Entomologist*, Vol. LIV, No. 5, pp. 97-99. Orillia, May 1922

The recent cultivation of sunflowers (*Helianthus* spp.) for fodder purposes has provided a new instance of hitherto harmless insects becoming pests

In Canada a large number of wild species of sunflower are found some of which are closely allied to the cultivated kinds and as the wild varieties have their insect enemies there is no reason why these should not spread to those under cultivation and thus become of economic importance

The sunflower-leaf beetle (*Calligrapha exclamatoris*), is a very common and widespread insect in Manitoba where it is found feeding upon the leaves of various species of wild sunflower. It seems to live exclusively on *Helianthus*, and for that reason, promises to be one of the most important insects attacking this plant. The beetle has already spread to cultivated sunflowers on which it breeds as rapidly as upon the wild kinds. The author gives a morphological and biological description of the different stages of the insect, both beetle and larvae feed upon the leaves of sunflowers. In nature, they are most frequently met with on perennial species such as *Helianthus giganteus*, though they have been noted in numbers upon *H. annua petiolaris* also, and from this have spread to cultivated species

There is but one generation of the insect in Manitoba. The adult form superficially resembles the Colorado potato beetle (*Leptinotarsa decemlineata*), but is considerably smaller. Sprays similar to those used for the latter pest are also effective against the Sunflower beetle.

The larvae of another beetle, *Mordellistina pustulata*, were first collected from the stems of the Red-root Pigweed (*Amaranthus retroflexus*) which had prematurely died. Later, they were found hibernating in sunflower stems some of which they had riddled with their tunnels. These larvae confine themselves largely to the pith, but also injure the more woody parts; they occur most frequently near the base of the plant, al-

though any portion of the stem may be infested. Plants thus injured have a stunted appearance and sometimes die. Several larvae may infest a single stem and these remain within the plant until the following spring when they pupate, the adult beetles make their appearance in June. A description is given of the morphological characters of the larva and of the adult beetle.

In addition to the beetles mentioned above, a weevil, *Desmoris constructus*, has been found feeding on the flowers of *Helianthus*, but it remains to be seen whether it will become of economic importance. G T

1125 - *Pyrausta penitalis* -- a Microlepidopteron parasitic on the Nymphaeaceae, *Nelumbo lutea* and *N. nucifera* in the United States. — AINSLIE, G. G. and CARTWRIGHT W. B. in *United States Department of Agriculture, Bulletin* No. 1076, 14 pp. pl., 1. Washington D. C., July 1922.

*Pyrausta ainsliei* Heinrich (1) and *Pyr. penitalis* Grote are two closely related species very similar in many morphological and biological characters to the maize borer (*Pyr. nubilalis* Hübner) (2) recently introduced into America from Europe. It therefore seemed possible that a close study of the life-history and habits of the two native species might bring to light some facts that would help to determine the potentialities of the new pest.

In order to make the habits of the American species better known a paper dealing with *P. ainsliei* from the biological standpoint, has already been published, the present paper treats of the life-history, habits and enemies of *Pyr. penitalis*.

The authors' work dates from July 1919, and was carried out at Kimberlin Heights and Knoxville in Tennessee where the Microlepidopteron was chiefly studied on the yellow lotus (*Nelumbo lutea*), this Nymphaeacea and *N. nucifera* are as far as is known at present, the only natural hosts of the insect.

The larvae feed on the leaves of *N. lutea* which is grown as an ornamental plant and not only destroy them, but also attack and deform the pods, thus spoiling many of the seeds.

In confinement in the laboratory the partly grown larvae found on lotus fed readily and completed their development on smartweed (*Polygonum pennsylvanicum*), buckwheat (*P. lagopyrum*) and dock (*Rumex crispus*). G T

1126 - The Banana Weevil (*Cosmopolites sordidus*), injurious also to Abaca (*Musa textilis*), in the Philippines. — CENDANA, S. M. in *The Philippine Agriculturist*, Vol. X, No. 8, pp. 367-370, pl. 5, 108. Batavia, Laguna, 1922.

Although reported first in the Philippines only twenty to thirty years ago, *Cosmopolites sordidus* Germ. judging from its wide distribution, was certainly in existence before that time, and has been the cause of serious losses both of banana and abaca plants (*Musa textilis*). In 1916 this coleopteron killed large numbers of banana and abaca plants in Pacts, La-

(1) See R. July 1921, No. 783. (Ed.)

(2) See R. May 1921, No. 585. (Ed.)

guna Province. To-day the Pacte abaca industry is practically ruined.

The insect is a serious pest throughout the Philippines, and attacks banana plants of all varieties and at all stages of development. Most of the injury is done to suckers of the size best suited for transplanting, that is, from 75 cm. to 1.5 m. high.

The first outward indication that a sucker has been attacked is its loss of vigour. As the attack continues the unopened leaves die and fall off. If the sucker is removed and sliced through, the bulb is found to be riddled with holes, tunneled out by the weevil. The older suckers are not killed as a result of attack, but are so weakened that the flowers produced are abnormally small. Observations made at the College of Agriculture, Los Baños, indicate that the small and medium sized varieties of banana are more liable to attack than the larger varieties. Further experimentation is however, necessary. The abaca appears on the other hand to be less readily attacked than the banana; here again further experiments are needed.

Detailed information is given as regards the habits and life history of the insect

The insect is undoubtedly distributed by the transportation of infested suckers and root stocks for propagating purposes. The beetle rarely flies, but is able to crawl along the ground and can cover at least 15 metres each night.

No natural enemies of *C. sordidus* have been discovered in the Philippines, where amongst other control measures tried, infested suckers have been soaked for varying lengths of time in water and in formaldehyde solutions of different strengths. It was found that formaldehyde has a negligible effect on the vitality of the insect. In water the larvae and pupae from both bananas and abacas died within 72 hours, and only in a few cases were the larvae found dead after 48 hours. The adults however appeared to survive and usually crept to the part of the suckers above water, and can thus in most cases be readily collected and killed.

The stools cut during the harvest should not be left in the fields as they would harbour the beetles and act as a breeding ground.

Plantations should as far as possible be kept in good condition and very old plantations should be cut down and the land ploughed. Crop rotation is also advised.

G. T.

1127 - *Tetranychus yotheresi*, a Mite Injurious to the Avocado and other Plants in Florida. — MOZNETTE, G. F., in *United States Department of Agriculture, Bulletin No. 1035*, 15 pp., figs 11, 1 coloured plate Washington, D. C., 1922.

The red spider, *Tetranychus yotheresi* Mc.G., was recognised as a formidable enemy of the avocado (*Persea gratissima*) in Florida as early as 1909, since which time the damage caused by it has increased each year.

In groves where the red spider abounds, the trees frequently become defoliated prematurely during the winter season. This generally results in an abnormal development of bloom the following spring, and the weakened trees are unable to set and hold a full crop of fruit.

The red spider punctures the leaves and sucks the contents forming white spots at the point of attack ; later, the leaf becomes red and appears scorched. The foliage so attacked soon falls.

*T. yothersi*, which was first named and described from specimens on the leaves of camphor (*Cinnamomum Camphora*) sent from Florida, has been found by the author on both the West Indian and Guatamalan varieties, of *P. gratissima*. It occasionally causes considerable injury to the mango (*Mangifera indica*), Camphor (*C. Camphora*) and the Australian silk oak (*Grevillea robusta*) in Florida. It has also been collected there on *Eucalyptus* sp., *Terminalia Arjuna*, *Anona squamosa*, *Cucumis sativus* and *Icacorea paniculata*.

In S. Carolina, the pest has been found on *Ulmus* spp *Salix* sp., *Quercus alba*, and *Hicoria Pecan* ; and in N. Carolina on *Ulmus* sp.

A description is given of the life-cycle, habits and biology of the mite.

The following predatory enemies attack *T. yothersi*; *Scholothrips sex-maculatus* Pergande, *Chrysopa lateralis* Guer., *Scymnus utilis* Horn, *Sc. kinzeli* Casey, and *Leptothrips mali* Hinds : of these *Sc. utilis* is the most formidable.

Several insecticides have been successfully used against the avocardo red spider. finely powdered sulphur, lime-sulphur spray, commercial sodium sulphide, and nicotine sulphate containing 40 % nicotine.

Dusting with powdered sulphur is by far the quickest method and would be very practical, but for the fact that the presence of other insect pests in addition to red spider necessitates the use of liquid insecticides.

During the winter, after the fruit has been gathered it is advisable to apply a lime-sulphur solution in the proportion of 1 gallon of concentrated solution to 60 gallons of water. When the temperature is above normal, or when the trees do not attain a thoroughly dormant condition, 1 gallon of the concentrate to 75 gallons of water can be used.

Sometimes the mites make their appearance in the autumn before the fruit is picked. At this season, a 40 % nicotine sulphate spray (in the proportion of 1 part to 900 parts of water) with the addition of 2 or 3 pounds of fish-oil soap to each 100 gallons of the diluted spray, is temporarily effective and does not spoil the fruit.

The spray rod and spray gun have both been used in these operations, but it was found that the latter gave more satisfactory results.

Orchards mulched in various ways are generally less infested with red spider in South Florida than those where clean culture is practised. The avocardo, however, seems to thrive best where mulching is carried out and the moisture is conserved.

One factor largely influencing the appearance and abundance of red spider in a grove is the vitality of the trees. Nothing is to be gained by allowing trees to suffer from want of proper attention such as mulching, fertilisers and culture.

G. T.

[1187]

1128 - The Beetle, *Ips Pini* as a primary Pest of *Pinus divaricata* and *P. resinosa* in Minnesota. — GRAHAM, S. A., in *The Canadian Entomologist*, Vol. LIV, No. 5, pp. 99-100 Orillia, May 1922

Although it has been generally established that *Ips pini* Say is normally a secondary parasite, and usually attacks only dead or dying trees, this beetle has also been known to kill healthy trees as actually occurred in Itasca Park during the summer of 1921. The specimens destroyed were ten in number, 7 being young, rapidly growing Jack pines (*Pinus divaricata*), varying from 2 ½ to 5 inches in diameter on the stump and 3 healthy Norway saplings (*P. resinosa*) about 15 years old.

Each of these trees was very heavily infested from the surface of the ground almost to the top by the first brood beetles, and must have been attacked simultaneously by a large swarm of the insects. Apparently the attack was concentrated upon the few trees killed, since a careful examination of surrounding pines failed to show any signs that other individuals had been infected. Probably the beetles were attracted by the presence of two freshly felled pines which had been seriously infested. So large a number of the insects were present that many were forced to find quarters in the standing trees near.

It is a curious fact that the beetles did not infest the large piles of recently-sawn pine-logs of which there were many in the neighbourhood. The small group of heavily infested trees were quickly discovered by woodpeckers which destroyed at least 90 % of the insects, both adult and larvae, thus preventing the attack from assuming serious proportions.

Although the felled trees lying on the ground which the author assumed to be the attraction, harboured quite as many of the insects as the standing trees, it is interesting to note that the woodpeckers did not work at all on these trees.

This fact would appear to show that considerable care must be exercised in the use of trap trees for bark beetles. It is believed that the insects can be attracted by trees that have recently been killed and are known as trap trees. After they have become infested, they can be destroyed, thus materially reducing the number of insects in the forest. The presence of newly killed trees in the neighbourhood of freshly cut logs clearly shows that trap trees, as they appear to have a tendency to concentrate the beetles, must only be used with the greatest caution. G. T.

GENERAL INFORMATION

1129 - **Development of Natural Resources in Portuguese East Africa** - HALL, H. H.  
(H. B. M. Consul General Lourenço Marques) in *Department of Overseas Trade Report on the Commercial Situation of Portuguese East Africa*, London, 1922

DEVELOPMENT  
OF  
AGRICULTURE  
IN DIFFERENT  
COUNTRIES

As regards agriculture, in which the country throughout is extremely rich there is great activity, particularly on the banks of the Zambesi and in the district of the Companhia de Moçambique, which is served by the port of Beira. On the Zambesi, as well as in the southernmost part of the country, sugar is produced in large and increasing quantities. The average annual amount exported during the last few years has been forty thousand tons. Some of the land under sugar-cane is said to give an average of forty-five tons of cane to the acre. In the territory of the Companhia de Moçambique land has been and is being taken up for the growing of maize, rice, tobacco, oil-seeds and other crops and for the rearing of cattle. The maize is stated to average fourteen bags to the acre. Towards the north of the country various large undertakings are actively extending coconut, sisal and other plantations, with machinery for treating the product for export. In the inland district of Tete, which lies between the Nyasaland Protectorate and Northern Rhodesia, a British company with headquarters at Capetown has quite recently started works for the manufacture of pulp from baobab trees.

Much attention has recently been paid by the Government of the country to the possibility of irrigating various suitable areas, notably in the valley of the Limpopo, where it has been found that there are about one hundred and fifty thousand acres of excellent alluvial land about forty miles from the sea, that can be irrigated, drained and protected from

floods : a small river which is navigable for small ocean-going steamers, runs some way into the area. Schemes are also being submitted for similar treatment of various areas in the valley of the Incomati River, amounting to about one hundred thousand acres in all.

A. d. B.

1130 - **Agriculture in Nigeria in 1921.** — FAULKNER, O., in *Nigeria Annual Report on the Agricultural Department for the year 1921*, 8 pp. Lagos, June 14 1922.

*Cotton.* — The American cotton bush ("Allen") was introduced from Uganda into the Province of Zaria and the neighbouring Provinces of Kans and Sokoto. Almost all the crop of 1921 in the northern Provinces, 10 000 bales, was American cotton, while in the previous year, out of an almost equal yield, there were only 5 500 bales of American cotton. The cotton is bought by the British Cotton Growing Association which paid from 1915-1916 to 1921-1922 respectively  $1\frac{3}{4}$  —  $1\frac{3}{4}$  —  $2\frac{3}{4}$  —  $2\frac{3}{4}$  —  $3\frac{1}{2}$  —  $4\frac{1}{2}$  — 2 pence per pound for unginned American cotton. The Agricultural Department encourages the development of cotton growing by distributing selected seed (about 2300 kg. in 1921) ; by inspecting the cotton brought to market stations, which is said to decrease the difference between the price offered by the British Cotton Grower's Association and that paid by agents and brokers ; by the selection of "Allen" cotton, which has already given encouraging results.

Cotton is the principal product exported from Northern Nigeria.

Cotton is very extensively grown in Southern Nigeria : in 1920-1921, 20 000 kg. of unginned lint were exported, which formed only a small part of the total output as a good deal is used by the natives for home weaving. In 1921-22, the export was only about  $\frac{1}{4}$  of that of the previous year, owing to the unfavourable season and the low price offered ( $1\frac{1}{4}$  pence per pound). In previous years the Agricultural Department had distributed seed of "Georgia" Cotton in Southern Nigeria ; in 1921, it distributed seed of "Allen" cotton (6860 qx.) brought from Northern Nigeria. This large scale experiment has not given definite results as the year was unfavourable : the inspectors at the market stations noticed some good lots of cotton grown from this seed, but much of the lint was not sufficiently ripe and was blemished.

Cultural experiments undertaken at the Moor Plantation of the Agricultural Department have not given conclusive results. The yield of the "Allen" variety was poor, but that of indigenous cottons was still less. Researches must therefore be renewed for the purpose of discovering a cotton suitable for growing in Southern Nigeria. The Department has already begun such work which includes : — Selection of native cotton ; experiments with a few good exotic cottons ; experiments to decide which is the best time for sowing.

Similar remarks apply to the Province of Florin.

*Cocoa.* — The cocoa tree was introduced into the Provinces of Calabar, Berrin and perhaps Onitoha also, long before it was of any importance for the Colony or for the old western Provinces. The quantity exported

rose from 1388 t. in 1908, to 18 232 t. in 1921, of which about 17 420 t. were exported from Lagos.

The cocoa exported from Lagos is grown very close to the coast or to the north-east of Ibadan, while in the intervening country there is little or none. This is due, among other reasons, to the climate, soil, railway, character of the people, etc., but specially to the action of the Southern Nigeria Agricultural Department: cocoa growing has only gained a footing in places where it is likely to be permanent. It is encouraged by the teaching of good methods of fermentation. Moreover, up to the March 31, 1921, 16 000 cocoa plants were distributed free of charge or sold and 272 000 beans were distributed gratis for sowing.

During 1921 the corresponding figures were 1500 plants and 5200 beans.

*Oil Palm.* — The methods which have been suggested and discussed by several authorities and commissions in agreement with the Colonial Office to increase the production of palm oil and drupes or to improve the quality of the oil are chiefly: — 1) The introduction of machinery to replace the native methods of extraction. 2) Improvement of local methods of extraction, which vary in different places. 3) Production and propagation of improved varieties. For Nigeria the first is the most and the last the least important matter; but it is the latter which has alone attracted attention.

Of the different varieties sown at the Moor Plantation, Calabar, Omitsha and Bénin have begun to bear. In all plots, except those planted with the common local variety, the palms are too few to make any estimate as to their yield. The varieties are not clearly characterised and besides those described in the text-books, intermediate forms are also met with.

*Kola nuts.* — For many years the Agricultural Department has encouraged the plantation of the "Gbanja" variety of kola, and has distributed altogether 212 000 nuts and 58 000 plants of that variety, of which 114 000 nuts and 8216 plants were distributed in 1921. The output of the southern Provinces is at present scarcely sufficient to support a regular trade, but the yield of the "Gbanja" variety which was introduced from the Gold Coast, is steadily increasing.

*Tobacco.* — Light Virginian tobacco has been grown in Florin, but up to the present time only partial success has been obtained.

*Rice.* — Ceylon swamp rice has, to a great extent, replaced local varieties in many parts of the Northern Provinces. At Pategi (Florin Province) a variety introduced from Guiana has been tested comparatively with the Ceylon rice; the results are encouraging.

*Other crops.* — A certain amount of success has been obtained, especially in the Northern Provinces, in the introduction of better exotic varieties, or in the selection of indigenous varieties of various cultivated plants, such as "guinea corn" (a variety of sorghum for grain), wheat and "coco-yams".

The Agricultural Departments of Southern and Northern Nigeria have been united into a single Department with the writer at its head.  
F. D.

1131 - **Agriculture in the State of Bahia, Brazil** (1). — BARBOSA DE SOUZA, Y. (Secretário da Agricultura, Indústria, Comércio, Viação e Obras públicas do Estado da Bahia), *Relatório apresentado ao Exm. Sn. Dr. J. J. Seabra, Governador do Estado*. Year 1920, 181 pp., 7 full page tabl. Bahia 1921.

**PRINCIPAL CROPS: Cotton.** — The "Serviço do Algodão" (Cottons Service) was instituted by Federal Decree No. 14 117 of March 27, 1920 for the encouragement of cotton growing. The "Centro Industrial do Algodão", which collaborates with the former in the control of "Lagarta rozada" (*Gelechia gossypiella*) (2), and of "Lagarta verde" helps in the same object.

**Sugar-cane.** — The crop might be much more widely grown. In 1919 and 1920 the sugar factories of the State produced 372 700 bags of sugar.

**Maize.** — This is one of the most extensively grown cereals and thrives well throughout the State. It covers about 150 000 ha. yielding about 2 100 000 qx. a year.

**Cocoa.** — Exported in large quantities this commodity forms one of the principal sources of wealth of the State. According to the "Sindicato dos Agricultores do Cacau" production reached a maximum of 814 412 bags of beans in 1918, but fell to 786 074 bags in 1919 and to 650 873 bags in 1920.

Other important crops are *tobacco, coffee, manioc, rice*, etc. The export trade is almost exclusively maintained by agricultural products. In 1920 it included: — 53 667 000 kg. of cocoa — 30 288 000 kg. of tobacco — 656 7000 kg. of coffee — 6 512 000 kg. of sugar — 2 765 000 kg. of leather and 750 000 kg. of hides — 2 525 000 kg. of "piasava" — 180 t. of timber — 58 000 kg. of rubber — etc.

The forests supply almost all the fuel (firewood and charcoal) consumed by the railways, shipping, factories and required for domestic use. Owing to heavy timber cutting the question of reafforestation arises; the writer suggests the formation of forest nurseries for this purpose.

**AGRICULTURAL ENCOURAGEMENT.** — Includes: — distribution of seeds, competitions with prizes, sales to farmers at cost price of ploughs and other agricultural implements, etc. The distribution of seeds and plants is entrusted to the "Inspeccoria do Serviço Agronomico" (Inspectorate of the Agricultural Service) and to the Bahia experimental and demonstration Staff. The seeds distributed in 1920 were chiefly garden seeds, cereals and seeds of leguminous forage plants.

**PUBLIC AGRICULTURAL SERVICES.** — These include: — agricultural stations — a station for experiments and demonstrations — a meteorological

(1) See R. July 1922, No. 681, Note (1). (Ed.)

(2) See R. Dec. 1921, No. 1306. (Ed.)

logical Service — the publication of the *Boletim de Agricultura* of the Secretariat of Agriculture, Industry, Commerce, etc. In 1920 about 1200 copies were distributed.

The cadastral map is being compiled; this is entrusted to the "Serviço de Terras" of the "Diretoria de Terras e Minas".

**AGRICULTURAL EXPERIMENTS.** — These are entrusted to the "Campo de Experiencia e Demonstração Dr. Antonio Moniz" at Bahia, the area of which is about 4.5 ha. In 1920, many varieties of pulse, cereals, forage plants, industrial plants, pot-herbs and vines were tried. Among other things it was noticed that the "Bento Vieira" variety of manioc could occupy the ground for 10 years and produce enormous roots which reached a length of 2.80 m. and weighed as much as 13 kg.

The "Florida beggar weed" (*Desmodium tortuosum*) did very well and its propagation in Brazil as a forage plant and green manure has consequently been recommended.

**AGRICULTURAL INSTRUCTION.** — Is entrusted to the "Aprendizado Agrícola Federal" of Villa de São Francisco and to the "Escola Agrícola S. Bentos das Lages" of Villa de São Francisco, founded in 1859, which confers the diploma of "engenheiro agrônomo".

**BREEDING.** — According to official statistics the State of Bahia contains: — 2 683 000 cattle — 825 000 horses — 587 000 donkeys and mules — 3 005 000 goats — 2 224 000 sheep — 2 410 000 pigs. The cattle and sheep are bred for slaughter.

There is a Federal Veterinary Inspectorate ("Inspectoria Federal de Veterinaria") in the State. Good breeding animals are to be purchased shortly and sold to breeders at cost price in order to found "Postos zootécnicos" (Zootechnical Stations), serving stations and to arrange for dipping.

**MEANS OF COMMUNICATION.** — 2000 km. of railway are in use and 400 km. are under construction and plans for the construction of 1700 km. have been approved.

The river and coastal shipping is subsidised by the State. The construction of about 350 km. of roads has just been undertaken.

The building of important hydro-electric power stations (on the Paraguaçu, Jaguaripe, Itahipe and the Una) has made it possible to begin the construction of electric tramways and telephone lines.

**COLONISATION AND IMMIGRATION.** — The State of Bahia took part in the recent negotiations with the Italian Government with the object of encouraging immigration to its territories, where agriculture can be considerably developed.

F. D.

1132 — **Destruction of Mosquitoes by Eels** (1). — DUBOIS, R., in *Comptes rendus hebdomadaires des séances de l'Académie des sciences*, Vol. 173, No. 10, pp. 431-432. Paris, Sept. 5, 1922.

RURAL  
HYGIENE

From experiments made by the writer it was found that young eels live well for a long time in very impure water and that in such water they

(1) See R. March 1920, No. 282 and Feb. 1921, No. 118. (Ed.)

are very active in destroying the larvae of mosquitoes, and possibly also the eggs of several intestinal worms. They are so voracious at the commencement of spring that the writer no longer found any anopheles larvae in ponds where there had been large numbers before the eels were introduced.

The writer thinks that it would be very advantageous to keep young eels in all waters containing larvae of mosquitoes, both in the case of drainage water and other very contaminated waters. The exceptional hardiness of these fish, their low cost, the facility with which they can be caught and transported in large numbers, make them preferable to gold-fish (which have been recommended for killing larvae) and suggest that they would be very useful for the control of malaria by natural means.

F. F.

AGRICULTURAL  
EXPERIMENT

1133 - **Effect of Aluminium Salts and of Acids in various Strengths on the Development of Plants in Water Cultures** (1). - CONNER, S O and SEARS, O II (Purdue University, Agricultural Experiment Station), in *Soil Science*, Vol XIII, No. 1, pp 23-33, 1 fig, 1 full page tabl, bibliography of 8 publications, New Brunswick, N. J. Jan 1922

In spite of the large amount of literature dealing with the effects of aluminium salts and acids on plants grown in water, it has not yet been possible, owing to the great variety in the methods used, to compare the results obtained.

In 1919 the writers made a series of experiments on this question on rye, maize and barley grown on sand and then transferred to TOTTINGHAM nutritive solutions. The following substances were experimented with: - nitric acid, sulphuric acid, hydrochloric acid, phosphoric acid, tartaric acid and the respective aluminium salts at 4 different strengths, (N/ 600, N/ 1200, N/ 2400, N/ 4800); sulphate of aluminium mixed with phosphoric acid and the three phosphates of lime (N/ 600); sulphate of aluminium mixed with silicic acid, silicate of lime; carbonate of lime and of magnesium; dextrose; mannite; glycerine and carbon. Equal strengths of the various salts and acids show the same degree of toxicity in cultures of rye and barley. When the plant was well developed, the acidity of the solution decreased considerably. Nitric, sulphuric and hydrochloric acids and the respective salts showed the same toxicity; tartaric acid was less toxic and phosphoric acid least of all. Other cultures were made in SHIVE's nutritive solutions  $R_4 C_5$  of various osmotic pressures (0.0025 atm.; 0.1; 0.4). With the strongest solutions there was greater growth and consequently greater change in the acidity. By treating rye, barley and maize in SHIVE's solutions with sulphuric acid and sulphate of aluminium and by changing the solution every day so as to have pH constant, it was found that at parity of pH, the acid is much more toxic than the salt. In the bottles containing the salts a varying quantity of precipitate was also found. On the other hand in HARTWELL's and PEMBEL's nutri-

(1) See R. Aug 1922, No. 813. Sept. 1922, No. 909 and No. 910. (Ed.)

tive solutions, which contain much less phosphate in proportion to the other elements, sulphate of aluminium showed itself much more toxic to barley than sulphuric acid of similar strength, and slightly more toxic to rye.

As the plant grows these nutritive solutions tend to become more acid.

We may conclude by stating that the toxicity of aluminium salts is due rather to the aluminium ion than to the hydrogen ion in the case of plants similar to barley, and that this toxicity decreases considerably by adding much phosphate to the nutritive solution. These results confirm the theories of HARTWELL, PEMBEI, and MIYAKA. The toxicity of acid soils is due in a great measure to their content of soluble salts of aluminium.

A. de B.

## CROPS AND CULTIVATION

1134 - **Effects of a dry, warm Year on Wheat Crops grown at Verrières.** — DE VILMORIN, J., in *Comptes rendus de l'Académie d'Agriculture de France*, Vol VIII, No 9, pp 311-312. Paris, March 1, 1922.

AGRICULTURAL  
METEOROLOGY

The meteorological conditions prevailing in 1921 caused a remarkable growth, rarely observed in a normal year, in a large number of southern varieties grown in the climate of the environs of Paris.

At Verrières the southern varieties of wheat, under the exceptionally warm temperature, took a place in the classification which is rarely attained by them. The order of classification of wheats at Verrières in 1921 is as follows:

Three new crosses, not yet propagated and sown on a large scale. 1) (Melbor × Grosse tête × J. P. × Alliés) — 2) (Grosse tête × Melbor × Hérison sans barbes) — 3) (Hâtif Inversable × Alliés); — three southern varieties Riéti — Bladette de Besplas — Rouge prolifique barbu, — a hybrid under examination: Wilhelmine wheat.

The Blé de la Paix, a new large-yield variety, is classed twelfth; the Inversable, thirteenth, and the Gironde, fourteenth.

Wheats belonging to cold regions, such as the Altkirch and Rouffach, also felt the influence of the season. They are classed 32nd and 36th only.

The best yields, obtained on cultures of transplanted wheat were as follows (in kg. per ha.): Melbor × Grosse tête × J. P. × Alliés, 18 190 — Grosse tête × Melbor × Hérison sans barbes, 17 885 — Hâtif Inversable × Alliés, 17 215 — Riéti 16 600 — Bladette de Besplas, 16 580 — Rouge prolifique barbu, 16 545 — Croisement composé (Mixed Cross), 16 500 — Wilhelmine, 16 430.

F. D.

1135 - **The Treatment of Soil with Ferrous Sulphate and its Influence on the Soil Solution obtained by the Lipman Pressure Method** — LIPMAN, C. P. (University of California) in *Soil Science*, Vol XIII, No 1, pp 55-56 New Brunswick, N. J., January 1922.

SOIL PHYSICS

The author applied ferrous sulphate to the soil of a lemon orchard and after an interval of several weeks took samples of the soil, from which he extracted the soil solution by the pressure method. On analysis this solu-

tion was found to differ in a marked degree from that obtained from land not treated with ferrous sulphate. The sulphate of iron had increased considerably the content of non-volatile solids in the soil solution and had precipitated dissolved organic matter. The iron had substituted itself for the common bases, calcium and potassium, and had increased the amounts of phosphorus, potassium and calcium in solution. A. de B.

**1136 - Zinc as a normal Constituent of Soil under Cultivation and of Plants. —**

MONTANARI, C, in *Le Stazioni sperimentali a varie italiane*, Vol. LIV, Nos. 7, 8, 9, 10, pp. 278-283, bibl. of 9 works. Modena, 1921

The presence of zinc in plants was discovered about 50 years ago by RAULIN, but it was only in 1911 that DELEZENNE proved the importance and wide diffusion of this metal in the various animal and plant tissues. The writer, repeating the experiments with the improved DELEZENNE method, examined about 10 soils in the Province of Pavia stretching from the left bank of the Po to the Apennines. Although they differed greatly in their mineralogical character, he found considerable traces of zinc in every one of them, the amount being from 7 to 11 mgm. per kg. of dry soil. Nothing certain is known yet as to the function of zinc in plant life. According to MAZI, it is indispensable to the growth of maize, and its absence would cause acute chlorosis.

The writer tested the chlorophyll extract of spinach for zinc, but the result was negative. The matter from which the chlorophyll had been extracted was however rich in zinc, viz., 25.3 mgm. of zinc per 100 gm. of dry matter in spinach leaves. It still has to be decided what plant organs contain the largest quantity. DELEZENNE believes that zinc exercises special catalytic action in connection with the function of chlorophyll and with the circulation and metabolism of complex organic substances.

A. de B.

**1137 - Base Exchange and Alkalinity in Egyptian Soils. —** PRESCOTT, J. A., in *The Cairo*

*Scientific Journal*, Vol. X, No. 106-107, pp. 58-64, bibliography of 15 works. Cairo, May 1922

The presence of sodium carbonate in the soil solution is one of the most frequent causes of infertility in Egyptian soils, although the areas affected are not usually extensive.

Sodium carbonate is one of the most difficult of soil constituents to determine; variations of 400 % may be obtained in analysis according to the method adopted. No extract of this substance can be obtained even with 40 % alcohol; the maximum quantities are obtained by a fairly low proportion of soil to water (1 : 20) and extraction at the temperature of boiling water. The only constant value is the hydroxyl ion concentration. Normal Egyptian soils and the original Nile silt are faintly alkaline (pH = 8).

In the author's opinion, the origin of sodium carbonate in Egypt is to be attributed to the reversible reactions between neutral salts, and zeolites and kindred compounds. The Nile alluvium contains more than 2 % of salts (chiefly an aluminosilicate complex, probably colloidal in character)

which can react with neutral salts by base exchange. The soil of Bahtim contains at least 10 % of such salts.

The author carried out a series of experiments which fully confirmed the truth of his theory. Fifty grammes of good Bahtim soil containing no sodium carbonate, only about 0.1 % of bicarbonate, and having a pH of 8.2 were treated with a 10 % solution of sodium chloride, and subsequently washed with alcohol. This treated soil sample gave on analysis 0.344 % sodium carbonate and 0.462 % of bicarbonate; its pH was 9.3. It had thus become similar to one of the worst cases likely to be found in cultivated land.

1138 - **Determination of the organic Matter in the Soil.** — BOUDORFF, K A., and CHRISTENSEN, R H., in *Tidsskrift for Planteavl*, Vol XXVIII, No 2, pp. 265-275 Copenhagen, 1922

After having completed the experiments, of which an account has already been published, which were made by CHRISTENSEN on the power of the soil to decompose mannite, the writers made preliminary investigations on the possibility of determining directly the mannite content of soil extracts. The results showed that the method employed up to the present for determining organic substances in soil extracts is not entirely satisfactory since the oxidation of the greater part of the mannite present does not allow a quantitative analysis. A special experiment made on the subject indicated that such analysis can only be carried out when a large excess of permanganate is present.

In consequence of the results obtained the writers recommend the following modifications.

Place a soil extract containing 0.25 gm. of soil in a glass with 50 cm. of diluted sulphuric acid (6. 200). Heat for 20 minutes in a dish, add 50 cm. of a normal  $\frac{1}{20}$  solution of oxalic acid and titrate with a normal  $\frac{1}{50}$  solution of permanganate of potash

1139 - **Partial Sterilisation of the Soil.** — RIVIERE, G., and PICHARD, G., in *Comptes rendus hebdomadaires des séances de l'Académie des Sciences*, Vol CLXXIV, No 7, pp 493 495 Paris, Feb 13, 1922

If arsenite of soda be added to a soil a great change takes place in its microbial flora and fauna. If the doses of arsenite of soda are below a certain limit (about 10 gm. per sq. m.), the higher plants do not suffer in any way, whereas the protozoa, which destroy the useful bacteria, die in large numbers.

Both before and after the war, the writers made experiments on 10 ha. of different soils, using various plants and their results are as follows: 100 kg. of arsenite of soda per ha. destroy the protozoa, but have an injurious effect on the higher plants; a dose of 21 to 42 kg. per ha. (= 2-4 gm. per sq. m.), does not injure them but encourages the growth of useful bacteria and has an indirect influence on yield, which is increased from 20 to 50 %. Owing to the low price of arsenite of soda it can be advantageously used for partially sterilising the soil in order to obtain more

abundant yields, without any temporary necessity for the addition of nitrogen fertilisers.

**1140 - Action of Carbonic Acid Liberated by Micro-Organisms in Improving Arable Land.** — STOKLASA (Professor at the Higher Technical School of Agriculture at Prague) in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. 8, No. 21, pp. 594-596. Paris, June 7, 1922.

The writer has studied the physiological functions of soil bacteria for 25 years; he first observed that fertility is in direct ratio with the number of bacteria contained in the soil, whatever be the nature of these bacteria. The best soils are always characterised by the presence of a large number of bacteria and, consequently, by great biological activity.

As this activity is manifested by respiratory changes — the liberation of carbon anhydride and the absorption of oxygen — it can be easily measured. The writer has constructed a special and very practical apparatus for this purpose. He measures the quantity of carbon anhydride liberated from 1 kg. of arable soil. In soils of medium fertility he found that in a layer 36 cm. thick, 1 kg. of soil liberates 30 mg. of carbon anhydride in 24 hours, which, in 5 million kg. of clayey soil, amounts to 150 kg. of carbon anhydride per day, and for 200 days growth in the year, 15 million kg. of carbon anhydride. This gas dissolves in the water contained by the soil and, in circulating, plays an important part in transforming insoluble mineral salts into soluble matter, especially phosphates and in a secondary degree, silicates; it also acts on the cations, transforming them into carbonates easily absorbed by the roots, which greatly increases the chlorophyll assimilation of the carbon. And as the absorption of the other elements (nitrogen, sulphur, phosphorus, hydrogen, oxygen, potash, calcium, magnesium, iron) is in constant ratio with the assimilation of carbon, it follows that plant nutrition and growth are greatly aided.

The respiration of the micro-organisms also causes a rise in the temperature of the soil which, for a depth of 10 — 30 cm. rises 1 — 2° C, or 4 — 8 million calories per ha., which should greatly influence the growth of the roots of plants.

Good results may be obtained by chemical fertilisers — nitrates, superphosphates, etc., and certain catalytic substances — but for a maximum yield the plants must also be supplied with carbon, in the form of carbonic acid; there is only one way of doing this, namely, by increasing the biological activity of the bacteria by means of biological fertilisers.

I. V.

**1141 - The Influence of Plants upon Oxidation Processes in the Soil.** — NELLER, J. R., (New Jersey Agricultural Experiment Station), in *Soil Science*, Vol. XIII, No. 1, pp. 139-158, Plate 1, bibliography of 66 works. Baltimore, March 1922.

The symbiotic relationship between leguminous plants and bacteria was established only after years of investigation. It is probable also that in the soil relationships of another nature exist between micro-organisms and plants. Certain germs may function more actively in the immediate vicinity of roots and may benefit the plants. The author's studies give

him reason to believe that some such relationship exists between oxidising bacteria and growing roots. The processes of oxidation which take place in the soil under the influence of micro-organisms are made evident by the formation of carbon dioxide. It thus becomes a question of ascertaining whether growing plants have any influence upon the rate of oxidation of soil organic matter.

The author gives a very thorough account of the records of research on this matter which helped to explain soil oxidation, especially those concerning nitrification and the influence of plants on oxidation. It is necessary to recall the work of SCHREINER and SULLIVAN ; TURPIN ; LAWES, GILBERT and WARINGTON ; KING and WHITSON ; FRAPS etc. The influence of plants on various nitrifying bacteria was recognised by BERTHELOT ; HEINZE ; BROWN ; that on bacterial flora in general by CARON ; STOKLASA and ERNST ; LECLAIR.

The investigations are not always in agreement and some even are contradictory, but, as RUSSELL stated, field experiments alone do not enable us to decide this question and the systematic laboratory investigation has still to be made. It was for this reason that the author considered that a review of the problem might be of value.

The carbon dioxide liberated by bacteria in the soil in the presence of plants is not always that which is available for direct estimation. As a matter of fact part of this is absorbed by the roots and used in photosynthesis. It is necessary to keep this in mind, as this carbon dioxide is in addition to that obtained by the leaves from the atmosphere, and there is no way of separating them. The author got over this difficulty by placing the soil and growing plants in enclosures through which air freed from carbon dioxide was drawn. Thus the only source of carbon dioxide within the enclosures was that produced by the soil bacteria, of which part was absorbed by the roots and part utilised in the photosynthetic process in the leaves. The carbon dioxide not taken up was drawn through absorption towers and estimated, and that fixed in the process of photosynthesis was determined by making a total carbon analysis of the plants.

Thus the total amount of carbon dioxide produced by micro-organisms was measured quantitatively. Allowance should be made for the small amount of carbon present in the seeds or young plants used in the experiment. Another sample of soil under identical conditions but without any plants served as a control. The difference between the quantities of carbon dioxide produced in the two experiments must be attributed to the greater or less activity of soil bacteria in the presence or absence of plants.

In one of these experiments a soil was used composed of white sand to which was added 10 % of a fertile loam. As compared with the control, soya beans gave an excess of 12.1 % carbon dioxide, wheat 25.2 % and barley 12.9 %. In another experiment an ordinary fertile soil was employed and the difference in carbon dioxide production was even more striking ; for soya beans it was 66 %, peas 70.8 % and for buckwheat 116.5 %. The author repeated the experiment, using the same soil again and obtained

in the case of a jar planted with soya beans, an evolution of carbon dioxide 66 % higher than that from unplanted soil.

The experiments thus show that growing plants have a beneficial influence upon oxidation activities in the soil, and suggests a symbiotic relationship between the soil oxidising organisms and the plants. L. V.

1142 - **The Classification of Soil Moisture.** — PARKER, F. W. (University of Wisconsin), in *Soil Science*, Vol. XIII, No 1, pp. 43-54, Figs. 4, bibliography of 22 publications New Brunswick, N. J. Jan 1922.

Soil moisture is generally classified under three forms, as hygroscopic, capillary and gravitational water. Recently BOUYOUKOS advanced the hypothesis that a portion of the soil water is inactive or unfree, and does not act as a solvent and suggested a new classification.

The author subjected this theory to experimental tests and found it to be inexact. The lowering of the freezing point is far greater than that indicated by the law of inverse proportions and is due to the presence of solid matter and not to the existence of inactive water. Experiments show that solid matter causes a freezing point depression of water, benzene or nitrobenzene in the film or capillary condition. If one part of the water absorbed by the soil became inactive, a solution added to the soil ought to become more concentrated; but this was not the case when tests were carried out with solutions of alcohol or glycerine. A number of investigators have shown that the water of certain inorganic hydrogels is not combined water. However these hydrogels contain a considerable amount of water which cannot be frozen and a still larger amount which would be regarded as unfree water under the new classification.

Experiments on the rate of evaporation of water from soils, the vapour pressure at different moisture contents, the equilibrium relations with seeds and the freezing-point depression due to solid material do not indicate the presence of different forms of soil water such as are given in the classification of BOUYOUKOS. The results obtained can be explained in the following manner. In the case of soil not fully saturated with moisture, the water is held to the soil particles by the force of adhesion. If the quantity of moisture decreases, the force of adhesion of the remaining water increases, and this causes a lowering of the freezing point, a diminution of the rate of evaporation and a decrease of vapour pressure. This force of adhesion is sufficient to prevent the water from freezing even at a very low temperature.

The water present is subjected to the same law over the whole experi-

mental field and the constant and critical points shown by the soil and varying degrees of water content are equilibrium values only and do not indicate any break in the physical condition of the soil moisture.

The old classification of soil moisture into hygroscopic, capillary and gravitational water is retained, notwithstanding certain objections, and may be regarded as at any rate, very useful.

1143 - **Experiments in the Improvement of Alkaline Soils by the Application of Gypsum and other Methods.** — HIBBARD, P. L. (Agricultural Experiment Station, University of California), in *Soil Science* Vol. XIII, No. 2. Baltimore, February 1922.

MANURES  
AND  
MANURING

The author describes several methods employed to restore the fertility of the land belonging to the University of California, which was formerly very productive, but now bears next to nothing owing to the large alkaline deposits. From 1914 to 1918, attempts had already been made to improve extensive tracts by means of drains intended to carry off the salts in solution; the results obtained were however far from encouraging. In 1919, a detailed study of the district was begun and one ton of material from each of the five localities to be studied was examined. It had been intended to treat the soils with gypsum only, but as this did not prove effective, several other methods were adopted. The results obtained were as follows:

By means of simply washing the soil with water, the excess salts could be removed. A soil which is exceedingly alkaline owing to the presence of sodium silicates, carbonates, or bicarbonates can be improved to a certain degree by the application of gypsum, but fertility is only insured by the immediate leaching action of water which washes the alkalis, and especially the salts, down to the lower layers, thus making it possible for the seeds to germinate in the upper layers which otherwise would have remained toxic.

A rise in the carbon dioxide content of the soil air decreases the alkalinity, and allows plants to grow. This can be obtained without difficulty by introduction of organic substances that decompose readily.

When a soil contains more than 0.5 % of sodium carbonate and other sodium salts, it is difficult to make it fertile by the application of gypsum, because the reaction between gypsum and sodium carbonate is reversible. In order to check the inverse reaction, the sodium salts in solution must be removed by drainage, for owing to the slight solubility of gypsum (about 0.25 %), it is useless to try and affect the direction of the reaction by increasing the proportion of this substance. Before the alkalinity of the soils is reduced by leaching, a flocculating agent such as gypsum or calcium bicarbonate should be added to prevent the formation of impermeable, puddled layers. Water containing sodium carbonate or bicarbonate should never be employed.

When the sodium chloride and sulphide are removed from a soil by leaching, a perceptible rise in its alkalinity, or a fall in its pH value, is often observed. The alkalinity may be sufficiently high to be toxic to plant life, but as a rule, the amount of alkalis present is so small that the

little carbon dioxide liberated by plants or produced by decomposing organic matter, suffices to keep it below the toxic limit.

A. de B.

1144 - **Injurious Action of Composts.** — PETIT, M. A., in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. 171, No. 21, pp. 1362-1364. Paris, May 22, 1922.

In this article, the writer describes some experiments made to find out and study the causes why composts are injurious to the growth of certain plants.

It had previously been proved that these composts after washing acquired a higher fertilising power. The writer observed that certain plants, *e. g.*, the *Primula obconica*, derive no benefit from this washing, while others, such as the hybrid cineraria, suffer from it. This is explained by the fact that the washing not only gets rid of injurious substances, but also carries away soluble matter which is easily assimilated. In the experiments made with the hybrid cineraria it was also observed that composts of recent formation, in which the process of denitrification is still active are more injurious than those of older formation.

Certain calcifugous plants, such as the ericaceous group (azaleas, rhododendrons, etc.), suffer from the addition of composts to the soil, even in slight doses. This, as the writer has proved by his experiments, should be attributed not only to the small quantity of carbonate of lime (1-1.21 %) always present in the composts but also partly to the action of injurious soluble substances. Indeed, the wrinkled calceolaria, for instance, becomes chlorotic in soil containing 1.21 % of carbonate of lime, whereas it remains green in one rich in humus and containing 2.56 % of limestone. The writer has also observed that the addition of ferrosulphate to unwashed compost in the proportion of 2 to 3 ‰, neutralises the injurious action (chlorosis) of this compost on certain plants, *e. g.* on the hortensia (*Hydrangea Hortensia*) and the wrinkled calceolaria. The beneficial action of ferrosulphate should be attributed exclusively to the iron; the addition of other sulphates (sulphate of potash, of aluminium and of manganese) had in fact no effect.

It was also observed that the use of washed compost has a beneficial influence on certain plants (the hortensia and calceolaria) only for a certain period, and that the same thing takes place when washed compost to which iron sulphate has been added, is used. After a certain time the plant begins to become yellow, and, to avoid chlorosis, a fresh dose of ferrosulphate is necessary. The writer comes to the conclusion that injurious soluble substances are continually forming during the decomposition of the compost.

Finally the writer has tried mixtures of compost and sand in varying proportions up to equal parts, without any satisfactory result. He obtained good results, on the other hand, by mixing with clayey soil. Very probably the clay with its very high absorbing power fixes the soluble substances which are injurious to plants.

The writer draws special attention to this last observation made in

the course of his experiments, because it shows the great importance also of the physical composition of the soil which is chosen for the preparation of fertilising mixtures.

L. M.

1145 - **The Value of Tetraphosphate as a Fertiliser** (1). — HUDIG, J. and MEIJER C., in *Verslagen van Landbouwkundige Onderzoekingen der Rykslandbouwproefstations*, No. XXV, p. 140-159, 8 figs. Gravenhage, 1921.

The authors describe the circumstances which led to the starting of the tetraphosphate industry, the methods of manufacture and the success or non-success of this war-time fertiliser up to the present day. The fertiliser does not require sulphuric acid in its preparation and any quality of phosphates can be used, even such as are not suitable for the manufacture of superphosphates.

After referring to the reports of MENOZZI and BELLUCI, the authors describe the investigations they have made respecting the value of tetraphosphate. The first experiment was made with oats grown in pure sand, in pots; these were given, as fertilisers, chloride of potash and magnesium sulphate; one set of these cultures were given nitrogenous fertiliser in the form of nitrate of soda and the other nitrate of ammonium. The eight pots of each of these two sets received respectively as phosphatic manure: phosphate soluble in water — phosphate only slightly soluble — insoluble phosphate — low grade crude phosphate — high grade crude phosphate — the same high grade crude phosphate, heated to 700° C and rapidly cooled — tetraphosphate — no phosphate at all. These experiments have shown that in a slightly acid medium, tetraphosphate and the two other crude phosphates are of value. The favourable results obtained with tetraphosphate on rice plantations may probably be attributed to the acidity of the soil. The fact that MENOZZI obtained unfavourable results was probably due to the fact that the soil used in his experiments contained a sufficiency of phosphates, or to its alkaline reaction. The cultures failed when grown in an alkaline medium with crude phosphate.

A second study was made by the authors by carrying out comparative field experiments with 17 % superphosphate, 18 % French, Somme phosphate and tetraphosphate containing 26 % of phosphoric acid. These trials showed that:

- 1) in alluvial soils tetraphosphate and Somme phosphate were equivalent, although in sands of the "Anna-Paulownapolder" tetraphosphate was superior to French phosphate.
- 2) in "roodoorgrond" super and tetraphosphate gave an increase of 13 % in yield;
- 3) in the 22 cultures in sandy soil which responded to tetraphosphate, 6 gave a better yield with the tetraphosphate than with Somme phosphate; of these 6 cultures, three gave higher yields with tetraphosphate than when super was used; in the remaining three cases the two fertilisers proved to be equally effective.

(1) See R. 1916, Nos. 35, 1063; 1920, No. 498; 1922, No. 385. (Ed.)

These results were obtained with cultures of red clover, lupins, peas and oats. On the other hand with cereals and potatoes, 4 instances were recorded in which tetraphosphate was inferior to crude phosphate.

The authors summarise their work as follows :—

1) In sandy soils which had received a manure with an alkaline reaction tetraphosphate did not give such good results as ground, crude phosphate, and was decidedly inferior to soluble phosphate.

2) In sandy soils to which had been added a manure with an acid reaction, tetraphosphate gave good results ; the best however were those with crude, ground phosphate. The yield with tetraphosphate was the same as that obtained with soluble phosphate

3) In the cases where tetraphosphate proved superior to superphosphate the result must be attributed to the acidity of the soil, which caused the superphosphate to be ineffective and to certain unknown factors in connection with plant requirements and soil reactions.

F. S.

1146 - **Various Grades of Basic Slag in Great Britain.** — I *The Journal of the Ministry of Agriculture*, Vol XXIX, No 6, pp 530-533 London, September 1922 — II ROBERTSON, G S (D Sc, F I C), Field Experiments with Rock Phosphates and Basic Slags, *Ibidem*, pp 519-530, figs 5 — III JURITZ CHAS, F M A (D Sc, F I C Chief Division of Chemistry), Basic Slag, the Change in its Composition *Journal of the Department of Agriculture*, Vol V, No 1, pp 76-79 Pretoria, July 1922

The Permanent Committee appointed in Great Britain by the Ministry of Agriculture to study the question of basic slag presented a report in 1921, and have now presented a second, in which they examine the situation and give an account of the experiments that have been carried out

The demand for ground basic slag by the farmers of the United Kingdom has increased since the pre-war period (1912) from 290 000 tons to some 400 000 or 500 000 tons (with a phosphate content of 11 000 000 to 12 500 000 units) per annum, and will probably still further increase, as is shown by the following figures

	Consumption		Deliveries year ending May, 31		Expert estimate of the quantity that could be consumed	
	pre war (1912)	1919	1920	1921	Sir T. H. MIDDLETON	Sir A. D. HALL
	tons	tons	tons	tons	tons	tons
England and Wales.	—	433 000	407 000	328 000	890 900	975 000
United Kingdom . . .	290 000	529 000	503 000	400 000	(32 820 000 units)	(37 050 000 units).

On the other hand, the production of unground basic slag has not increased correspondingly. Prior to the war, it was about 400 000 tons, rising in 1919 to 1920 to 701 000 tons, but in 1920-21 falling again to less than 400 000 tons. Moreover, there was a reduction in quality in consequence of the substitution of the acid OPEN HEARTH process for the BES-

SEMER process. The slag now obtainable contains on an average only half the percentage of phosphate present in pre-war days, and much of it shows reduced solubility according to official tests.

The demands of the farmer have been met to some extent by importation from abroad. Thus, while in 1913 the balance of exports over imports was 114 000 tons, in 1920 and 1921 it was respectively 6000 and 38 000 tons. Export was however in these years prohibited except by licence. In view of the probability that the quality of the basic slag manufactured on the continent may deteriorate as it has in the United Kingdom, by the gradual substitution of the OPEN HEARTH for the BESSEMER process, it would be unwise for British farmers to rely to any serious extent on importation.

Further, after careful investigation it appears that little if any change in actual engineering processes is likely to improve either the output or quality of slag. From the point of view of steel manufacture basic slag is relatively unimportant, on the average rather less than 4 cwt. are obtained per ton of basic steel produced, and while a ton of steel has been worth from £27 in 1920 to £17 in 1921, the 4 cwt. of slag are not worth more than 2s. to the steel-manufacturer and only about 6s. on the market. The steel-maker therefore cannot afford to lengthen his processes or make them more costly or hazardous.

The quality of basic slag is determined by the process employed, and the total amount producible is regulated by the demand for steel, neither of these factors can be influenced to any appreciable extent by the requirements of the farmer.

The Committee have examined the possibility of substituting ground mineral phosphates for basic slag and of increasing their effectiveness. One of the slags tested in the field in 1921 gave considerably better results than could have been expected from its chemical composition. Other experiments in the same direction are now in progress. A typical North Ayrshire mineral phosphate is included in the Rothamsted trials, and the experiments carried out in various countries are being repeated at the Rothamsted Station.

Owing to the exceptionally severe drought in 1921, very few results were obtained in any of the field trials, but in any case the trials must extend over several seasons before definite conclusions can be reached.

So far as present information goes, it may be stated that: a) The highly soluble OPEN HEARTH basic slags have the same agricultural value per unit of phosphoric acid as the old BESSEMER slags.

b) The slags of low solubility have a lower value, but in some circumstances the difference is not very marked. There is however considerable difference in the effectiveness of this group which is probably due to the fact that it is composed of materials of very different nature, although the citric solubility test fails to distinguish satisfactorily between them.

c) The mineral phosphates also have a lower value, but in some cases, they are worth more than might have been expected.

As a result of these trials, the Committee hope to be ultimately able to :

1) Map out the country into regions where the high soluble slag can and cannot be replaced effectively by low soluble slags and mineral phosphates.

2) Advise the Ministry whether the annual output of very low grade slag (under 15 % phosphate) which amounts to some 70 000 to 140 000 tons, could not be used with advantage after being mixed with mineral phosphates.

The Committee are further of opinion that the official solubility test needs revision.

II. — The author examines the various kinds of basic slag, and the phosphates that could be used to replace them, and describes the experiments made in this direction.

The basic slags now obtainable may be divided into three types: —

1) *High Grade*, containing from 33-42 % of phosphate. Part of this supply consists of the rapidly diminishing remnants of the Basic Bessemer Slag, and this class will probably completely disappear.

2) *Open Hearth Basic Slag* containing from 15 to 32 % of phosphate.

3) *Open Hearth Fluorspar Slag* containing from 15 to 32 % of phosphate.

Types 1 and 2 have a citric solubility of 80-95 % and are of equal value per unit of phosphate. Type 3 has a citric solubility of 6-50 %, and it is this type of slag that is of uncertain value, for it cannot be distinguished by appearance. How much of the present supply belongs to this type it is impossible to say, but the proportion is likely to increase in the future.

One of the possible substitutes for the old type of basic slag is ground mineral phosphate. The various rock phosphates are not identical in character — they differ in their phosphate content, which is usually high, in chemical composition, and citric acid solubility which is intermediate between that of types 1 and 2 and of type 3. Experts however differ as to the extent to which citric solubility may be taken as a measure of the relative value of the various phosphates. The following table gives the principal rock phosphates with their characters:

Name of Phosphate	Origin	Approximate Phosphate content %	Citric Solubility %
Gafsa . . . . .	North Africa . . . . .	56-64	38
Egyptian . . . . .	" " . . . . .	56-60	35
Algerian . . . . .	" " . . . . .	58-66	33
Florida Soft . . . . .	United States . . . . .	48-54	27
Tunisian . . . . .	North Africa . . . . .	54-60	24
Tennessee . . . . .	United States . . . . .	30-60	23
Nauru . . . . .	Oceania . . . . .	82-88	21
Makatea . . . . .	Oceania . . . . .	82-86	19
Florida Pebble . . . . .	United States . . . . .	70-76	18

Several experiments were made in Essex from 1915 to 1919. Three types of basic slag were used and several rock phosphates and superphosphates. Meadow land poor in phosphoric acid was selected for the trials, and eight experimental centres were laid down, the following soil formations being represented: London Clay, Boulder Clay and Chalk. Other experiments were carried out in North Ireland on different types of arable land land.

#### CONCLUSIONS FROM THE FIELD EXPERIMENTS.

1) Open Hearth Fluorspar basic slags are not as effective as the soluble types. They have however a considerable value and are more effective than the solubility figures would suggest. Where the rainfall is high and the soil sour, they are nearly as good as the more soluble types, but where the conditions are reversed, their inferiority is more clearly marked. For the manuring of grassland the author is of opinion that if the value of the highly soluble slags is taken as 100, the fluorspar basic slags have a value of 50-70.

2) The results of all the experiments agree in showing that rock phosphates have a higher manurial value than has hitherto been supposed. On sour soils and when the rainfall is high, they may even prove superior to the best grades of basic slag. In all cases, they have proved more effective than the fluorspar slags. Of the various types of rock phosphates Gafsa seems the most suitable for direct application. On sweet soil or where the rainfall is low the more soluble types of North African phosphates (Gafsa, Egyptian, Algerian and Tunisian) are superior to the richer, but less soluble and harder types, such as Florida Pebble.

III. — The author gives a short account of the work and findings of the Committee. He examines the possibilities of improving the lowest grades of slag by their reintroduction into the blast furnace, and excludes the idea that other constituents such as manganese can have any value in improving the quality of basic slags. He quotes the opinion of Dr. F. J. RUSSELL, the President of the Committee, who stated on the subject of basic slags that though types with high solubility come into action more quickly and produce a larger return the first season, the low soluble slags may increase in effectiveness, so that after 5 years there may be little difference between the two.

1147 — **Potassic Deposits in Poland.** — *Les Mécuriales Agricoles*, Vol. VI (Second series), No. 18, p. 138. Antwerp, May 5, 1922.

Potassic salts have hitherto been worked in Poland only in the neighbourhood of Kalusz in Galicia, but there is reason to believe that potassic deposits exist in other regions of Galicia and notably in the vicinity of de Bochnia and Wieliczka.

Prof. MICHAELIS is of opinion that beds of potassic salts are also to be found in Posen; these would form the extension of corresponding deposits in Germany.

The output at Kalusz used to be extremely small, the total extraction (in tons) being only.

1913	1919	1920	1921 (6 months)
2 344	2 500	10 293	6 737

The amount extracted in 1921 was at least six times larger than the pre-war out-put, but it will only satisfy a small fraction of the requirements of Poland, which country must for the present remain dependent upon foreign sources for its supply of potassium. A. de B.

**1148 - Pot Culture Tests on the Availability of Potassium in Greensand Composts.** - SMITH, A. M. Agricultural Experiment Station, College Park, Maryland), in *Journal of the Association of Official Agricultural Chemists*, Vol V, No. 1, pp. 133-136 Washington, D. C., August 1921 (1).

The author describes experiments made by himself with a view to ascertaining the possibility of the use of glauconite as a fertiliser. This mineral, which is commonly known as greensand, consists chiefly of the hydrous silicate of iron, aluminium and potassium. It forms extensive deposits in New Jersey, Maryland and Virginia; the present investigations have therefore great practical importance for these States. Greensand can be applied to soil either composted or uncomposted. Previous work at the Maryland Agricultural Experiment Station (2) had shown that composting greensand with sulphur and organic matter changed a considerable part of the insoluble potassium into a water soluble form.

The author carried out his experiments with barley in glazed pots, each pot held 2800 gm. of sandy loam containing only 0.82 % potassium. To the control pots ammonium sulphate and monocalcic phosphate only were added. The other pots received an equal amount of potassium, in the form of sulphate and pure unmixed greensand, or else a mixture of greensand, sulphur and manure, or greensand compost containing organic matter and sulphur.

Some experiments were made at the same time in the absence or presence of calcium carbonate. Each treatment was in duplicate.

The results obtained show that under favourable conditions, on a soil low in potassium, an application of greensand alone increases the yield of barley. On the same soil, in the absence of calcium carbonate the addition of the mixture greensand + sulphur + manure, and the application of compost greatly injured the crops, whereas in the presence of calcium carbonate excellent results were given.

The author also found that when the compost was applied, large quantities of free acids were liberated in the soil; observations made to determine the water soluble acidity of the compost also indicated the presence of large amounts of soluble iron and aluminium salts. It is to these salts that the author attributes the reduction in yield, produced by the mixture and

(1) See R. March 1921, No. 257. (Ed.)

(2) *Journ. Assoc. of Offic. Agr. Chemists*, IV, 375, 1921. (Ed.)

compost when there is not sufficient lime to convert them into a form that is not injurious to plant life. This is in agreement with the work of other investigators.

To sum up : the author has proved by his experiments that the potassium contained in a greensand-sulphur-manure compost (in the presence of sufficient lime) has practically the same availability as an equivalent amount supplied in the form of potassium sulphate. L. M.

1149 - **The Nitrogen Industry in Germany.** — I MURAOUR, H. (Chef de service des experts chimistes à la Commission militaire interalliée de Contrôle en Allemagne), *L'azote en Allemagne avant, pendant et après la Guerre*, in *Chimie et Industrie*, Vol VIII, No 1, pp 169-175, figs 5 Paris, July 1922 — II MATIGNON, C, *L'Industrie des matières azotées en Allemagne*, *ibidem*, pp 176-184 (1)

I. — The total amount of nitrogenous substances used in Germany before the War was over 240 000 tons ; of these, 200 000 tons were employed for agricultural purposes, which (taking the cultivated area as 35 million hectares), means at the rate of 6 kg. of nitrogen per hectare. This includes only mineral nitrogen, not the nitrogen supplied by organic fertilisers.

As regards nitrates, Germany was entirely dependent on importation before the War. She imported annually from Chile 800 000 tons of saltpetre containing on an average 15 % of nitrogen, that is to say, 120 000 tons of nitrogen, while she obtained from Norway 2 400 to 10 000 tons of synthetic nitrate. On the other hand, the gas industry annually produced 550 000 tons of ammonium sulphate which is equivalent to 110 000 tons of nitrogen. The cyanamide output is difficult to estimate ; it appears that the maximum production was 40 000 tons with 8 000 tons of nitrogen. Finally, by the HABER-BOSCH process, 2 017 tons of synthetic ammonia were made, which represents 1661 tons of nitrogen.

The total nitrogen consumption during the War has been reckoned at 940 000 tons, of which 514 000 tons were applied to military uses, and 426 000 tons employed for agricultural purposes. Thus less than 50 % was used for agriculture than in times of peace, and the crops were considerably reduced. When the war began, Germany possessed the following nitrogen reserves : 6 000 tons under the form of Chile saltpetre, 20 000 tons under the form of Norwegian saltpetre and of cyanamide, and 20 000 tons under the form of ammonium sulphate. In March 1915, these reserves were exhausted but 5 000 tons, taken chiefly from Antwerp, supplied the explosives factories until May 15, the date when the great factories of synthetic nitric acid belonging to the B. A. S. F. at Oppau and Merseburg were in full work.

During the War, Germany imported 8000 tons of nitrogen from Norway ; the coke and gas industries supplied 400 000 tons, whereas in pre-War times, their annual output was only 60 000 tons ; the cyanamide factories produced 168 071 tons, and the synthetic ammonium factories 240 436 tons. At first, the factories of synthetic ammonia were only able to supply a very dilute acid which had to be converted into nitrate before a concen-

(1) See R. Oct. 1922, No. 102<sup>B</sup>. (*Ed*)

trated acid could be obtained. From these nitrates and the nitrate reserves 182 200 tons of nitrogen were obtained under the form of nitric acid. Subsequently, by directly concentrating the dilute nitric-acid, 35 860 tons of nitrogen were obtained.

Since the War, owing to the fall of the mark, Germany has tried to dispense with imported food stuffs and forages, which before the War had reached the value of 3 million marks, trusting to intensive agricultural production to provide the necessary supply. By the Treaty of Versailles, she lost 5 million hectares of arable land, but the reclaiming of new land will soon bring up the cultivated area to the pre-War figure, viz. 35 million hectares. The nitrogen consumption has already exceeded the 200 000 tons used annually during the period preceding the War, and will soon rise to 500 000 tons. The demand now exceeds the supply which has decreased owing to the Oppau disaster and the shutting down of the Knapsack and Walshut factories. A vigorous and successful campaign has been started to induce farmers to use more nitrogenous fertilisers.

As a result of all these changes, the amount of Chile nitrate imported at present is almost negligible, hardly reaching 31 000 tons. The gas and coke industries now supply 110 000 tons of nitrogen as they did before the War; the cyanamide factories could furnish 500 000 tons, representing 100 000 tons of nitrogen. The nitrogen output of the B. A. S. I<sup>2</sup> will be 300 000 tons, which at 30 marks the kg., represents the value of 9 thousand million marks. The amount of nitric acid made by the electric-arc process is the same as before the War, viz., 1272 tons annually.

Factories making nitric acid by ammonium synthesis can produce 111 456 tons of nitrogen, while the nitrogen output of those which obtain it by the concentration of the dilute acid may be 1338 tons.

Before the War, Chile was the country that produced most nitrogen, 392 000 tons; Germany followed with 122 000 tons, after which came England, 88 000 tons; the United States 35 000 tons; France, 16 500 tons, Austria-Hungary 10 500 tons; Belgium 9 800 tons, and Norway 9 600 tons.

At the present time, Germany ranks first with 500 000 tons of nitrogen, which is nearly the total pre-War output of the seven great nitrogen-producing countries. This must not however be regarded as her maximum production, for schemes are under consideration for the construction of other large factories for the manufacture of cyanamide at Pisteritz, and the utilisation of the waterfalls in Bavaria.

II. — Even before the War, Germany was the country that consumed the greatest amount of nitrogen, 218 250 tons. Next followed the United States, 146 000 tons; France 68 000 tons; England 43 000 tons, and Belgium 35 000 tons.

During the last 20 years, Germany has succeeded in increasing by 60 % the returns from her land which although inferior to that of France is much more highly productive. Germany uses for every hectare of land fit for cultivation 8 kg. of nitrogen, France uses 3, England 6.25 and Belgium 17.04.

In the German agricultural programme it is estimated that the annual

consumption of nitrogen this year will reach 500 000 tons. Over a thousand million marks have been expended by Germany in building new factories, but without them in 1921 alone she would have been obliged to import 230 000 tons of nitrate from Chile, which means an outlay of 400 million gold-marks, or 27 thousand millions of paper-marks.

The seven societies engaged in the development of the HABER-BOSCH process, which form the Chemical Industry Consortium, possess a total capital of 1762 millions, to which must be added compulsory obligations amounting to 153 millions. Before the end of 1922, their annual output will be 300 000 tons of nitrogen.

In addition to the old fertilisers, the "Badische" has put on the market several new compounds: ammonium hydrochlorate, ammonium nitrosulphate, ammonium potassic nitrate.

Germany is not satisfied with having been freed from the necessity of importing nitrate but also intends soon to export it, and to enter into competition with Chile on all the markets. Further, she has acquired the means of producing in future hitherto undreamt of quantities of explosives, an amount eight times larger than France could ever manufacture.

1150 - **The Transformation of Ammonia into Urea.** — MATIGNON, C., and FRÉSAQUIS, M. in *Comptes rendus hebdomadaires des séances de l'Académie des Sciences*, Vol. XIV, No. 7 pp. 435-157. Paris, February 1922.

The authors give a report of their studies on the transformation of ammonium carbonate into urea, a process by which in 4 hours 1 % of ammonia was obtained at 130° C, 6 % at 135° C, and 41 % at 145° C. As the reaction is a dehydration process, an attempt to accelerate it was made by the use of catalysts that proved most effective at low temperatures, but were useless at 150° C. The urea thus obtained is very pure and melts at 133° C. It can be separated from the carbonate and other salts present by evaporation in a water-bath, the operation is quantitative.

The results of the authors' studies have enabled them to devise a systematic method for the industrial manufacture of urea, a highly concentrated nitrogenous fertiliser.

1151 - **The Decomposition of Ammonium Nitrate by Heat.** — SAUNDERS, H. L., in *Journal of the Chemical Society*, Vols. CXXI and CXXII, No. 714, pp. 698-711. London, April 1922.

This experiment was undertaken with the object of obtaining further information regarding the manner in which ammonium nitrate decomposes when heated. The three points the author proposed to elucidate were: the nature of the decomposition of pure ammonium nitrate at moderate temperatures — the modifications in this decomposition in the presence of small quantities of the impurities commonly occurring in commercial nitrogen — the nature of the explosive decomposition.

The first part of these experiments was directed to the decomposition of specially purified ammonium nitrate dried at 100° C.

A very ingenious apparatus was used by the author which enabled him

to follow accurately the decomposition of ammonium nitrate at different temperatures and to collect the gaseous and liquid products of the process. He found that pure dry ammonium nitrate decomposes only slowly at 200° C. The nitrate first melts at 169° C, then separates into nitric acid and ammonia; it then begins to evolve a gas containing 98 % of nitrous oxide. Free nitrogen, nitrogen peroxide, and nitric oxide are always present. The amount of free nitrogen is nearly 2 % up to 260° C and considerably more at higher temperatures. The average amount of nitrogen peroxide and nitric oxide between 220° C and 260° C was 0.001 % of each.

The liquid products of the reaction contained nitric and nitrous acids.

In another series of experiments, the author studied the influence exercised upon the decomposition of commercial ammonium nitrate, heated to a moderate temperature, by the impurities usually present in this nitrate. The commonest of these impurities are the chlorides of ammonium and sodium, the sulphates of ammonium and sodium nitrate.

In order to study the modifying influences of these substances, pure nitrate and mixtures of each of the salts (specially purified by recrystallisation) were made. Various proportions of these salts were introduced, but the amount never exceeded the percentage found in the commercial product.

In the first place, a series of mixtures were made containing quantities of ammonium or sodium chloride ranging from 0.1 to 2 %. It is difficult to state definitely the temperature at which decomposition takes place; the process is always accompanied at the beginning with a remarkable rise in the temperature. When any mixture is raised to a particular temperature, there is first a passive period varying in length from a few minutes to one hour and a half. How long it lasts depends upon the amount of impurities present, on the temperature, and possibly on the presence of free nitric acid (VELEY, *Chemical News*, 1883, XII, 299). Then a new reaction sets in, and chlorine is evolved and is always present in the gas formed. The composition of the gas produced at the beginning of the decomposition of mixtures of nitrate and chlorides is very different from that of the gas evolved in the normal decomposition of pure ammonium nitrate, for in some cases, the nitrous oxide falls 50 %, while the percentage of nitrogen increases. During the first decomposition period, there is a rise in the temperature of the mixture (20°-80° C), till it has attained a maximum, after which it again falls. The composition of the gas remains constant during the first period for any particular mixture, but as soon as the temperature begins to fall (most of the chloride having decomposed) it gradually approximates to that of the gas evolved at the same temperature during the decomposition of pure nitrate.

Nitric acid is always present, as well as hydrochloric acid, in the water condensed during the decomposition. The action of the chlorides of ammonium and sodium is very similar, but that of ammonium chloride is more marked.

Ammonium sulphate added to the nitrate in the proportions of 1 and 2 % does not produce any special modifications in the decomposition pro-

cess. The gas evolved sometimes however contains a trace of ammonia. A 1 % mixture of sodium sulphate does not influence the decomposition reaction between 220° C and 250° C.

Mixtures with 1 and 2 % of sodium nitrate are without characteristic action.

In a third series of experiments, the author studied the explosive decomposition of ammonium nitrate. A suitable apparatus was selected and tested for the maintenance of a vacuum. The decomposition products were carefully collected and analysed.

It was found that the decomposition by explosion of ammonium nitrate — even at the lowest temperature at which an explosion will occur — is very different from normal decomposition. The amount of nitrous oxide is greatly diminished, and the gas contains nitrogen peroxide, nitric oxide and nitrogen in the approximate ratio 2 : 4 : 5.

The explosion is accompanied by a yellow flame not unlike that of ammonia burning in oxygen.

The results of the author's three sets of experiments may be summarised as follows : pure ammonium nitrate decomposes into nitrous oxide and water to the extent of 98 % between 210° C and 260° C. At some point near 300° C other oxides of nitrogen are evolved, the action proceeding explosively. At the moment of the explosion, the pure nitrate decomposes in a totally different manner, giving nitrogen peroxide, nitric oxide and nitrogen in the ratio 2 : 4 : 5.

Among the products of normal decomposition, nitrogen is always present, in the proportion of about 2 % up to 260° C ; immediately after explosion, the percentage of nitrogen is 46.

As regards the ordinary impurities occurring in ammonium nitrate, the experiments showed that small quantities of sodium sulphate and sodium nitrate do not influence normal decomposition.

On the other hand, small quantities of the chlorides have a remarkable effect. Their action is of a catalytic character and the decomposition process is modified by even 0.01 % of chloride of sodium, or of ammonium.

In the presence of chlorides, there is always chlorine in the gases evolved, the amount depending on the quantity of the chloride and on the temperature. There may be from 30 to 50 % of nitrogen in these gases.

The liquid products of the reaction always contain hydrochloric acid as well as nitric acid.

1152 - **Borax (1) in Fertilisers and its Effect on Potato Growth and Yield.** — BROWN, B.F. (Biochemist, Office of Soil-Fertility Investigations, Bureau of Plant Industry, U. S. Department of Agriculture), in *U. S. Department of Agriculture, Bulletin No. 998*, figs. 10, bibliography of 9 works. Washington, D. C., July 1922.

Injury to field crops through the use of fertilisers containing borax was first observed by CONNER, in Indiana, in 1917. Many serious cases of borax injury were reported in 1919, when ample proof of the poisonous

(1) See *R. Jan.* 1919, No. 25. (Ed.)

action of this compound was given. In 1920, a series of well-controlled field tests were conducted on four different types of soil bearing crops of potatoes, maize, peas and cotton respectively.

The author gives an account of the results obtained in Maine on loam; the borax was applied at the rate of 1 to 400 pounds per acre and there were 12 experiment plots. The fertilisers containing borax were applied differently in the three sections: in section 1, they were applied in the furrow 6 days before planting; in section 2, they were applied in the furrow at the time of planting; in section 3, they were sown broadcast and well raked into the soil before planting.

After one month, the number of plants in the control plots was 343; these plots had received 1 ton fertiliser per acre but no borax. The plot that had received 10 lb. of borax per acre had 284 plants. The 20 lb. application showed 205 plants; the 50 lb. application 116; the 100 lb. application 38; the 200 lb. 18 and the 400 lb. application only 12 plants. At the end of the second month, the author inspected the sections and found great differences in them. The section which had been treated in the usual manner by applying the fertiliser in the furrow immediately before planting was the most seriously affected, while that in which the fertiliser-borax mixture was introduced into the furrow some time before planting had suffered least. As the quantity of borax increased the toxic effects progressively increased also. In section 2 the injury was apparently produced with 3 or 4 lb. per acre and certainly with 5 lb., the injury with 10 lb., or more, was very noticeable. During the investigational survey in Maine in 1919, the amount of anhydrous borax found in commercial fertilisers ranged from 0.73 to 2.3%. In view of the fact that 2000 lb. represents the usual quantity of fertiliser applied per acre, it is clear that the amount of borax applied varied from 14.6 to 46 lb. per acre. The type of field injury shown in 1919 was similar to that found in the 20, 30 and 50 lb. applications in the borax experiment.

Some of the injurious effects noted in both seasons were as follows: failure of seed to germinate, dying back of underground shoots, bleaching of foliage, or in less serious cases, marginal yellowing of leaflets, reduction in yield. Yield when 50 lb. of borax were applied per acre, was decreased 55% in the second section and 40% in the first and third sections.

A. de B.

1153 - **Chill's Sulphur Supply.** — HOFFICER, H. G. in *Engineering and Mining Journal Press*, Vol CXIII, No 23, pp 995 1000, figs 8 New York, June 1, 1922.

The sulphur deposits of Chili (1) are little known, as the working of these vast beds has been hindered by their altitude and the lack of proper transport facilities. Under good management these mines on the Pacific Coast could compete with the sulphur mines of Texas, as they are of great value owing to the great extent of the beds.

(1) See R. Mar. 1920, No. 303. (Ed)

The statistics of the sulphur industry are as follows :

Year	Production	Exports	Imports	Consumption
t.	t.	t.	t.	t.
1909. . . . .	4 507	193	none	4 700
1910. . . . .	3 822	1 400	"	5 224
1911. . . . .	4 457	4 013	"	8 464
1912. . . . .	4 431	4 451	"	8 552
1913. . . . .	6 647	1 961	"	8 608
1914. . . . .	10 008	526	"	10 534
1915. . . . .	9 769	711	"	10 450
1916. . . . .	14 879	1 080	"	15 959
1917. . . . .	15 942	47	2 555	15 434
1918. . . . .	19 557	none	6 406	13 151

The exportation statistics are given below :

Country	1917		1918	
	t.	value in dollars	t.	value in dollars
Argentina . . . .	1 976	106 720	3 025	241 500
Bolivia . . . . .	41	2 224	51	7 670
Brazil . . . . .	1 227	66 276	2 573	157 300
Uruguay . . . . .	248	13 371	260	23 000
Totals	3 492	288 591	6 211	425 470

The sulphur deposits are all of volcanic origin and are situated at an altitude of 4000 to 6000 metres ; the beds are often 7 to 10 m. in thickness, 95 % of which is sulphur. The working and refining methods are still very primitive and the climatic conditions render working extremely difficult.

The reserves of the sulphur mines are estimated approximately at 5 530 000 t. with an average sulphur content of 60 %. After the gradual, but inevitable exhaustion of the sulphur deposits of Sicily and Japan, there will be only two large sources of this mineral, so far as is known at present, these being the sulphur mines of Mexico and of the Chilean Andes. The exploitation on a large scale of these mines is merely a matter of time.

1154 - **Accidental Flora imported in Wool and the Question of its Acclimatization in Germany** (1). — SCHENCKRENAUM, R., in *Mitteilungen der deutschen Landwirtschaftsgesellschaft*, Year XXXVII, No. 38, pp. 572-573. Berlin, Sept. 23, 1922.

The accidental flora of Döhren (near Hanover), where there is a large establishment for washing wool, has been several times the object of re-

AGRICULTURAL  
BOTANY  
CHEMISTRY  
AND  
PHYSIOLOGY  
OF PLANTS

(1) Two papers on this subject have been published by the *Hannoversche Land und Forstwirtschaftliche Zeitung*, the first (No. 1, p. 16, Jan. 6, 1922) by the writer, written on the invitation, addressed to him, as a specialist in adventitious plants of the Hanover Chamber of Agriculture ; the second (No. 18, p. 282, May 6, 1922) by M. L. WITTMACK. (*Author's note*).

search and study since 1889. It has been ascertained that the accidental species, which have certainly been introduced in foreign wool, number several hundreds, and every year fresh kinds are observed. The question arises as to which of these species are really acclimatized in the country: it may be said that none have been able to survive for long. Thus, according to Prof. ASCHERSON, *Xanthium spinosum*, a native of South America and now spread all over America, in the Mediterranean countries, Central Europe, Western Asia, South Africa and Australia, have been considered as acclimatized at Döhren; but the writer has pointed out the contrary. During the war the importation of foreign wool was suspended and *Xanthium* disappeared almost completely, to reappear when importation was renewed. It is beyond all doubt that the climate of their new home does not suit these plants and that the insects for cross-fertilizing them are not found there. A few fructify well but do not produce seed capable of germinating. That in spite of this certain species such as *X. spinosum*, *Medicago arabica* and *M. hispida* Gaertn. (= *M. denticulata* Willd.) appear every year in very large quantities must be attributed to the importation in the wool of fresh seed capable of germinating.

Some species of *Medicago* have been observed at Döhren since 1889:—*M. hispida* with the varieties *macracantha*, *confinis* and *apiculata*; *M. arabica*, *M. laciniata* from southern countries in the Mediterranean basin, *M. ciliaris*, native of Mediterranean countries, and *M. minima*.

HEINTZE (*Hann. Land und Forstw. Zeitung*, No. 9, March 3, 1922), has drawn attention to the fact that fruits of *M. denticulata* and of *M. arabica* were found, in 1921, in the wool of several German flocks. But the writer is in agreement with M. WITTMACK on the subject and does not think that there is any fear that these species will be propagated in Germany; the same is true for the varieties of *M. hispida*, for *M. laciniata* and *M. ciliaris*. Regarding *M. minima*, the writer was doubtful in 1912 whether it was able to acclimatize itself, and in fact it has not done so up to the present: it grows only in places which it reaches with the refuse from wool washing, along the railway lines or in the fields where this refuse is used as manure. German breeders have nothing to fear from *M. minima*.

The seeds separated from the wool by washing cannot be successfully sown; their germinative power is very limited; if sheep were sent to graze in pastures sown with these seeds the fruits would attach themselves to the wool and would decrease its value. The writer thinks that the few seeds of *Medicago* found by the wool washing establishment at Döhren in German wool are seeds of exotic species mixed with seeds of inferior quality.

F. D.

1155 - **Study on the Pollen of Fruit Trees.** — CASELLA, D. (*Cattedra di Arboricoltura della R. Scuola Sup. di Agricoltura in Portici*), pp. 24, 4 pl., bibliography of 46 publications. Cosenza, 1922.

In fruit trees imperfect setting of the flowers is due to numerous causes. The writer has undertaken its study, selecting among anemophilous trees the vine and the mulberry and among entomophilous trees the Rosaceæ such as the apple, pear, peach, apricot, almond and plum.

The writer refers to and confirms certain opinions already maintained and adds some personal observations. Firstly he examines the influence of meteorological conditions. A light wind helps pollinization because it transports the pollen of anemophilous plants without scattering. Moreover, by favouring evaporation, it accelerates dehiscence ; finally by shaking the flowers it facilitates the opening of the anther. On the other hand a strong wind scatters the pollen and blows away the insects which assist in pollinization ; it may also break off the flowers and break the branches. Hail has a similar injurious effect. Rain washes away the pollen and makes it burst and germinate prematurely in the anthers ; it causes browning and necrosis of the stigma ; makes transport of the pollen by wind impossible ; washes away the sugary excretions which attract insects, keeps the insects away and prevents them from feeding on the flowers. In the vine during rain, the hood adheres to the stigma and obstructs the anther ; in the Rosaceæ the stamens adhere to the style ; if the stamens are longer than the style, the stigma remains immersed in the water and comes off ; if, later, the water evaporates, the stamens regain their normal position and the anthers dehisce, but meanwhile the germinative power of the grains of pollen which have burst or germinated has diminished. Mist is just as injurious as rain ; its moisture causes partial bursting and premature germination of the pollen and necrosis of the stigma ; pollinization is specially hindered by a thick mist, which deposits a film of water and sometimes small drops. Light and solar heat accelerate all vital functions and consequently pollinization ; moreover they have an indirect action inasmuch as they cause the secretion of nectar and the production of colours and scents which attract insects ; they also stimulate the insects themselves. A high temperature accelerates the germination, the bursting of the pollen grains and the elongation of the pollen tubes. On the other hand, low temperatures retard the dehiscence of the anthers, hinder the germination of the pollen and prolong the duration of the elongation of the pollen tube.

The writer has made numerous observations on pollen and ascertained that not only does the pollen vary in different species but also in certain cases in different varieties and that, in certain varieties of fruit trees, the pollen from the same anther has various forms and dimensions and a different percentage of grains which contain no protoplasmic substance.

The writer undertook numerous tests on the germination of pollen. With this object he tried to use little drops of liquid taken from the stigma of the almond and difficult to collect, as well as the juice of the plum, pure water, moist air, etc. He found that the best was a solution of saccharose in the proportion of 10 % (apple), 15 % (pear), 20 % (almond). He often found abnormal teratologic forms of which he gives a description. The pollen grains of the vine always emit a bubble which persists at the insertion of the pollen tube and keeps it inflated.

The writer has studied germinative power in various conditions. It remained constant for each variety of fruit tree. Pollen from diseased plants was relatively more sterile. The influence of temperature was greater : the optimum temperature was 15° C for the almond, 20° C for the vine.

Fungicidal and insecticidal preparations were almost all decidedly injurious. The writer also tested the effect of these preparations on the setting of vine-flowers: he painted them on the stigmas with a brush. All the preparations were injurious. Sulphur, to which some persons attribute a beneficial action on setting, was also injurious, and it is probable that the beneficial action attributed to the sulphur is due to the dissemination of the pollen helped by the movement of the air and of the cluster at the time of applying the sulphur. Water proved injurious; it intensified the harmful effects of the fungicides and insecticides on the germinative power. The use of such substances should be regulated so as to obtain the advantages which are desired from them, without injury to production. L. V.

1156 - **Characteristic Proteins in Maize.** — SHOWALTER, M F, and CARR, R H (Division of Agriculture Chemistry of Purdue University) in *The Journal of the American Chemical Society*, Vol XLIV, No 9, pp 2019-2023 Easton, Pa, Sept 1922
